3. How often have you had pain or discomfort in any of these areas over the last week?

❑ 0 Never
❑ 1 Rarely
❑ 2 Sometimes
❑ 3 Often
❑ 4 Usually
❑ 5 Always

4. Which number best describes your AVERAGE pain or discomfort on the days that you had it, over the last week?

❑ ❑ ❑ ❑ ❑ ❑ ❑ ❑ ❑ ❑ ❑
0 1 2 3 4 5 6 7 8 9 10
NO PAIN — PAIN AS BAD AS YOU CAN IMAGINE

Urination

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

Impact of Symptoms

7. How much have your symptoms kept you from doing the kinds of things you would usually do, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

8. How much did you think about your symptoms, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

Quality of Life

9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that?

❑ 0 Delighted
❑ 1 Pleased
❑ 2 Mostly satisfied
❑ 3 Mixed (about equally satisfied and dissatisfied)
❑ 4 Mostly dissatisfied
❑ 5 Unhappy
❑ 6 Terrible

Urinary Symptoms: Total of items 5 and 6 = _____

Quality of Life Impact: Total of items 7, 8, and 9 = _____

FIGURE 131-3. National Institutes of Health Chronic Prostatitis Symptom Index.

Type III prostatitis is characterized by pelvic pain, often associated with lower urinary tract symptoms and pain during or after ejaculation. Digital rectal examination findings also vary. Type IV prostatitis is, by definition, asymptomatic.

The hallmark of chronic prostatitis is a complex of symptoms that wax and wane. A brief, self-administered questionnaire (Fig. 131-3) has been developed and validated to quantify symptoms for clinical practice and research protocols.

DIAGNOSIS

Whereas acute prostatitis is relatively straightforward to diagnose, chronic prostatitis is more challenging. The symptom complexes of chronic prostatitis and BPH overlap, and BPH may be misdiagnosed in older men with chronic prostatitis. Although men can and do get both conditions, pain generally distinguishes chronic prostatitis from BPH. A PSA test is not indicated for the evaluation of chronic prostatitis; however, if a PSA test is performed and the level is found to be elevated, this should not be ascribed to chronic prostatitis/chronic pelvic pain syndrome.

Type I prostatitis is diagnosed primarily by clinical findings and a positive urine culture. Prostate massage is not recommended because of concern for precipitating bacteremia.

Type II and type III prostatitis are traditionally diagnosed with the four-glass test. This segmented, quantitative culture technique involves culturing initial-stream urine, midstream urine, expressed prostatic secretions after

massage, and post–prostate massage urine. The simplified two-glass test involves culture and microscopic examination of urine obtained before and after prostate massage; it is easier for all concerned, with similar sensitivity and specificity. Type II prostatitis is characterized by the presence of uropathogenic bacteria, whereas type III prostatitis is defined by the absence of uropathogens in the setting of genitourinary pain. Type IV prostatitis is usually diagnosed incidentally by prostate biopsy or by the finding of leukocytes in prostatic secretions collected for infertility evaluations.

Differential Diagnosis

The diagnosis of type III prostatitis is challenging because it is a diagnosis of exclusion; therefore, a careful evaluation is necessary to rule out other causes of pelvic pain that may be associated with lower urinary tract symptoms and sexual dysfunction. The differential diagnosis for type III prostatitis includes BPH and prostate cancer. The patient's sexual history may suggest a sexually transmitted disease (Chapter 293), and a medical history of genitourinary instrumentation or sexually transmitted disease may suggest a urethral stricture. The physical examination may detect a hernia (Chapter 144) or a scrotal mass (Chapter 206). A urinalysis revealing hematuria should prompt evaluation for a kidney stone (Chapter 128) or bladder cancer (Chapter 203). A urine culture is important to exclude urinary tract infection (Chapter 292).

PREVENTION AND TREATMENT

Rx

There is no proven preventive strategy for any type of prostatitis.

Type I prostatitis is relatively easy to treat. Antibacterial agents that normally diffuse poorly into prostatic fluid work well, probably because intense inflammation enhances penetration. The choice of antimicrobial is driven by culture results. Parenteral antibiotics (e.g., ciprofloxacin 400 mg IV every 12 hours) are necessary for sicker patients, but oral fluoroquinolones (e.g., ciprofloxacin 500 mg orally every 12 hours or levofloxacin 500 mg orally daily) or trimethoprim-sulfamethoxazole (one double-strength tablet orally every 12 hours) is adequate for outpatients. Treatment for 4 weeks is generally recommended. Modification of the dosing of fluoroquinolones is advised in patients with renal impairment.

Type II prostatitis is more difficult to treat because prostatic fluid becomes alkaline with chronic inflammation, reducing antibiotic penetration. The fluoroquinolones (e.g., ciprofloxacin 500 mg orally every 12 hours or levofloxacin 500 mg orally daily) and trimethoprim-sulfamethoxazole (one double-strength tablet orally every 12 hours) penetrate the prostate, but the penicillins, cephalosporins, aminoglycosides, and nitrofurantoin do not. The duration of treatment is generally 4 weeks.

Type III prostatitis often engenders frustration on the part of the physician and confusion and dissatisfaction on the part of the patient. Because the cause is unknown, affected men receive various empirical therapies. Antibiotics, α-blocker therapy, and pregabalin have not been beneficial.[9,10]

For type IV prostatitis, no treatment is recommended.

PROGNOSIS

The untreated natural history of all types of prostatitis is poorly defined. Most patients with type I prostatitis respond well to antibiotics, but some may progress to chronic prostatitis. Complications of type I prostatitis include prostatic abscess, acute urinary retention, septicemia, and, rarely, vertebral osteomyelitis. Type II prostatitis can cause repeated urinary tract infections. Both type II and type III prostatitis have been associated with decreased fertility, although this relationship is not certain.

132 CHRONIC KIDNEY DISEASE

WILLIAM E. MITCH

DEFINITION

Chronic kidney disease (CKD) refers to the many clinical abnormalities that progressively worsen as kidney function declines. CKD results from a large number of systemic diseases that damage the kidney or from disorders that are intrinsic to the kidney (Table 132-1). A glomerular filtration rate (GFR) persistently below 60 mL/minute/1.73 m^2, which is below the level of kidney function expected to occur with aging, defines clinically significant CKD.

In CKD, the damage is rarely repaired, so loss of function persists. This distinguishes CKD from acute kidney damage (Chapter 122), which can be repaired to permit the return of kidney function. The chronic loss of kidney function generates even more kidney damage and more severe clinical abnormalities. As a result, CKD progressively worsens even if the disorder that caused it becomes inactive.

CKD describes a spectrum of clinical dysfunction that ranges from abnormalities detectable only by laboratory testing to uremia. *Uremia,* which literally means "urine in the blood," results from the accumulation of unexcreted waste products and the metabolic abnormalities they induce. When the kidney fails to perform most of its functions, the clinical state is called *end-stage renal disease* (ESRD), and dialysis or transplantation is required to sustain life (Chapter 133). However, the progressive and chronic nature of CKD permits the institution of treatment strategies that can slow the loss of kidney function. In addition, many symptoms of uremia can be ameliorated or eliminated, thereby postponing ESRD.

EPIDEMIOLOGY

The increase in the number of patients with ESRD in the United States and other industrialized countries has features of an epidemic. In the United States, the prevalence of CKD continues to increase (Table 132-2). An estimated 13.1% of the U.S. population, representing about 26 million noninstitutionalized individuals older than 20 years, has stages 1 through 4 CKD, and 65% of these have stage 3 or 4 CKD. The prevalence of albuminuria is nearly 10%, representing approximately 19 million adults. Notably, the prevalence of ESRD (stage 5 CKD) has increased by 82% over the past decade or two, from nearly 800 per million persons in the U.S. population to more than 1400 persons per million.

Two disorders account for more than 70% of all new ESRD patients in the United States: 45% of patients have diabetes mellitus (Chapters 236 and 237), and 27% have hypertension-induced kidney damage (Chapter 67). The increasing prevalence of CKD is due in part to the increasing prevalence of diabetes and obesity, plus the aging of the population and an increase in the proportion of minority populations, who seem to be more susceptible to developing CKD. Other epidemiologic factors that increase the risk of progressive CKD include cardiovascular disease, smoking, albuminuria, hyperlipidemia, and a family history of CKD.

PATHOBIOLOGY

The intact nephron hypothesis helps explain the importance of GFR as a measure of remaining kidney function. The nephron consists of the glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct. Individuals are born with 0.75 million to 1.25 million nephrons per kidney. If nephrons are lost, new ones are not regenerated. The intact nephron hypothesis maintains that each nephron functions as an independent unit, so the sum of the function of all remaining nephrons determines the whole kidney's GFR, the most accurate estimate of remaining kidney function.

Physiologic and metabolic functions of the kidney include the regulation of blood pressure, several endocrine functions, and ion concentrations in the extracellular and intracellular fluids, as well as the excretion of waste products (Table 132-3). The breadth of these functions yields several direct and derivative consequences of CKD. For example, a limitation in the ability to excrete acid causes hyperventilation and a decrease in P_{CO_2}. In muscle, acidosis activates the ubiquitin-proteasome enzymatic process to degrade muscle protein, causing loss of muscle mass. In bone, acidosis causes loss of calcium and phosphates; this response, plus the secretion of parathyroid hormone (PTH) and decreased activation of vitamin D, demineralizes bone and makes it susceptible to fracture.

Balance and Steady-State Considerations

Metabolic balance is the state in which the intake or production of a substance equals its elimination. For example, a loss of functioning units (nephrons) impairs the ability to excrete sodium, but remaining nephrons adjust to excrete a greater fraction of the sodium filtered by each glomerulus. Similar phenomena occur in the excretion of other ions and substances, allowing the patient with CKD to avoid their accumulation. The ability to achieve balance has a limit, however; if the intake of sodium or other ions or molecules destined for excretion by the kidney is not regulated, complications of CKD will arise.

A related concept is that of steady state. A patient is in steady state when intake and production equal output and metabolism. A single parameter that integrates input and output may, if stable, be taken as indicative of a steady state. Thus, constant weight indicates that sodium intake is balancing sodium output. A steady state does not, however, indicate a normal state; for example, a patient who is grossly edematous may have a stable weight.

The Tradeoff Hypothesis

Another important principle, the tradeoff hypothesis, refers to the activation of pathophysiologic responses that produce adverse consequences. A classic example in CKD patients involves the responses activated to achieve sodium balance. Kidney damage initially reduces salt excretion, leading to sodium retention, expansion of extracellular fluid, and a rise in blood pressure.

TABLE 132-3 FUNCTIONS OF THE KIDNEY AND IMPAIRMENT OF KIDNEY FUNCTION IN PATIENTS WITH CHRONIC KIDNEY DISEASE

KIDNEY FUNCTION	CONSEQUENCES OF DYSFUNCTION
Maintain concentration and body content of electrolytes and fluid volume	Hyponatremia, hyperkalemia, low total potassium content, hypocalcemia, hyperphosphatemia, decreased tolerance to electrolyte or mineral loading
Regulate blood pressure	Hypertension, cardiovascular disease
Endocrine mediator	Anemia (low erythropoietin), hypertension (renin system activation), bone disease (secondary hyperparathyroidism), low vitamin D activation, prolonged half-lives of peptide hormones (e.g., insulin)
Waste product excretion	Anorexia, nausea, soft tissue deposition of oxalates and phosphates, neurologic dysfunction, loss of muscle protein

TABLE 132-2 PREVALENCE OF STAGES OF CHRONIC KIDNEY DISEASE AND FREQUENCY OF COMPLICATIONS

STAGE	DESCRIPTION	GFR* (mL/min/1.73 m²)	ADULT PREVALENCE (MILLIONS)†	SYMPTOMS OR SIGNS
1	Chronic kidney damage; normal or increased GFR	>90	3.6	Anemia 4% Hypertension 40% 5-yr mortality 19%
2	Mild GFR loss	60-89	6.5	Anemia 4% Hypertension 40% 5-yr mortality 19%
3	Moderate GFR loss	30-59	15.5	Anemia 7% Hypertension 55% 5-yr mortality 24%
4	Severe GFR loss	15-29	0.7	Hyperphosphatemia 20% Anemia 29% Hypertension 77% 5-yr mortality 46%
5	Kidney failure†	<15 or dialysis	0.5	Hyperphosphatemia 50% Anemia 69% Hypertension >75% 3-yr mortality 14%

*The formula for estimating the glomerular filtration rate (GFR) of adults with chronic kidney disease (CKD) is derived from data obtained during the National Institutes of Health Modification of Diet in Renal Diseases trial: $GFR = 186 \times [\text{serum creatinine}]^{-1.154} \times [\text{age}]^{0.203} \times [0.742 \text{ if patient is female}] \times [1.212 \text{ if patient is black}]$.
†Rate prevalent end-stage renal disease/million; United States Renal Data System Annual Report 2008.
Results based on the CKD Surveillance 2009 Report from the Centers for Disease Control and Prevention (unpublished).

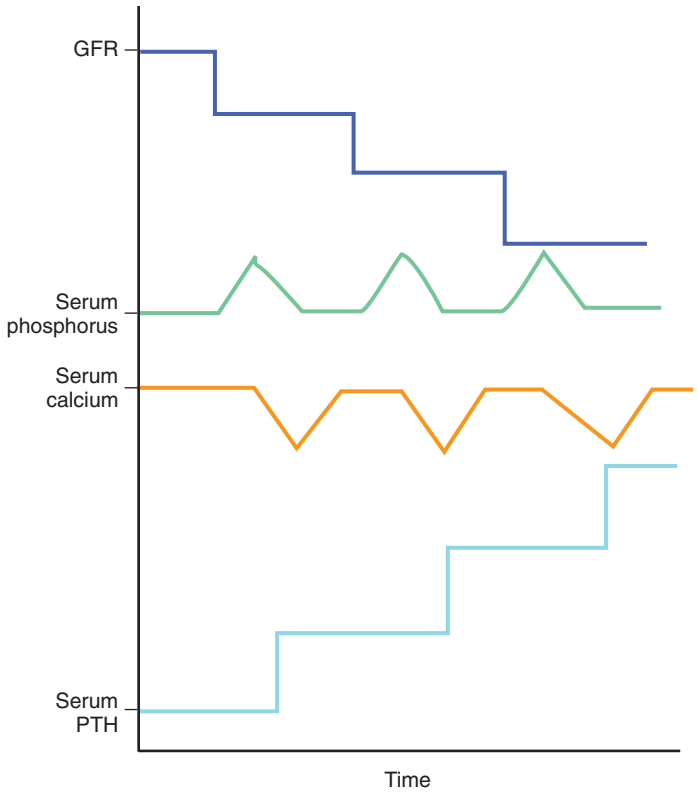

FIGURE 132-1. A decrease in glomerular filtration rate (GFR) is followed by an increase in serum phosphorus and a decrease in serum calcium. An increase in serum parathyroid hormone (PTH) returns phosphorus and calcium to normal levels.

Although a higher blood pressure initially is beneficial because it increases the filtration and excretion of sodium, the tradeoff for maintaining sodium balance is volume-dependent hypertension. Another proposal is that this increased sodium excretion is mediated by an increase in circulating Na^+, K^+-ATPase inhibitors, which increase the sodium concentration in tubular cells, reducing the cells' ability to reabsorb filtered sodium. Thus, the tradeoff for the increased ability to excrete sodium despite a loss of kidney function is that the patient loses the ability to reduce sodium excretion rapidly when salt intake is abruptly reduced. Inappropriately high salt excretion leads to loss of extracellular volume, impaired kidney perfusion, and a decrease in the GFR.

The most extensively studied tradeoff is the adaptation that stimulates secondary hyperparathyroidism (Fig. 132-1). When CKD impairs the kidney's ability to excrete phosphates, they accumulate in extracellular and intracellular fluids and lead to the physicochemical formation of calcium-phosphate complexes that reduce the level of ionized calcium. This process, in turn, stimulates the calcium-sensing receptor to increase the production and release of PTH. PTH release is beneficial because it suppresses the reabsorption of phosphates by the proximal tubule and thereby increases phosphate excretion. As the accumulation of phosphates decreases because of their excretion by the kidney, the ionized calcium rises to suppress PTH production. The tradeoff, however, is that the new steady-state levels of ionized calcium and phosphate can be maintained only as long as the circulating PTH concentration is increased (see Fig. 132-1). This higher level of PTH stimulates osteoclastic activity and leads to renal bone disease (see later).

Hypertension

Hypertension, like anemia, is almost universal in CKD patients and is often the first clinical indication of CKD. The coincidence of CKD and high blood pressure is particularly important because hypertension contributes to the development of cardiovascular disease, which is the leading cause of morbidity and mortality in CKD patients. Hypertension in CKD patients largely reflects an expanded extracellular volume owing to a salt-rich diet plus an impaired capacity to excrete sodium; activation of the renin-angiotensin-aldosterone system also plays a role. The normal response to retained sodium is an increase in extracellular volume, which raises blood pressure and increases sodium excretion, leading to a balance between sodium intake and the excretion of salt. In the renewed steady state, however, salt balance can be maintained only as long as blood pressure is high. Two practical implications arise from these relationships. First, treatment of hypertensive patients with vasodilating drugs alone is frequently unsuccessful; when vasodilator drugs reduce blood pressure, the initial decrease in sodium excretion leads to sodium retention, expansion of extracellular volume, and a rise in blood pressure. Second, hypertension in CKD patients may not respond to diuretic therapy because a salt-rich diet can cancel the benefits of diuretics even in normal adults.

Another mechanism for hypertension in CKD patients is activation of the renin-angiotensin-aldosterone system and the sympathetic nervous system, as evidenced by circulating levels of renin and aldosterone that are too high for individuals who are hypertensive. Inhibitors of the renin-angiotensin-aldosterone system slow the loss of kidney function. Evidence for activation of the sympathetic nervous system includes higher circulating levels of norepinephrine, which not only causes vasoconstriction but also suppresses the production of nitric oxide.

Endocrine Disorders

CKD, even in patients with serum creatinine values as low as 2.5 mg/dL, reduces the ability of insulin to stimulate glucose uptake by muscle and other organs, an abnormality known as *insulin resistance* (Chapter 237). The result is a transient increase in blood glucose that causes a compensatory increase in insulin release to maintain blood glucose levels near normal. In insulin-resistant CKD patients, the failure is due to a post-receptor defect in cell signaling, including an impaired ability to activate phosphatidylinositol 3-kinase and its downstream kinase Akt. The importance of this abnormality is that the reduced function of these enzymes in muscle cells impairs the metabolism of both glucose and protein, causing loss of muscle protein. Insulin resistance in nondiabetic CKD patients is generally associated with blood glucose values within the normal range; blood glucose levels rarely exceed 200 mg/dL.

One possible cause of insulin resistance in CKD is metabolic acidosis (Chapter 120). Acidosis also activates the degradation of muscle protein, impairs the ability of growth hormone to stimulate insulin-like growth factor-I (IGF-I), depresses circulating levels of thyroxine (T_4) and triiodothyronine (T_3), and increases levels of thyroid-stimulating hormone (Chapter 233). Fortunately, most of these adverse metabolic changes can be reversed simply by treating CKD patients with sodium bicarbonate or other alkalizing agents.

Another mechanism that affects endocrine status in CKD patients is the kidney's impaired ability to degrade small proteins, including several hormones. For example, diabetic CKD patients can progressively lose the ability to degrade insulin and may even develop hypoglycemia if they are treated with their usual dose of insulin. Impaired degradation of peptides by the damaged kidney can also affect the interpretation of the circulating PTH concentration because PTH is not fully degraded when the kidney is damaged; the PTH immunoassay may recognize one or more PTH fragments, which may be misinterpreted as representing excessively high levels of PTH.

In patients with stage 4 CKD, normochromic, normocytic anemia (Chapter 161) is almost universal, principally owing to impaired production of erythropoietin by interstitial cells in the kidney. However, anemia may be detected even in patients with stage 2 CKD and serum creatinine values just above the normal range. Other factors contributing to anemia in CKD patients include a shortened half-life of erythrocytes and deficiencies of vitamins and iron.

Renal Bone Disease

Renal bone disease, also called *renal osteodystrophy,* afflicts virtually all CKD patients to different degrees. Bone biopsies of patients with renal bone disease range from features indicative of increased bone turnover (i.e., greater numbers of osteoclasts, osteoblasts, and osteocytes) to abnormalities reflecting low bone turnover (i.e., reduced numbers of osteoclasts and osteoblasts and the accumulation of demineralized matrix). Patients with high bone turnover have high circulating PTH levels, whereas those with low bone turnover exhibit only a mild increase in circulating PTH. A third type of pathology is mixed uremic osteodystrophy, which has features of hyperparathyroidism and defective mineralization, presumably because increased PTH activates osteoclasts to reduce bone mass, while abnormalities in mineralization of bone result in an increase in fibrosis. Specifically, CKD produces hyperphosphatemia (see Fig. 132-1) because the intake of phosphates exceeds their excretion. Hyperphosphatemia stimulates the development of renal

bone disease in two ways. First, the physicochemical interaction between phosphates and "free" or ionized calcium lowers the level of ionized calcium and reduces the interaction between calcium and the calcium receptor. Decreased activation of the calcium receptor causes the parathyroid gland to hypertrophy and PTH production to rise; it also stimulates osteoclast activity, resulting in loss of bone mass. Second, hyperphosphatemia acts directly on the parathyroid glands to stimulate PTH production. Other factors that contribute to CKD-induced bone disease include defects in cellular signaling by the calcium receptor and changes in vitamin D metabolism.

A G protein–coupled plasma membrane protein present in chief cells of the parathyroid gland and in certain renal tubular cells responds directly to calcium ions. The interaction of this receptor with calcium or with cinacalcet, which is a small, orally available molecule that activates the calcium receptor, suppresses the expression and release of PTH from parathyroid chief cells. In contrast, hyperphosphatemia and a decreased level of circulating ionized calcium increase the production and release of PTH (see Fig. 132-1). These responses can be negated by cinacalcet because it effectively suppresses the production and release of PTH even when there is hyperphosphatemia and decreased ionized calcium. Consequently, use of this drug requires careful monitoring to avoid hypoparathyroidism and even hypocalcemia.

Another factor that regulates the circulating calcium level and plays a role in the development of renal bone disease is vitamin D. The activation of vitamin D proceeds by repeated hydroxylation of the parent molecule, cholecalciferol (vitamin D_3). The initial hydroxylation occurs in the liver, where 25-hydroxyvitamin D_3 is formed. This form of vitamin D stimulates the absorption of calcium and phosphates from the intestines and is believed to change the function and metabolism of muscle and possibly other organs by mechanisms that are poorly defined. Moreover, recent evidence indicates that CKD patients who have low circulating values of 25-hydroxyvitamin D_3 experience an increase in the risk of all-cause mortality, thereby supporting the conjecture that the function of 25-hydroxyvitamin D_3 extends beyond serving as a precursor for the most active vitamin D, calcitriol.

Calcitriol is produced when a 25-hydroxycholecalciferol 1α-hydroxylase in the proximal tubules of the kidney hydroxylates 25-hydroxyvitamin D_3. The activity of 1α-hydroxylase changes in response to factors that regulate mineral metabolism: for example, its activity is decreased by hyperphosphatemia, and the decrement in calcitriol decreases the intestinal absorption of calcium and phosphates. However, the β-glucuronidase klotho confers the tissue specificity of fibroblast growth factor-23 (FGF-23), a hormone that increases the renal excretion of phosphates. Both klotho and FGF-23 are involved in the regulation of calcitriol production, but exactly how these factors influence the development of renal bone disease has not been defined.

Because the 1α-hydroxylase enzyme is expressed mainly in proximal tubule cells, progressive loss of kidney function causes calcitriol deficiency. This deficiency, in turn, results in impaired absorption of both calcium and phosphates from the intestine; the resulting decrease in calcium should stimulate 1α-hydroxylase activity to produce more calcitriol. If this is not possible because of a decrease in proximal tubular function, serum calcium decreases, thereby increasing PTH production. Depressed calcitriol production also can augment PTH production by reducing the level of vitamin D receptor in the parathyroid gland, promoting the development of hyperparathyroidism even before hypocalcemia has developed.

Soft tissue calcification, which is the deposition of calcium phosphate crystals and inflammation in the vessels and soft tissues, is common when the product of the concentrations of serum calcium and phosphorus exceeds 60 mg^2/dL^2, but it can occur with lower levels. The deposition of crystals seems to be linked most closely to an increase in the local concentration of phosphates, emphasizing why the serum phosphorus level should be kept in the normal range.

Accumulation of Uremic Toxins

In diets containing protein-rich foods, protein is metabolized to amino acids that can be used to build body protein stores (Fig. 132-2). Alternatively, the amino acids are metabolized to form urea or potentially toxic products that are excreted when kidney function is normal. The serum creatinine level is determined by the degree of renal insufficiency and the rate of creatinine production, which is proportionate to lean body mass. As a result, a serum creatinine concentration of 1.4 mg/dL in an adult with a small muscle mass signifies a much greater loss of kidney function than it does in an individual with a large muscle mass. In addition, the amount of creatinine excreted in 24-hour urine collections can vary by up to 25%, making creatinine clearance of limited use in determining the degree of kidney damage in CKD patients.

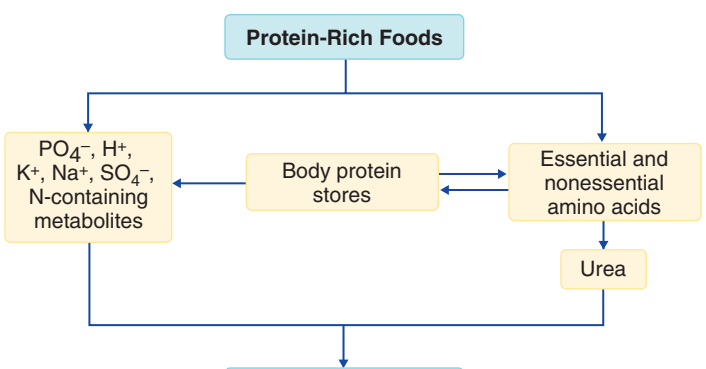

FIGURE 132-2. The breakdown of dietary protein enlarges the pool of essential and nonessential amino acids that can be used to synthesize body protein. Protein breakdown also increases the production of urea and other nitrogenous waste products, and it is accompanied by the increased intake of inorganic ions that must be excreted.

Because creatinine is formed from creatine, which is highly concentrated in muscle, extensive cooking of dietary meat converts creatine to creatinine. Consequently, eating a meal containing a large amount of well-cooked meat raises the amount of creatinine excreted. Even if meat and high-protein foods are eliminated from the diet of CKD patients, at least 4 months are required to reach a new steady state. In terms of extrarenal creatinine clearance, the degradation rate of creatinine, presumably by bacteria in the gut, is so small that it is virtually undetectable in patients with normal kidney function; when serum creatinine rises above 5 mg/dL, however, degradation can contribute to creatinine clearance.

With CKD, the accumulation of peptides (also known as *middle molecules*) is associated with disorders that range from the induction of anorexia to neurologic abnormalities. Another potential toxin is indoxyl sulfate, a product of tryptophan metabolism; it has been linked to progressive kidney damage and the symptoms of uremia. High uric acid levels, which are related to excess protein intake, can cause gout (Chapter 281) and may be linked to the development of hypertension and inflammatory responses in blood vessels. Besides generating potentially toxic metabolites, diets containing protein-rich foods also increase the intake of phosphates, sodium, potassium, acid, and other ions that must be eliminated.

Ideally, circulating levels of uremic toxins should be monitored, but measuring these levels is not practical. The blood urea nitrogen (BUN), however, provides an index of the level of uremic toxins because the production of urea is directly proportional to the metabolism of proteins and hence the production of other unexcreted waste products (see Fig. 132-2). Thus, the load of waste product production can be approximated from the 24-hour excretion of urea nitrogen as long as the patient is in the steady state (i.e., BUN concentration and body water are stable). In general, the ratio of BUN to serum creatinine is 10 : 1 in normal adults or CKD patients. When the BUN concentration is below this ratio, it can be concluded that the patient is eating a protein-restricted diet. If the BUN concentration exceeds 10 times the serum creatinine concentration, three possibilities should be considered. First, the patient may have gastrointestinal bleeding or may be suffering from a severely catabolic condition (e.g., trauma or high-dose glucocorticoid administration). Second, the patient may be eating excessive amounts of protein, yielding more urea than the impaired kidney can excrete. Finally, there may be extracellular volume depletion with active proximal tubular reabsorption of sodium and fluid and concomitant passive reabsorption of urea; the result is a rise in BUN. The corollary is that a decrease in urea production is associated with a decrease in the load of uremic toxins. For this reason, the production of urea should be kept to a minimum that is consistent with maintaining body protein stores. To accomplish this goal, the dietary content of protein should be monitored and manipulated to decrease urea production (see later).

Progression of Chronic Kidney Disease

Persistence of diseases affecting the kidney (e.g., diabetes or inflammatory conditions such as systemic lupus erythematosus) is not the only factor that determines the rapidity of the loss of kidney function. Even when the disease that initially damaged the kidney is no longer active, kidney function continues to decline, probably because systemic hypertension, hemodynamic injury

Efferent arteriolar vasoconstriction
Nonhemodynamic responses in the kidney
Macrophage infiltration and inflammation
Interstitial matrix accumulation
Increased transforming growth factor-β
Increased plasminogen activator inhibitor type 1
Increased aldosterone

*Includes the proposed actions of angiotensin II that can contribute to the development of cardiovascular disease and progressive loss of kidney function.

TABLE 132-5 COMPLICATIONS OF CHRONIC KIDNEY DISEASE

AFFECTED SYSTEM	CAUSE OR MECHANISM	CLINICAL SYNDROME
Systemic symptoms	Anemia, inflammation	Fatigue, lassitude
Skin	Hyperparathyroidism, calcium-phosphate deposition	Rash, pruritus, metastatic calcification
Cardiovascular disease	Hypertension, anemia, homocysteinemia, vascular calcification	Atherosclerosis, heart failure, stroke
Serositis	Unknown	Pericardial or pleural pain and fluid, peritoneal fluid
Gastrointestinal	Unknown	Anorexia, nausea, vomiting, diarrhea, gastrointestinal tract bleeding
Immune system	Leukocyte dysfunction, depressed cellular immunity	Infections
Endocrine	Hypothalamic-pituitary axis dysfunction	Amenorrhea, menorrhagia, impotence, oligospermia, hyperprolactinemia
Neurologic	Unknown	Neuromuscular excitability, cognitive dysfunction progressing to coma, peripheral neuropathy (restless leg syndrome or sensory deficits)

to the kidney, proteinuria, and accumulation of nephrotoxins all contribute to progressive damage.

The belief that hypertension causes progressive loss of kidney function is based on several observations. First, hypertension alone can damage the kidney; malignant hypertension damages the endothelial cells of the afferent arteriole and the glomerulus and may even cause thrombosis in these vessels. Second, chronic hypertension is frequently associated with ischemic injury to glomeruli owing to transmission of the blood pressure into the afferent arteriole and glomerulus, causing glomerulosclerosis. Third, the degree of hypertension is directly correlated with the rate of loss of kidney function. Fourth, effective treatment of hypertension slows the progression of CKD. Although it is sometimes difficult to determine the extent to which hypertension is a cause or an effect of CKD in an individual patient, hypertension is strongly associated with progressive kidney injury and with the development of cardiovascular disorders.

Experimentally, angiotensin II–related, progressive glomerular damage (Table 132-4) arises from preferential constriction of the glomerular efferent arteriole to a greater extent than in the afferent arteriole. The imbalance in arteriolar vasoconstriction increases intracapillary pressure and tends to raise glomerular filtration (the hyperfiltration mechanism), but the tradeoff for any increase in GFR is damage to glomerular capillaries. Because angiotensin II is the mediator of preferential efferent arteriolar constriction, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) may prevent both hyperfiltration and damage to the kidney.

The benefits of treatment with ACE inhibitors or ARBs may extend beyond reducing hyperfiltration. Angiotensin II has growth factor properties, and it activates transforming growth factor-β, plasminogen activator inhibitor type 1, and other cytokines, thereby aggravating interstitial damage to the kidney (see Table 132-4). Aldosterone may also contribute to the development of interstitial damage and collagen deposition in the kidney. However, blocking the actions of aldosterone can cause hyperkalemia.

Patients receiving ACE inhibitor or ARB treatment experience a reduction in albuminuria, presumably because of a decrease in the pressure within glomeruli. Experimental evidence suggests that albumin or some component of albumin (e.g., lipids or molecules bound to albumin) may injure kidney cells; therefore, reducing albuminuria may be directly beneficial. Because the degree of albuminuria is related to the rapidity of the loss of kidney function, reducing albuminuria is a treatment goal.

CLINICAL MANIFESTATIONS

Unfortunately, progressive loss of kidney function produces no clinically distinct signs or symptoms. Findings that should raise the possibility of CKD include urinary abnormalities, such as hematuria or repeated urinary infections, or the appearance of hypertension and/or edema. The possibility of CKD should also be considered in patients with chronic hypertension, diabetes, or albuminuria and those with a family member with CKD.

As the GFR declines, clinical abnormalities become more frequent. Even when CKD is advanced (stage 4; see Table 132-2), however, the symptoms are mostly nonspecific. Some patients complain only of exercise intolerance, fatigue, or anorexia. If these symptoms are present, serum creatinine and BUN levels should be measured, and the urine should be examined for albuminuria. As CKD progresses, patients frequently have anemia, metabolic acidosis, hyperkalemia, hyperphosphatemia, hypocalcemia, and hypoalbuminemia, each of which can be associated with specific symptoms (Table 132-5).

Specific syndromes are associated with proteinuria and CKD. For example, severe albumin losses (>3 g/day) plus edema and hypercholesterolemia define the nephrotic syndrome (Chapter 123), which can lead to the loss of the relatively small (59 kD) vitamin D–binding protein plus the attached 25-hydroxyvitamin D_3, thereby aggravating bone disease. Advanced proteinuria can also be associated with losses of clotting factors IX, XI, and XII, causing coagulation defects (Chapter 177). Conversely, urinary losses of antithrombin III can result in thrombosis (Chapter 174), especially when inflammation-induced increases in the levels of acute phase reactant proteins lead to hyperfibrinogenemia.

Bone Disease and Extraosseous Calcification

Some patients with renal bone disease complain of vague, ill-defined pain in the lower back, hips, knees, and other locations. Advanced bone disease can cause such severe pain that it impairs the ability to exercise, aggravating the tendency to lose muscle mass. With advanced renal bone disease, minimal trauma may produce fractures.

Another clinical syndrome related to renal bone disease is the development of vascular calcification, which causes vascular stiffness and increases systolic blood pressure, thereby participating in the development of left ventricular hypertrophy. A more disabling manifestation is the development of calcifications in the tunica media of blood vessels (i.e., Mönckeberg's sclerosis) as well as calcifications that impair the function of multiple organs, including the lungs, myocardium, and skin. Calcification of the skin and cutaneous vessels is seen in the syndrome of calciphylaxis.

DIAGNOSIS

If CKD is suspected, emphasis should be placed on eliciting a history of hypertension, urinary abnormalities, and treatment with drugs that might affect kidney function (Chapter 122). The family history should focus on the presence of family members with kidney diseases, kidney stones, or surgery involving the urinary tract, as well as diabetes and hypertension. The physical examination should include lying and standing blood pressure measurements in both arms and a search for findings associated with CKD, such as skin abnormalities, persistent itching, a palpable polycystic kidney (Chapter 129), evidence of decreased lean body mass, peripheral edema, and neurologic abnormalities.

Staging

The severity of CKD is divided into five stages according to persistent reductions in estimated GFR (see Table 132-2). Two assessments of impaired kidney function are necessary: GFR and degree of albuminuria. Generally, the GFR can be estimated based on the serum creatinine level, age, body weight, gender, and race (see Table 132-2). The serum creatinine concentration is influenced by both kidney function and creatinine production, and the latter is directly proportional to lean body mass plus a small contribution from dietary meat. Notably, the serum creatinine concentration can remain in the nominally normal range until as much as 50% of kidney function is lost. Consequently, an elevated serum creatinine level means that both kidneys are functioning inadequately and that more than 50% of nephrons and nearly 50% of kidney function have been lost. By itself, the serum creatinine level is too variable to be used as a measure of GFR, but repeated values can be used to assess how rapidly changes in GFR are occurring. For example, changes in the reciprocal of the creatinine level (1/serum creatinine) yield a linear relationship with the rate of GFR loss (Fig. 132-3). Deviations from linearity signal a change in the course of CKD.

Other methods of estimating kidney function are not as accurate. For example, the BUN concentration is determined not only by the remaining kidney function but also by the amount of protein in the diet.

A careful microscopic examination of the urine is critical. Erythrocytes and erythrocyte casts in urine sediment are consistent with glomerulonephritis (Chapter 123), fine granular casts plus protein suggest diabetic kidney disease (Chapter 126), leukocytes plus fine and coarse granular casts suggest interstitial nephritis (Chapter 124), and eosinophils in the urine suggest a drug reaction with interstitial damage (Chapter 124).

Microalbuminuria is defined as 30 to 300 mg albumin/24 hours or 30 to 300 mg albumin/g creatinine in an initial morning urine specimen. Albuminuria is defined as excretion rates that are greater than those of microalbuminuria. The measured magnitude of albuminuria in a 24-hour urine collection depends on a full collection. An equally accurate alternative is to measure the ratio of albumin to creatinine concentrations in the first morning urine specimen on 3 separate days.

The urea nitrogen content of the 24-hour urine collection also allows calculation of the amount of dietary protein, which is composed of 16% nitrogen (see Fig. 132-2; Table 132-6). When the amount of urea nitrogen excreted in the steady state (i.e., when weight and BUN are stable) is added to the nonurea nitrogen excreted daily—which can accurately be estimated as 0.031 g nitrogen/kg ideal body weight/day—total daily nitrogen excretion can be calculated. If the total amount of nitrogen excreted exceeds the nitrogen contained in the prescribed diet, possibilities include dietary nonadherence, gastrointestinal bleeding, or a catabolic illness.

Other Laboratory Tests

Blood chemistries that evaluate the consequences of CKD include concentrations of sodium, potassium, chloride, bicarbonate, calcium, and phosphorus, as well as uric acid levels. The blood glucose level and hemoglobin A_{1c} level should be monitored in diabetics, and serum complement levels should be measured in patients with inflammatory diseases of the kidney. The hematocrit and/or hemoglobin level should be assessed and monitored because anemia often appears with even mild renal dysfunction and tends to progress as CKD progresses, owing to reduced erythropoietin production and/or iron deficiency. Iron deficiency can be recognized if the serum iron level is low, the serum ferritin concentration is less than 200 ng/mL, and the transferrin saturation level is less than 20% (Chapter 162). To detect CKD-induced bone disease, levels of PTH, alkaline phosphatase, calcium, and phosphorus should be obtained.

Imaging

The initial evaluation should include an ultrasound examination of the kidney and bladder to ensure that there is no obstruction of urine flow (Chapter 125). Enlarged kidneys suggest that CKD is due to diabetes, HIV-associated nephropathy, or infiltrative diseases (e.g., amyloidosis). Small kidneys, especially with a shrunken kidney cortex, suggest chronic glomerular or interstitial diseases (Chapter 124). If the size of the two kidneys differs substantially, stenosis of the renal artery (Chapter 127) of the smaller kidney should be considered, especially in hypertensive patients.

TABLE 132-6 ESTIMATION OF DIETARY PROTEIN FROM 24-HOUR UREA NITROGEN EXCRETION

ASSUMPTIONS

The patient is in the steady state, and neither the serum urea nitrogen concentration nor body weight is changing; there is no edema.
The patient is in nitrogen balance, so that nitrogen intake equals nitrogen excretion.
Protein is 16% nitrogen.
The nonurea nitrogen excretion (the nitrogen in urinary creatinine, uric acid, and peptides plus feces) is 0.031 g nitrogen/kg/day.

CASE 1

A 50-year-old patient with a stable weight of 70 kg is prescribed a diet containing 0.8 g protein/kg/day. His 24-hr urea nitrogen excretion is 6.8 g nitrogen/day. How much protein is he eating?
His diet should contain 70 kg × 0.8 g protein/kg, or 56 g protein. His intake of nitrogen from this diet is approximately 9 g (56 g protein × 0.16 = 8.96 g nitrogen). His nitrogen excretion is 6.8 g urea nitrogen + 2.17 g nonurea nitrogen/day (70 × 0.031 g nonurea nitrogen/kg/day). The total nitrogen excretion is 8.97 g, so the patient is compliant with the prescribed diet.

CASE 2

A 40-year-old woman weighing 60 kg is confident that she is eating a diet containing 0.6 g protein/kg/day. Her 24-hr urea nitrogen excretion is 10 g nitrogen/kg/day. Does she require additional investigation?
Her diet should contain 60 kg × 0.6 g protein/kg, or 36 g protein. Therefore, her intake of nitrogen is approximately 5.8 g (36 g protein × 0.16 = 5.76 g nitrogen). Her nitrogen excretion is 10 g urea nitrogen + 1.86 g nonurea nitrogen (60 kg × 0.031 g nonurea nitrogen/kg/day). Her total nitrogen excretion is 11.9 g/day, far in excess of the amount of protein she believes she is eating. Consequently, the patient requires investigation for gastrointestinal bleeding.

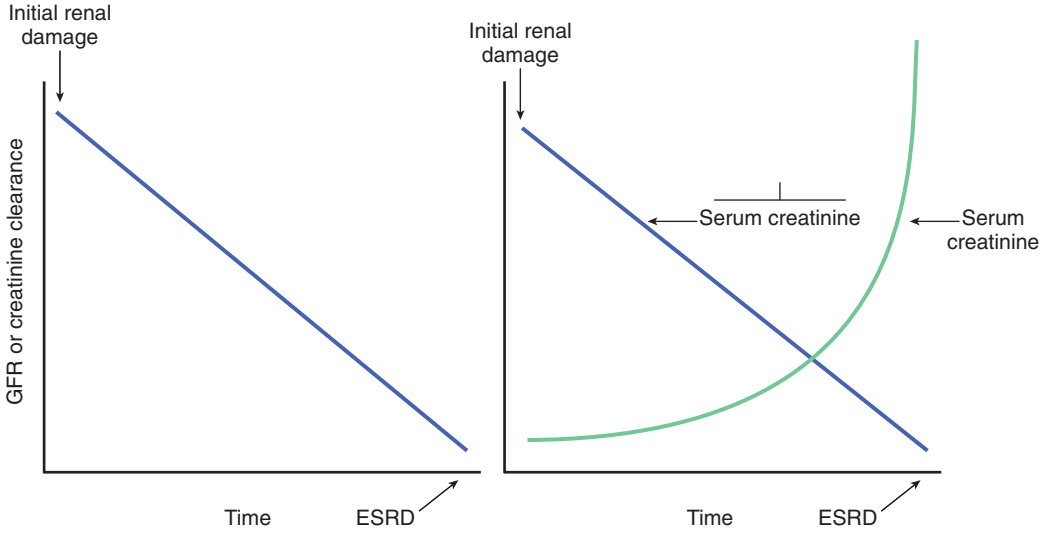

FIGURE 132-3. The course of renal insufficiency from initial renal damage to end-stage renal disease (ESRD; left panel). The course is estimated most easily by the reciprocal of serum creatinine (right panel). TREATMENT

Because the risk of developing cardiovascular disorders is increased in CKD, the first goal of treatment is to reduce blood pressure to reduce mortality.[1] Therapy with an ACE inhibitor or ARB should be started to slow the loss of kidney function.[2-4] The preferred strategy is to begin at the lower recommended doses (see Table 67-5 in Chapter 67) and titrate upward until blood pressure is controlled (usually to a goal of 130/80 mm Hg) and albuminuria is decreased. In patients with type 2 diabetes, a systolic blood pressure goal of 135 to 140 mm Hg is preferable to a goal of less than 120 mm Hg, and a blood pressure of about 140/85 mm Hg is as good as 130/80 mm Hg for reducing the progression of hypertensive renal disease.[5,6] Combining an ACE inhibitor and an ARB provides no additional benefit in terms of protecting the kidney and is associated with more frequent adverse events,[7] so this combination is not recommended. Adverse effects of ACE inhibitors or ARBs include an increase in the serum creatinine level and/or hyperkalemia, especially in patients with bilateral renal artery stenosis. In these cases, the fall in GFR is due to a lowering of intraglomerular blood pressure, which reduces albuminuria and slows the loss of GFR, not to additional kidney damage; therefore, an increase in serum creatinine concentration after starting therapy should not trigger an automatic discontinuation of ACE inhibitor or ARB therapy. However, any unexpected changes in the serum creatinine level should stimulate the consideration of progressive CKD from an increase in blood pressure, infection, drugs that adversely affect kidney function, or exacerbation of the underlying renal disease. If no other reason for a decrease in kidney function is uncovered, the ACE inhibitor or ARB treatment should be continued, but with a 50% reduction in dose.

Hyperkalemia occurs with ACE inhibitors and ARBs because reduced angiotensin II decreases the release of aldosterone. Other causes of an increase in serum potassium should be considered (e.g., treatment with nonsteroidal anti-inflammatory drugs or potassium-sparing diuretics, or an increase in potassium-rich foods) and addressed. If needed, the addition of a loop diuretic (e.g., 40 mg furosemide when the serum creatinine level is <3 mg/dL and higher doses for more advanced CKD) may treat hyperkalemia successfully.

The blood pressure goal of 130/80 mm Hg almost always requires additional therapy, including dietary salt restriction to 2 g sodium/day. This goal is equivalent to 86 mEq sodium/day and is achievable if patients avoid salt-rich foods. For patients who develop problems with inhibitors of the renin-angiotensin system, other vasodilators, such as nondihydropyridine calcium-channel blockers (e.g., diltiazem, verapamil), seem to have fewer side effects than dihydropyridine drugs (e.g., amlodipine). Despite their ability to combat hypertension, vasodilators other than ACE inhibitors and ARBs are not as effective for reducing albuminuria, and they can cause peripheral edema. The loop diuretics are preferred for patients with more advanced CKD because they maintain renal blood flow, have few adverse effects, and, unlike thiazide diuretics, remain effective even at GFRs below 25 mL/minute. As renal insufficiency advances, high daily doses of loop diuretics (e.g., 80 to 160 mg furosemide orally) may be required to reduce extracellular volume. The dose-response relationship of loop diuretics is sigmoidal, so once a dose is identified as being effective in producing loss of edema and body weight, it should not be reduced or given in divided doses.

Stage 1 and Stage 2 Chronic Kidney Disease

In patients with stage 1 or 2 CKD, uremic symptoms are unusual because there is sufficient kidney function to control the levels of potential uremic toxins. Therapy therefore emphasizes reducing blood pressure to 130/80 mm Hg, intensive treatment of the underlying disease (e.g., normalization of blood glucose concentration in diabetic patients), and monitoring changes in albuminuria and loss of GFR (Fig. 132-4).

Dietary salt restriction is routinely recommended, and many patients require a diuretic (see Table 67-5 in Chapter 67) because an ACE inhibitor or ARB rarely controls hypertension unless steps are taken to avoid salt

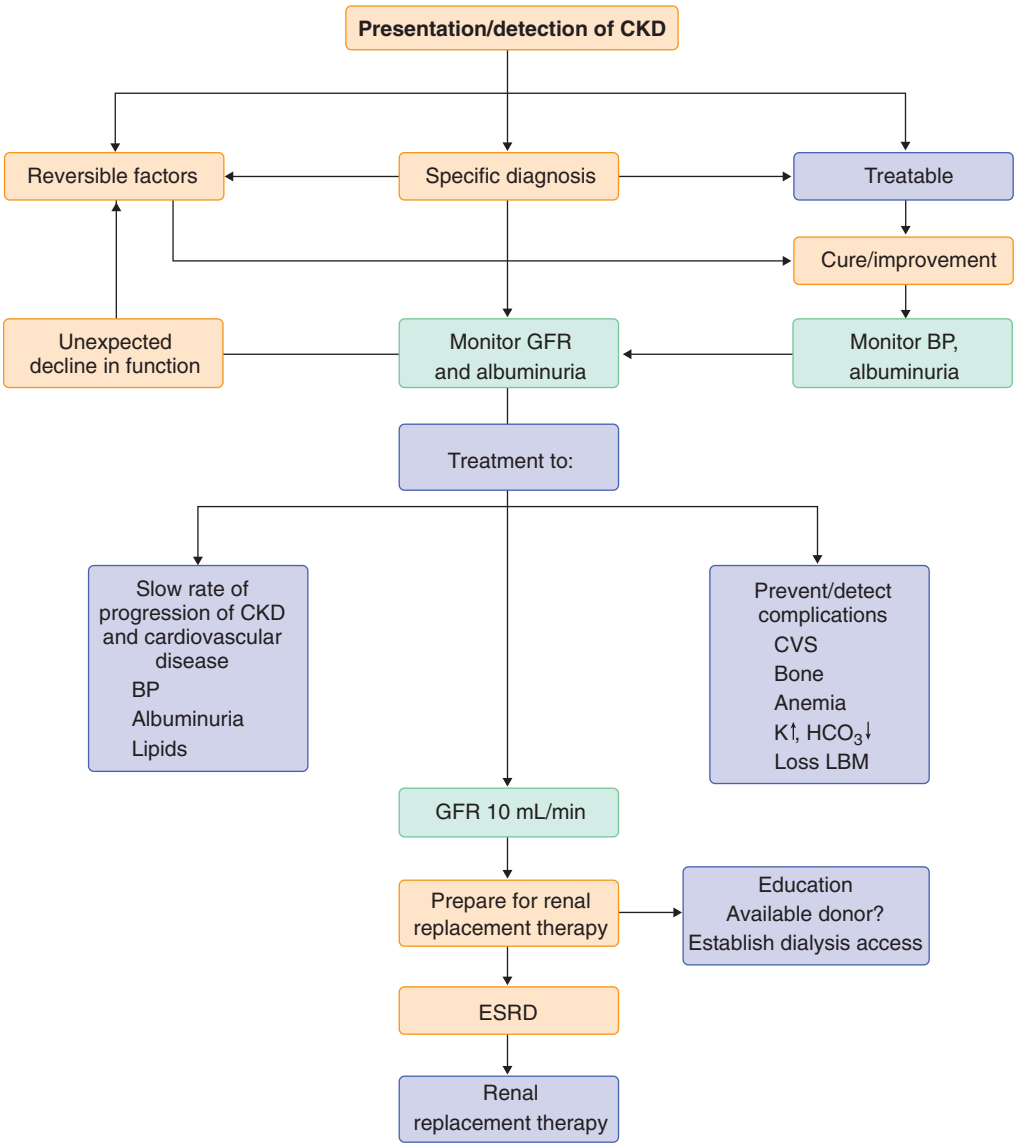

FIGURE 132-4. Management of patients in the various stages of chronic kidney disease (CKD). BP = blood pressure; CVS = cardiovascular system; ESRD = end-stage renal disease; GFR = glomerular filtration rate; LBM = lean body mass.

accumulation. A critical tactic is to monitor body weight; if weight and edema increase, it signifies salt retention. Conversely, a rapid loss of weight and edema would be the first clue that the diuretic dose should be reduced.

Stage 3 and Stage 4 Chronic Kidney Disease

Patients with stage 3 CKD should be referred to a nephrologist to maximize preventive measures and to search for remediable disorders. When stage 4 CKD is reached, a nephrologist should instruct patients about the advantages of therapies such as dialysis or transplantation (Chapter 133).

In stage 3 and stage 4 CKD, the doses of many renally excreted drugs must be adjusted downward to prevent overdosing. Treatable complications of CKD, including hypertension, secondary parathyroidism, acidosis, and uremic symptoms must be addressed. Radiologic tests with nephrotoxic contrast dye should be avoided if possible.

The development of many CKD complications (see Table 132-5) requires modification of the diet. An unrestricted high-protein diet contains an excess of salt, acid precursors, and phosphates and can lead to the development of metabolic acidosis, hyperphosphatemia, edema, hypertension, and uremic symptoms. CKD patients with any of these complications should initiate a diet consisting of 0.8 g protein/kg ideal body weight/day to maintain body protein stores and reduce the likelihood of developing other complications. Calorie intake should be limited to 30 kcal/kg ideal body weight/day for largely sedentary patients, with more for those who still exercise vigorously. If CKD-induced uremic symptoms persist, dietary protein can be restricted to a minimum of 0.6 g protein/kg/day, with a calorie intake of 30 kcal/kg/day. With either diet, successful implementation requires the advice, guidance, and close monitoring of a dietitian to take advantage of the patient's food preferences. Compliance can be monitored by measuring the 24-hour excretion of urea nitrogen (see Table 132-6), and the adequacy of protein stores should be assessed regularly by measuring body weight and serum protein levels. Although low-protein diets may not slow the loss of kidney function, they reduce uremic symptoms and can delay the need for dialysis without compromising the maintenance of protein stores.[7] Most patients on a protein-restricted diet should receive a multivitamin to sustain levels of water-soluble vitamins, but they should take fat-soluble vitamins only for documented deficiencies.

Renal Bone Disease

Treatment of renal bone disease relies on correcting the principal disorder, which is the accumulation of phosphates. This is best detected by measuring the serum phosphorus level after a normal meal. In patients with more advanced CKD (e.g., late stage 3 or stage 4) and an increased PTH level, treatment is directed at reducing the serum phosphorus level to the normal range. Because kidney damage limits the capacity to excrete phosphates, the dietary content of phosphates must be reduced to less than 1000 mg/day. If dietary restriction proves insufficient to control serum phosphorus, "phosphate binders" (see Table 121-4 in Chapter 121) should be added to the treatment regimen to promote the formation of poorly absorbed complexes of phosphates in the gastrointestinal tract. Once complexed, the phosphates are poorly absorbed by the intestine. Aluminum hydroxide binders should be avoided because they are associated with aluminum deposition in bone, where they inhibit normal bone formation and have been associated with neurotoxicity. Other phosphate binders include calcium carbonate (initially one or two 500-mg tablets with each meal), calcium acetate (initially one or two 667-mg tablets with each meal), sevelamer hydrochloride (400- to 800-mg tablets, initially 2 g/day in divided doses), or lanthanum carbonate (750 mg to 1 g/day with meals). Calcium-containing binders must be used cautiously to avoid hypercalcemia and the deposition of calcium phosphate in soft tissues. Conversely, calcium-containing agents are preferred for hyperphosphatemia in association with hyperkalemia (Chapter 119) or neuromuscular irritability, as demonstrated by a positive Trousseau's sign (Chapter 253). The non-calcium-containing phosphate binder sevelamer decreases the progression of aortic and coronary artery calcification when compared with calcium-containing binders. Lanthanum carbonate is a newer binder, and experience with this agent is more limited. For patients with serum phosphorus levels less than 6 mg/dL, calcium-based binders are generally recommended, but the dose should not exceed 2 g calcium/day to reduce the risk of soft tissue calcification. When the serum phosphorus level is higher or higher doses are required, sevelamer is the preferred phosphate binder. If the serum phosphorus level exceeds 7 mg/dL, aluminum-based binders (600 mg of concentrated aluminum hydroxide solution with each meal) can rapidly decrease the serum phosphorus level, but use of this drug should be limited to a week to avoid aluminum toxicity. In all cases, the cornerstone of therapy is to reduce phosphate intake, which generally requires dietary protein restriction because protein-rich foods contain excess phosphates.

Calcitriol, which increases the intestinal absorption of both calcium and phosphates, has the unique ability to suppress the development of hyperparathyroidism. However, calcitriol should not be given to patients who have increased circulating levels of phosphates. Low serum levels of 25-hydroxyvitamin D_3 in CKD patients are associated with increased mortality; patients with low levels of calcitriol and 25-hydroxyvitamin D_3 can be treated with cholecalciferol 1000 units/day. Careful monitoring is needed to avoid hypercalcemia or urinary calcium values above 250 mg/day.

In a patient who develops calciphylaxis, treatment options are few and are directed mainly at reducing serum phosphorus with phosphate binders and aggressively restricting dietary phosphate. If the disorder persists despite correcting the serum phosphorus level, a trial of cinacalcet (initial dose 30 mg, increasing as needed to achieve a reduction in PTH) is warranted. With advanced calciphylaxis, successful treatment requires parathyroidectomy.

Anemia

Because of the decreased absorption of oral iron in patients with advanced CKD, ferumoxytol (two 500-mg IV injections separated by 3 to 8 days) provides a better response than oral iron supplements, with a low risk of side effects.[8] In pre-dialysis patients, treatment with erythropoietin (e.g., weekly injections of darbepoetin alfa 0.45 µg/kg) corrects anemia and improves quality of life.[9] Caution is necessary, however, because fully correcting the hemoglobin concentration has been associated with an increased risk of stroke.[5,6] Consequently, erythropoietin-stimulating agents should be used to maintain the hemoglobin concentration between 10 and 12 g/dL.

Atherosclerosis

The increased risk of cardiovascular complications is linked, in part, to high circulating levels of homocysteine and low-density-lipoprotein cholesterol (Chapter 51). However, interventions to reduce homocysteine have not decreased the risk of cardiovascular complications in patients with CKD. Statins have not benefited patients on dialysis but appear to benefit patients with stage 2 or early stage 3 CKD,[10,11] and possibly those with the nephrotic syndrome.

PROGNOSIS

Because the rate of loss of kidney function varies widely, even in patients who have the same type of kidney disease, it is critical to monitor the course of declining kidney function in each CKD patient by plotting the estimated GFR or 1/serum creatinine versus time (see Fig. 132-3). If the serum creatinine level remains unchanged after 4 months, it is likely that the rate of loss of kidney function has been slowed. Monitoring albuminuria provides additional information about the progressive loss of GFR, because the decline in GFR increases with rising degrees of albuminuria; in addition, persistent microalbuminuria, and especially albuminuria, is associated with an increased risk of cardiovascular disease and a more rapid loss of kidney function. Diabetic patients who decrease their albuminuria reduce their risk of major cardiovascular events and slow their rate of loss of kidney function.

Although population data are of limited value for the individual patient with CKD, epidemiologic studies indicate that one third of patients with stage 4 CKD (see Table 132-2) will progress to ESRD within 3 years. Dialysis or transplantation is generally required when the serum creatinine reaches 10 mg/dL; however, patients should be informed about treatment options well before this stage of CKD because the frequency of complications rises sharply when dialysis is initiated on an emergency basis.

Cardiovascular disease is the most common cause of mortality in CKD. It is present in many patients even in the early stages of kidney disease. Other contributors to the high mortality of CKD include diabetes, anemia, increased low-density-lipoprotein cholesterol levels, vascular calcification, and perhaps increased cysteine levels.

TREATMENT OF IRREVERSIBLE RENAL FAILURE

NINA TOLKOFF-RUBIN

Therapeutic options for irreversible end-stage renal disease (ESRD) include hemodialysis, peritoneal dialysis, and renal transplantation. Each of these approaches to renal replacement therapy has its unique risks and benefits. Currently, approximately 350,000 patients are on dialysis in the United States, and the ESRD population is projected to grow by about 7% per year.

The physician and the patient should recognize that these treatment modalities also can be complementary, thereby allowing flexibility of care under different clinical circumstances. The key is early identification of patients with progressive renal failure to enable them to make an educated choice that fits their lifestyle and medical situation. Careful planning can decrease emergency hospitalizations, complications, and costs. Early evaluation also enables identification of potential living donors so that preemptive transplantation can be performed.

INDICATIONS FOR RENAL REPLACEMENT THERAPY

The decision as to when to institute dialysis depends on the patient's signs and symptoms rather than an absolute level of blood urea nitrogen (BUN) or serum creatinine (Table 133-1). The benefits of early initiation of dialysis include the avoidance of malnutrition, fluid overload, and the deleterious effects of prolonged exposure to the accumulation of phosphorus, β_2-microglobulin, and other uremic toxins. However, early initiation of dialysis is no better than standard care.■

Hyperkalemia (Chapter 119) unresponsive to diuretics, ion exchange resins, and dietary restriction in the face of electrocardiographic (ECG) changes is an absolute indication for dialysis to avoid life-threatening arrhythmias. Volume overload refractory to intravenous diuretics, increasing lethargy, difficulty concentrating, nausea, and anorexia may be manifestations of the uremic syndrome requiring dialytic therapy. Intervention should occur before the progression of uremic encephalopathy, seizures, and coma or the development of pericarditis or pericardial tamponade (Chapter 77). Emergency hemodialysis is more costly because such patients typically lack vascular access, are sicker, and often require prolonged hospitalization.

TABLE 133-1 INDICATIONS FOR DIALYSIS IN CHRONIC KIDNEY DISEASE

Uremic encephalopathy or neuropathy
Pericarditis or pleuritis
Bleeding attributable to uremia
Fluid overload refractory to diuretics
Hypertension poorly responsive to medication
Persistent hyperkalemia, metabolic acidosis, hypercalcemia, hypocalcemia, or hyperphosphatemia refractory to medical therapy
Malnutrition or weight loss
Persistent nausea and vomiting

HEMODIALYSIS

Dialysis substitutes two major renal functions: *solute removal* and *fluid removal*. In hemodialysis, solute removal occurs predominantly by diffusive clearance, which is the movement of solutes from the blood compartment to the dialysate compartment across a semipermeable membrane. Several basic principles apply. Clearance is higher for smaller molecules. The greater the concentration gradient between the blood and the dialysis solution, the more rapidly diffusion occurs. The net transfer of solute increases as membrane surface area increases. Membrane permeability is determined by the specific characteristics of the membrane, such as pore size, charge, and quaternary conformation. Higher flow rates allow greater solute removal, especially if the flow of dialysate is countercurrent to blood flow, thereby maximizing the gradient across the membrane.

Solute removal can also occur by the process of convection, the movement of solutes by bulk flow in association with fluid removal (solvent drag). Although the convective mass transfer of solutes may not play a dominant role in conventional hemodialysis, convection does play a significant role in high-flux dialysis and in continuous venovenous hemofiltration (CVVH).

Fluid removal in hemodialysis occurs by the process of ultrafiltration. The ultrafiltration rate is determined by the hydrostatic pressure gradient across the dialysis membrane, called the *transmembrane pressure*. Ultrafiltration increases if positive pressure is applied to the blood compartment or if negative pressure is applied to the dialysate side of the dialysis membrane. During dialysis, the ultrafiltration rate is adjusted to obtain the desired fluid loss.

The hemodialysis machine has three main components: (1) the dialyzer (i.e., the dialysis membrane); (2) a pump that regulates blood flow; and (3) a dialysate solution delivery system. In addition, the machine has many safety devices to monitor arterial and venous pressures, concentration of ions and temperature in the dialysate, and air and blood leaks (Fig. 133-1).

Under most circumstances, solute removal and fluid removal occur simultaneously. However, if vigorous ultrafiltration is attempted during conventional hemodialysis, patients frequently complain of muscle cramping, nausea, and vomiting. Moreover, during aggressive fluid removal systemic vascular resistance may decrease, thereby reducing blood pressure. Separating ultrafiltration from dialysis enables efficient fluid removal with greater hemodynamic stability. Osmotic changes are minimized with isolated ultrafiltration (i.e., fluid removal in the absence of solute removal). As a result, vascular resistance is well maintained, and, consequently, less hypotension occurs despite large fluid shifts.

Performing Hemodialysis

Hemodialyzers

The hollow-fiber dialyzer is composed of thousands of parallel capillary tubes. Blood flows through the capillary tubes, and dialysate flows in a countercurrent direction, bathing the outside of the capillary tubes (see Fig. 133-1). Dialysis membranes made of polycarbonate, polysulfones, polyacrylonitrile, or polymethylmethacrylate are less proinflammatory, provide better filtration rates, and improve survival compared with earlier cellulose-based membranes.

Access

To perform hemodialysis on a repetitive basis, access to the circulation is essential. An arteriovenous fistula involves anastomosis of the radial or brachial artery to the cephalic or basilic veins, with subsequent "arterialization" of the superficial forearm veins to enable blood flow rates up to 400 mL/minute. The most frequent problem is failure of the fistula to mature, particularly in patients with peripheral vascular disease or diabetes. In patients with progressive chronic kidney disease, the nondominant arm should be spared from venipuncture and a fistula should be placed in advance of the need of hemodialysis because the fistula usually takes 6 to 8 weeks to mature. Guidelines recommend elective placement of a fistula when the serum creatinine exceeds 4 mg/dL, the creatinine clearance falls to less than 25 mL/minute, or the initiation of hemodialysis is anticipated within 1 year.

Synthetic arteriovenous grafts, which can be used when a native fistula cannot be placed, have higher rates of thrombosis and infection. A third option is percutaneous dual-lumen catheters, which are placed preferentially in the internal jugular vein with a segment of the line tunneled under the skin.

Anticoagulation

Contact of patient's blood with the dialysis membrane and the tubing leads to activation of the coagulation cascade. Thrombus within the catheter can

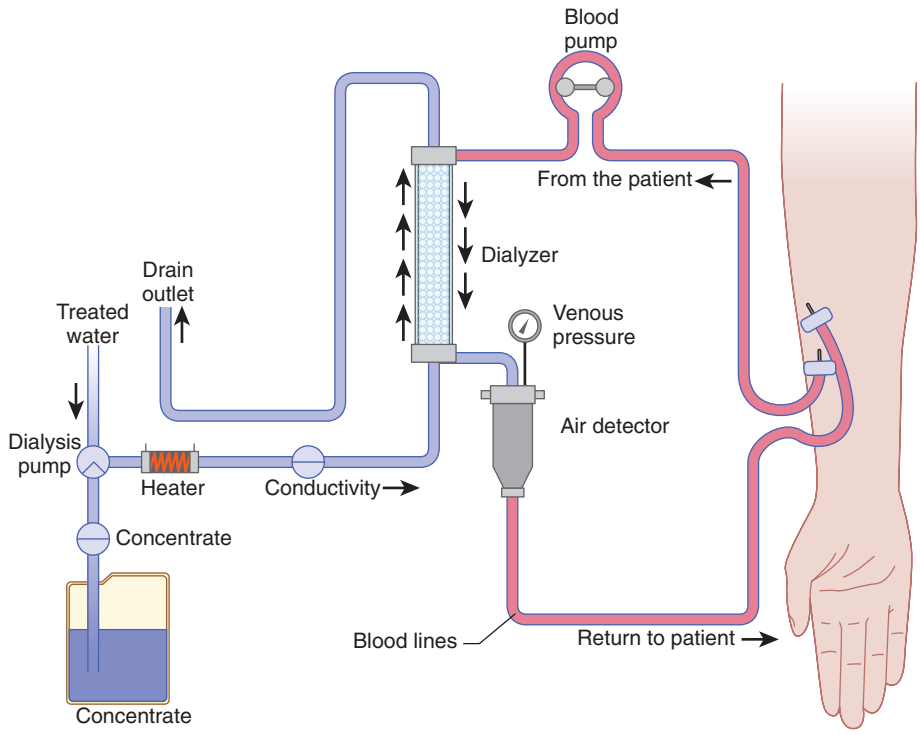

FIGURE 133-1. Hemodialysis. Treated water is mixed with concentrated dialysate. The dialysate solution flows around the fibers of the hollow-fiber dialyzer counter-current to the blood flow through the dialyzer. A computerized ultra-filtration control device regulates fluid removal (Modified from http://www.gml-dialyza.cz/Obrazky/hemodialysis.jpg.)

obstruct blood flow and also serve as a nidus for pathogens. Heparin (dosed at 500 to 1000 units/hour) is usually required to prevent clotting, but it may cause bleeding or heparin-induced thrombocytopenia (Chapter 175).

In patients at high risk for bleeding, hemodialysis can be performed without anticoagulation. Heparin-free dialysis requires a high blood flow rate and frequent flushing of the system with normal saline. Many patients also develop a procoagulant state caused by the development of anticardiolipin (Chapter 177), lupus anticoagulant antibodies, or high homocysteine levels, which may contribute to the tendency for clotting in the dialyzer and vascular access systems.

Dialysate Solution

The dialysate is a balanced solution of sodium, potassium, calcium, magnesium, chloride, and dextrose, with bicarbonate as a buffer. During dialysis, the sodium concentration is usually maintained at 135 to 140 mEq/L. A higher sodium dialysate concentration helps prevent hypotension, muscle cramps, nausea, vomiting, headaches, and seizures during hemodialysis; the sodium concentration can be programmed to return to normal range by the end of hemodialysis. Mannitol can also be used to prevent dialysis disequilibrium syndrome. The potassium concentration in the dialysate can be adjusted from 0 to 4 mEq/L but is generally maintained at 2 mEq/L in chronic outpatient dialysis centers with central delivery systems. The calcium concentration is usually 2.5 mEq/L.

Because patients are exposed to large volumes of water during each hemodialysis treatment, purity of the water is essential. A charcoal filter removes organic toxins such as chloramines, whereas reverse osmosis or de-ionization of the water effectively removes aluminum, fluoride, and copper. Chronic exposure to aluminum can lead to dialysis dementia, bone disease, and erythropoietin-resistant anemia.

Complications

Complications during Hemodialysis

In addition to vascular access problems, the most common complications during hemodialysis are hypotension, muscle cramps, nausea, vomiting, headache, and chest pain. Although excessive fluid removal is the most frequent cause of hypotension, other potential causes if the hypotension persists after fluid replacement include sepsis, myocardial ischemia, pericardial tamponade, arrhythmias, and active bleeding. Antihypertensive agents may need to be withheld before dialysis to avoid hypotension.

Air embolus, which is the most dreaded technical complication of the hemodialysis procedure (Chapter 98), presents with agitation, cough, dyspnea, and chest pain. As soon as the diagnosis is suspected, the patient should be positioned with the left side down in an attempt to trap air in the right ventricle. One hundred percent oxygen should be administered.

Vascular Access Infections

Although tunneled lines provide immediate and convenient access to the circulation, the surrounding skin and the catheter hubs are the primary sources of bacteria. Infectious complications of the vascular access account for nearly 75% of all cases of bacteremia in the ESRD population. If a patient presents with possible catheter-related bacteremia, blood cultures should be obtained both from the catheter and from a peripheral vein.

Because most vascular access infections are caused by staphylococcal organisms (Chapter 296), which carry high rates of mortality, recurrence, and metastatic complications, empirical vancomycin, 1 g every 3 days for at least 2 weeks while monitoring blood levels, is usually used in institutions with an increased incidence of methicillin-resistant staphylococci. However, the indiscriminate and prolonged use of vancomycin should be avoided to prevent the emergence of vancomycin-resistant organisms, especially *Enterococcus* species. If the patient has any evidence of systemic sepsis with hemodynamic instability, the line should be pulled promptly and reinserted only after blood cultures are negative for at least 48 hours and the patient has defervesced. In the interim, dialysis can be performed femorally or through a temporary nontunneled catheter.

In patients with a prompt response to antibiotic therapy, antimicrobial agents should be administered for at least 2 to 3 weeks. A prolonged course of antibiotic therapy (4 to 8 weeks) is recommended if there is persistent bacteremia or fungemia after catheter removal or if there is evidence of endocarditis (Chapter 76), septic arthritis (Chapter 280), osteomyelitis (Chapter 296), epidural abscess (Chapter 421), or other metastatic infection.

Long-Term Complications in Hemodialysis

Anemia

The development of a normochromic normocytic anemia (Chapter 161) parallels the progression of chronic kidney disease, and almost two thirds of patients who start dialysis have hematocrit levels less than 30% and hemoglobin levels less than 10 g/dL. Decreased erythropoietin production is the major cause, but contributing factors include a shortened life span of red blood cells, uremic inhibitors of erythropoiesis, iron deficiency owing to poor iron absorption, gastrointestinal bleeding, loss of blood with frequent blood sampling, and losses during hemodialysis. Folic acid is removed by dialysis, so folate replacement is necessary. Infection, inflammation, malignancy, and high parathyroid hormone levels can also inhibit red blood cell maturation. Aluminum toxicity, either from aluminum contamination of the

water supply or through the use of aluminum-containing phosphate binders, has been associated with microcytic anemia in dialysis patients with normal iron stores.

Erythropoietin

The administration of erythropoietin (50 to 100 U/kg intravenously three times weekly depending on the baseline hemoglobin level), together with repletion of iron stores, folic acid supplementation, and treatment of concomitant infection, is effective in correcting the anemia of chronic renal disease. The target hemoglobin level, with or without the use of erythropoietin, should be no higher than 12 g/dL because a number of studies have shown that higher levels are associated with increased mortality rates, particularly due to cardiovascular events and strokes.■ Failure to provide an adequate supply of iron is the most common cause of erythropoietin treatment failure. The best way to replenish the iron stores in dialysis patients is intravenous iron (Chapter 162). A transferrin saturation level (serum iron ÷ total iron-binding capacity × 100%) of less than 20% and a ferritin level of less than 100 ng/mL are indications for intravenous iron therapy in dialysis patients. Erythropoietin resistance also occurs in the presence of ongoing infection, inflammation, hyperparathyroidism, or aluminum toxicity.

Malnutrition

Hypoalbuminemia is associated with an increased mortality among patients undergoing dialysis. Patients with an albumin level of less than 3.0 g/dL have a 2-year mortality rate of up to 40%, in comparison with the expected mortality rate of 20%. Marked catabolism, anorexia, and severe diet limitations during the predialysis period lead to loss of lean weight. After the initiation of dialysis, patients usually have an improved appetite, and their protein intake should be at least 1.2 g/kg per day for a total caloric intake of 35 cal/kg/day. Water-soluble vitamins, including folic acid, need to be replaced because they are depleted during dialysis.

Chronic Kidney Disease and Cardiovascular Disease

Cardiovascular disease, which is the most important cause of death among patients with chronic kidney disease, accounts for approximately 50% of the deaths among patients on dialysis and among recipients of renal allografts. Two thirds of patients with chronic kidney disease have diabetes mellitus or hypertension, but the rates of cardiovascular disease and mortality are also elevated among patients with primary renal diseases such as glomerulonephritis. Among patients younger than 45 years of age, cardiac mortality is 100 times greater than in the general population.

In patients initiating dialysis, the main cardiac abnormality is left ventricular hypertrophy. A number of studies have shown a direct correlation between an elevated serum phosphorus concentration (>5.5 mg/dL), a calcium-phosphorus product (Ca × P) greater than 56, and mortality in hemodialysis patients. A striking degree of coronary and aortic calcification has been demonstrated in young adults with ESRD using electron-beam tomography (Chapter 56). These findings have led to a decrease in the use of calcium- versus non-calcium-containing phosphate binders, such as sevelamer and lanthanum carbonate.

Decreased synthesis of the active principal form of vitamin D (1,25-$[OH]_2D_3$) contributes to the secondary hyperparathyroidism of dialysis patients, and pulse-dose intravenous activated vitamin D is used to suppress synthesis of parathyroid hormone (PTH) directly and to prevent skeletal complications. However, randomized trials are needed because the aggressive use of vitamin D analogues may also increase vascular calcification or ossification. Recent retrospective studies suggest that therapy with pulse-dose activated vitamin D improves the survival of patients undergoing chronic hemodialysis and that paricalcitol in particular may provide a survival advantage over calcitriol.

Renal Osteodystrophy

Three forms of bone disease are seen in patients with renal failure. *Osteitis fibrosis cystica* is a condition in which there is increased bone turnover owing to secondary hyperparathyroidism. *Osteomalacia* (Chapter 252) is characterized by an increase in unmineralized bone (widened osteoid seam) as well as low bone turnover. *Adynamic bone disease* is a condition in which there is low bone turnover. Although bone biopsy remains the gold standard for determining the form of renal-associated bone disease, the diagnosis is typically made chemically, guided by serum PTH, calcium, phosphorus, and alkaline phosphatase, as well as the clinical scenario.

At present, adynamic bone disease is the principal bone lesion in dialysis patients, mostly as a result of oversuppression of PTH with overzealous use of calcium-containing binders and vitamin D analogues. Fractures and hypercalcemia can occur. Adynamic bone disease, defined by bone biopsy or intact serum PTH less than 100 picograms/mL, is treated by allowing the PTH to rise by avoiding calcium-containing binders and vitamin D analogues and by using non-calcium-containing phosphate binders, such as sevelamer or lanthanum, to control hyperphosphatemia.

Dialysis Dose

The time-averaged concentration of urea and nutritional status, as determined by protein catabolic rate, is an important determinant of morbidity and mortality in hemodialysis. It is better for patients to be dialyzed longer and be well nourished than to have a low BUN value and be dialyzed for shorter periods. The prescription of hemodialysis is tailored to the patient's size and protein intake. The best method for determining the adequacy of hemodialysis is urea kinetic modeling, a dimensionless formula that determines the fractional urea clearance per treatment normalized to the volume of urea distribution. K is the dialyzer clearance, t is the time (duration) of dialysis therapy, and V is the volume of distribution of urea, which is approximately equal to the total body water. When supplied with simple clinical information (predialysis and postdialysis weights, ultrafiltration volume, hematocrit, and predialysis and postdialysis BUN, as well as the dialyzer clearance), computer software programs perform the calculation. Guidelines recommend a single pool Kt/V greater than 1.2 to minimize uremic complications and hospitalizations. Increasing the chronic dose of dialysis beyond a Kt/V of 1.4 does not appear to increase survival,■ but chronic hemodialysis six times per week generally improves outcomes compared with conventional hemodialysis three times per week.■ Similarly, nocturnal hemodialysis, performed six or seven nights a week at home for 6 to 8 hours, improves solute clearance, controls serum phosphate, and provides excellent blood pressure control with a reduction in medication requirements.■ It also can improve kidney-specific measures of quality of life.■ A family member can help perform the treatment, or the patient can be monitored at a central station through closed-circuit television. This intensive dialysis modality may be a bridge to transplantation or a long-term option when the patient is not a transplantation candidate.

Continuous Renal Replacement Therapy

Critically ill patients with renal failure are frequently hemodynamically unstable, are hypercatabolic (e.g., sepsis, severe burns, brain injury, liver failure, trauma), and require large amounts of fluids (e.g., nutrition, antibiotics). Standard hemodialysis may be complicated by hypotension, in part owing to rapid fluid and solute removal. Slow, low-efficiency hemodialysis performed with low blood flows for 6 to 8 hours daily is one alternative for unstable dialysis patients with renal failure. However, patients with liver failure, traumatic brain injury, or coma do not tolerate the rapid osmolarity changes produced by hemodialysis, which can cause severe brain edema and herniation. In contrast, during CVVH, the rate of fluid removal through venovenous filtration is slower, and solute clearance relies on convection (solvent drag) rather than diffusion, which does not cause such acute changes in osmolarity.

CVVH requires central venous access (double-lumen catheter) and blood flows between 150 and 200 mL/minute. Blood under pressure passes down one side of a highly permeable membrane, thereby allowing both water and solutes up to a molecular weight of about 60 kD to pass across the membrane. In contrast to hemodialysis, urea, creatinine, and phosphate are cleared at similar rates (convective clearance) during hemofiltration. The filtrate is discarded, and the fluid lost is partially replaced with a solution containing the major crystalloid components of the plasma at physiologic levels. However, if further clearance is needed in highly catabolic patients, diffusive dialysis (CVVH) can be added by passing dialysis solution through the dialysate compartment.

Heparin anticoagulation (500 to 1000 U/hour) is usually required to maintain the patency of the CVVH circuit, except in patients who are at high risk for bleeding. An effective method of regional anticoagulation is the use of a calcium-free citrate replacement fluid administered in a separate central line before filtration; citrate chelates calcium in the blood, thereby preventing clotting of the hemofilter. If the patient cannot metabolize citrate, usually because of liver failure, an anion gap metabolic acidosis will develop. The presence of a low ionized calcium and a high total calcium level also is a clue indicating citrate toxicity. Patients who have liver failure and

contraindications to heparin often can tolerate CVVH without anticoagulation using bicarbonate-containing replacement solution.

Presently, there is no evidence from randomized trials that demonstrates that CVVH offers a survival advantage compared with intermittent hemodialysis in patients with acute renal failure, despite the advantages of CVVH in enabling the removal of large amounts of fluid with improved hemodynamic stability and excellent metabolic and acid-base control. Increasing the dose of CVVH (ultrafiltration rates of >35 mL/kg/hour versus 25 mL/kg/hour) does not improve survival in critically ill patients with acute renal failure.[3,4]

PERITONEAL DIALYSIS

Approximately 10% of patients with ESRD in the United States and more than 50% of those in the United Kingdom, Mexico, Canada, and Australia receive continuous ambulatory peritoneal dialysis (CAPD), which provides survival rates comparable to those of hemodialysis, when adjusted for patient age and comorbid conditions. CAPD obviates the need for vascular access, which is a major challenge in diabetic patients, young children, and patients with severe vascular disease. Moreover, peritoneal dialysis can be performed without anticoagulation, thereby decreasing the possible risk for bleeding. Because peritoneal dialysis is a slow, continuous process, it avoids the marked hemodynamic and osmotic shifts associated with hemodialysis. Patients can be taught to do the procedure at home, thereby giving them a sense of control and independence. Also, peritoneal dialysis enables greater liberalization of diet with respect to salt, potassium, protein, and fluid. Peritoneal dialysis, when feasible, is the treatment modality of choice in children because it avoids frequent needle sticks, and, most importantly, allows children to grow.

Performing Peritoneal Dialysis

Peritoneal dialysis uses the patient's own peritoneal membrane for removal of waste products and fluid (Fig. 133-2). During chronic peritoneal dialysis in an adult, 2 to 3 L of dialysate solution containing electrolytes in physiologic concentrations (to correct acid-base and electrolyte disturbances) and varying concentrations of glucose are infused into the peritoneal cavity through a peritoneal catheter. After a specified dwell time varying between 3 and 6 hours per exchange, the fluid is drained, and the process is repeated. The removal of solute from the body, which depends on a concentration gradient between the blood and peritoneal fluid, occurs by diffusion across the peritoneal membrane. Osmotic ultrafiltration is achieved by the addition of increasing concentrations of glucose to the dialysate solution. The osmotic pressure generated by the glucose draws water from the extracellular fluid and the tissues into the peritoneal fluid. However, the net ultrafiltration rate decreases during the exchange, because of glucose absorption.

In peritoneal dialysis, membrane characteristics vary from one individual to another. The peritoneal equilibration test (PET) is a semiquantitative clinical test commonly used to characterize the transport functions of the peritoneal membrane. The standardized PET procedure consists of a 4-hour dwell using 2 L of 2.5% glucose-containing dialysate solution; equilibration ratios are then determined between plasma and dialysate for creatinine at 0, 2, and 4 hours. The PET also enables measurement of net fluid removal by examining the ratio of dialysate glucose at 4 hours to dialysate glucose at time zero.

Patients who have a high dialysate-to-plasma creatinine ratio and achieve rapid equilibration of creatinine and urea across the peritoneal membrane tend to lose their osmotic gradient for fluid removal. Therefore, high or rapid transporters tend to have excellent solute clearance but have difficulty with ultrafiltration. They do well with frequent exchanges and short dwell times that can be achieved with the automated cycler machine, commonly at night while the patient sleeps.

Patients who have low dialysate-to-plasma ratios for creatinine and urea tend to do best with long dwells and high volumes of dialysate to maximize diffusion. These patients usually have excellent ultrafiltration and excellent fluid removal.

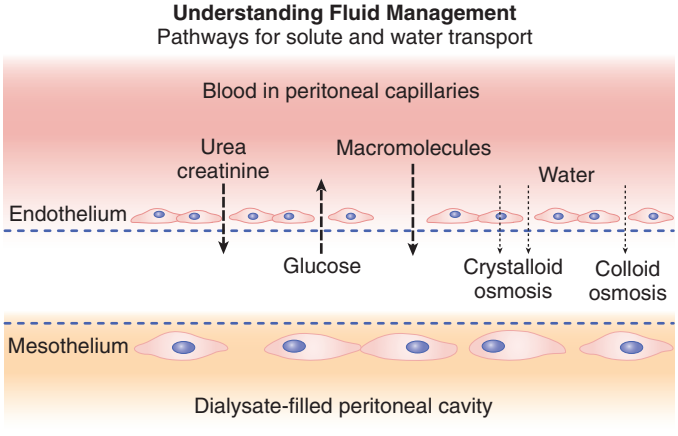

FIGURE 133-2. Solute and water transport in peritoneal dialysis. Various pore systems in the vascular wall. The small interendothelial pores are involved in the transport of low-molecular-weight solutes and in water transport. Large pores allow the passage of macromolecules. Crystalloid osmosis induces water transport partly across the small pores, but also through ultrasmall transcellular water channels. Colloid osmosis induces fluid transport only across the small pore system. The mesothelium is not an osmotic barrier. (From Andreucci VE, Fine LG. *International Yearbook of Nephrology*, 1997. Oxford, UK: Oxford University Press; 1998.)

Peritoneal Dialysis Dose

Clearance of small solutes is a key predictor of survival in patients undergoing peritoneal dialysis, and residual renal function also plays a critical role. Current guidelines advocate a minimal target Kt/V urea of at least 1.7 per week. Every effort should be made to maintain residual renal function as long as possible by avoiding nephrotoxins such as nonsteroidal anti-inflammatory drugs, iodinated contrast agents, and aminoglycosides. As residual renal function diminishes over time, the peritoneal dialysis prescription needs to be adjusted accordingly.

Complications

Infection

Infection remains the most common problem in patients undergoing CAPD, and it represents the most frequent cause for catheter removal and discontinuation of therapy. Infection can occur at the exit site, with purulent or bloody drainage, erythema, tenderness, or induration; around the subcutaneous tunnel of the catheter, with redness, swelling, or tenderness; or in the peritoneal cavity (peritonitis). The diagnosis of peritonitis should be entertained if a patient presents with abdominal pain and cloudy dialysate; patients frequently have fever, nausea, and vomiting. Abdominal tenderness, often with rebound, is frequently found on physical examination. The major diagnostic criterion is the cell count in the peritoneal fluid. Patients with peritonitis typically show a white blood cell count higher than 100/mm^3 with a predominance of neutrophils. Lymphocytes may predominate with fungal or mycobacterial infections. Prompt recognition and treatment are critical to avoid relapsing or refractory infections that require catheter removal.

For exit site and tunnel infections, *Staphylococcus aureus* is the most common responsible organism. Initial empirical oral or intravenous therapy therefore should cover gram-positive organisms. Oral penicillinase-resistant penicillins (e.g., dicloxacillin, 250 to 500 mg twice daily for 14 days), fluoroquinolones (e.g., ciprofloxacin, 250 to 500 mg twice daily for 14 days), trimethoprim-sulfamethoxazole (e.g., 40/800 mg for 14 days), or cephalosporins (e.g., cephalexin, 500 mg twice daily for 14 days) are recommended. Vancomycin should be avoided as first-line therapy except for methicillin-resistant *S. aureus*. *S. aureus* nasal carriage is a recognized risk factor for exit site and tunnel infections. Mupirocin nasal ointment used twice daily for 5 days every 4 weeks, or mupirocin ointment applied to the exit site, significantly reduces the incidence of *S. aureus* exit site infections.

In patients with peritonitis, *Staphylococcus epidermidis* (Chapter 296) is the most common organism, usually the result of contamination, such as in the introduction of skin bacteria due to breaks in sterile technique. The introduction of disconnect systems has led to a reduction in the overall rate of *S. epidermidis* peritonitis. *Pseudomonas* species infection (Chapter 314) accounts for 5 to 8% of the episodes of CAPD peritonitis; it is often difficult to eradicate because of the development of a biofilm on the catheter, and the catheter often needs to be removed. Fungal infections are extremely difficult to eradicate despite appropriate antifungal therapy because of the development of biofilm, so many institutions remove the peritoneal dialysis catheter as soon as the diagnosis of fungal peritonitis is made.

Another major cause of peritonitis (Chapter 144) is intra-abdominal pathology such as a perforated diverticulum (Chapter 144), ruptured appendix (Chapter 144), ischemic bowel (Chapter 145), incarcerated hernia (Chapter 144), pancreatitis (Chapter 146), or gynecologic conditions (Chapters 205, 243, and 244). The major diagnostic clue is the presence of polymicrobial enteric organisms on culture, particularly the presence of anaerobic organisms in the dialysate. An abdominal computed tomography

(CT) scan may help identify the anatomic site of the lesion. Although free air may be seen in asymptomatic patients undergoing peritoneal dialysis, the presence of free air should raise the possibility of a perforated viscus, which requires emergency surgery.

For the treatment of CAPD-related peritonitis, current guidelines recommend intravenous or intraperitoneal vancomycin (e.g., 1 g every 5 to 7 days, as guided by serum levels, for at least 2 weeks) or a cephalosporin (e.g., cefazolin, 15 mg/kg in one exchange per day) together with intravenous or intraperitoneal administration of a third-generation cephalosporin with antipseudomonal activity (e.g., ceftazidime, 1 to 1.5 g in one exchange per day) or gentamicin (0.6 mg/kg in one exchange per day or 80 mg IV) as initial empirical therapy. Once culture and sensitivities results are available, the antibiotic prescription should be tailored to avoid gentamicin, if possible, to preserve residual renal function. Therapy should be continued for at least 2 weeks.

Other Complications

Mechanical problems of CAPD include catheter malfunction owing to omental wraps and blood or fibrin clots in the catheter lumen, catheter migration, and abdominal hernias caused by increased intra-abdominal pressure with large volumes of dialysate. Metabolic complications include hyperglycemia and hypertriglyceridemia from high glucose loads, weight gain, and protein loss, especially during an episode of peritonitis. Because peritoneal dialysis requires daily multiple exchanges, it is essential to assess for compliance on an ongoing basis and to ensure that the patient has an adequate support system to avoid "burnout."

The high glucose concentration of the standard CAPD dialysate not only contributes to metabolic abnormalities but also inhibits the function of leukocytes and affects the long-term function of the peritoneal membrane. A dialysate that contains 7.5% icodextrin is a safe and effective substitute for hypertonic glucose and is effective in patients with ultrafiltration failure. This alternative may decrease the metabolic consequences of long-term glucose use and help preserve peritoneal membrane function.

PROGNOSIS

Although dialysis acutely prevents death from uremic complications, the mortality rate among patients undergoing chronic dialysis therapy remains high, at about 20% per year in the United States. Age and comorbid conditions such as diabetes, cardiovascular disease, nutritional status, and infection all contribute significantly to the high mortality in this population.

RENAL TRANSPLANTATION

Successful renal transplantation offers patients the best quality of life. They are liberated from potassium and fluid restrictions, are free to travel and work, and achieve correction of metabolic abnormalities and anemia with restoration of normal renal function. Moreover, in comparison with hemodialysis, renal transplantation also improves long-term survival in both diabetic and nondiabetic patients.

Because renal transplantation offers patients the best chance for quality as well as quantity of life, it is essential to evaluate candidates early and, if possible, proceed directly to preemptive transplantation if a living donor can be identified. The ideal form of renal transplantation for patients with type 1 diabetes mellitus (Chapter 236) and nephropathy is from a living related donor, followed by pancreas or islet cell transplantation from a deceased donor. If a living donor is unavailable, simultaneous pancreas and kidney transplantation should be pursued from a deceased donor. Although successful pancreas transplantation does not reverse the established macrovascular and microvascular complications of long-standing diabetes mellitus, it improves blood glucose control and quality of life and may prevent the progression of retinopathy and autonomic neuropathy. Islet cell transplantation after renal transplantation is presently under investigation.

Pretransplantation Evaluation of the Recipient

The potential renal transplant recipient must have irreversible ESRD and no evidence of active infection or malignancy. In addition to a careful history and physical examination, the evaluation must address the likelihood of compliance and exclude unmanageable patients with psychosis, substance abuse, or alcohol abuse.

Systemic Diseases

A careful cardiovascular evaluation is critical, including stress testing with imaging (Chapters 56 and 71) and a coronary angiogram if any evidence of ischemia is demonstrated, particularly in diabetic patients. In view of the increasing recognition of calcific aortic stenosis (Chapter 75) and hypertension in patients with ESRD, an echocardiogram (Chapter 55) should be obtained to assess valve area as well as systolic and diastolic function.

Likewise, a careful evaluation of carotid and peripheral vessels should be undertaken because the new kidney will be anastomosed to the iliac vessels. The new kidney's ureter may be implanted into the recipient's bladder, or the patient's own ureter may be used. Further urologic testing may be needed if a neurogenic bladder is suspected or if there is a history of obstructive uropathy (Chapter 125). Bilateral nephrectomies are required if there is persistent, smoldering infection unresponsive to chronic suppressive antimicrobial therapy or there is severe polycystic kidney disease.

It is recommended that patients with Goodpasture's syndrome (Chapter 123), systemic lupus erythematosus (Chapter 274), or antineutrophil cytoplasmic antibody–positive vasculitis (Chapter 278) become clinically and serologically quiescent before transplantation. A number of primary glomerular diseases (Chapter 123) have been shown to recur in the renal allograft, including focal segmental glomerulosclerosis, membranous glomerulonephritis, membranoproliferative glomerulonephritis, and immunoglobulin A (IgA) nephropathy. Diabetic nephropathy also may recur after transplantation and can be prevented by combined kidney-pancreas transplantation. Combined kidney-liver transplantation can cure oxalosis (Chapter 212).

Infectious Diseases

Serologic determination of human immunodeficiency virus (HIV; Chapter 394) and hepatitis B and C virus infection (Chapter 151) status should be obtained. In this era of highly active antiretroviral therapy, HIV positivity is no longer an absolute contraindication to transplantation. Although patients with hepatitis C do better with renal transplantation than dialysis, with time liver failure is the major cause of morbidity and mortality. It is therefore critical to stage patients with hepatitis C before transplantation, by means of liver biopsy, viral load determination, measurement of the α-fetoprotein level, and a CT scan looking for hepatocellular carcinoma (Chapter 202) and portal hypertension (Chapter 157). The possibility of a combined kidney and liver transplantation needs to be explored. Combined therapy with pegylated interferon and ribavirin may be indicated after transplantation but requires cautious monitoring and usually is not well tolerated. Post-transplantation interferon therapy may trigger allograft rejection, possibly by upregulation of genes for the major histocompatibility complex and various cytokines. Severe hemolytic anemia may occur with ribavirin administration and should be avoided in dialysis patients.

All patients waiting for renal transplantation should be vaccinated against hepatitis B, although the response rate appears to be less than 50%. If a patient is positive for hepatitis B surface antigen, a DNA viral load determination and liver biopsy should be obtained for staging. Lamivudine or entecavir therapy may be initiated either before or after transplantation. Once again, if there is significant cirrhosis (Chapter 156), consideration should be given to combined kidney-liver transplantation.

Patients with a newly positive purified protein derivative (PPD) skin test (Chapter 332) should ideally be treated before transplantation. A patient with positive PPD and negative chest radiograph before transplantation may be closely monitored. If the patient has a positive PPD and a history of previous disease or a positive chest radiograph, treatment with isoniazid is indicated starting 1 to 2 months after transplantation.

Patients also should be evaluated for previous exposure to varicella. If the varicella titer is negative before transplantation, an attempt at vaccination may be undertaken. If the patient remains varicella antibody negative or has not been vaccinated, varicella-zoster immune globulin should be given on exposure to patients with chickenpox or herpes zoster (Chapter 383) because the immunosuppressed host is at risk for fulminant varicella with pulmonary infiltrates, pancreatitis, and liver disease.

Special attention needs to be directed to patients from tropical areas, where *Strongyloides stercoralis* (Chapter 365) is endemic. A *Strongyloides* titer should be obtained; if it is positive, the infection should be treated before immunosuppression because fulminant disease can occur after transplantation. If a patient comes from an area where schistosomiasis (Chapter 363) is endemic, diagnosis and treatment should be initiated before transplantation.

Identifying Donors

Living Donors

The demand for deceased donors far exceeds the supply of organs, and the waiting list for cadaver renal transplants is now 4 to 5 years in all blood groups throughout most of the United States. As a result, living organ donation

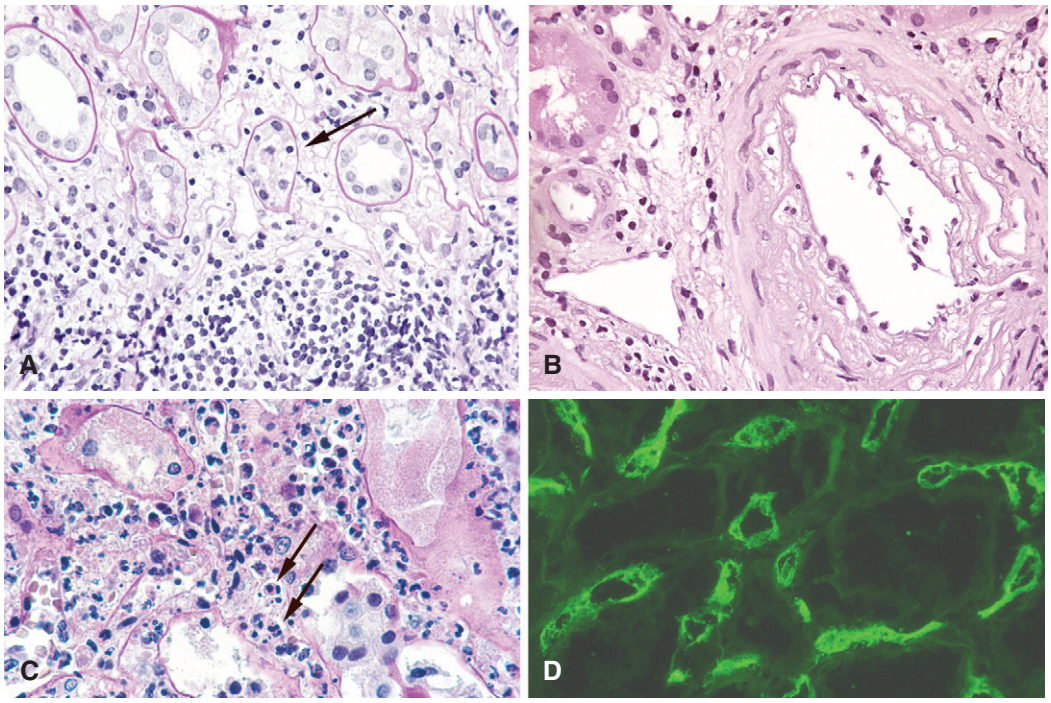

FIGURE 133-3. Histology of renal allograft with acute cellular rejection (A and B) and acute humoral rejection (C and D). A, Interstitial mononuclear infiltrate. The *arrow* points to an area with tubulitis. **B,** Arteritis. Note the accumulation of inflammatory cells beneath the intima, which is characteristic of acute cellular rejection type 2 (Banff classification). **C,** Acute humoral rejection. The peritubular space is occupied by an inflammatory infiltrate with the presence of polymorphonuclear neutrophils *(arrows)*. **D,** Positive C4d staining in the peritubular capillaries by immunofluorescence, a hallmark of humoral rejection.

accounts for more than 50% of the transplantations now being performed. Living donation is generally safe, and both the short- and long-term outcomes for the recipient are better with a living donor. Results from a living unrelated donor transplant are equivalent to a one-haplotype parental match, with a 1-year graft survival rate of 92%, thereby suggesting that the quality of the organ is as important as or more important than the closeness of the genetic "match." Donors require a complete medical examination and a psychological evaluation by physicians and psychiatrists independent of the recipient to ascertain their health and the voluntary, altruistic nature of the donor's decision.

For the donor, the immediate risk of surgery is a mortality rate of 0.05%, in addition to the pain, time out of work, and possibility of phlebitis or pulmonary embolus, urinary tract infection, wound infection, or pneumonia. Laparoscopic donor nephrectomy in carefully selected patients allows for a faster recovery and more rapid return to work.

The long-term risks of having one kidney include the slightly increased risk of proteinuria, chance of trauma, and development of cancer in the one remaining kidney. Although isolated cases of chronic renal failure have been reported after donation, for the most part long-term mortality is not affected by kidney donation. Nevertheless, all donors must be carefully monitored long term.

Deceased Donors

The shortage of deceased organs for transplantation has led to the increased use of kidneys from donors older than 55 years of age or with a history of hypertension or cerebrovascular accident. In these situations, a donor kidney biopsy is performed to assess the degree of fibrosis, sclerosis, and vascular disease; if deemed appropriate, these kidneys are then offered with informed consent to older potential recipients or patients with multiple access problems. Although there may be a 10% difference in survival between these kidneys and standard deceased donor kidneys at 3 years, the potential benefit to the recipient is the opportunity to terminate dialysis without waiting on the list for 4 years or longer.

Another alternative is the use of organs from donors who die from traditional cardiac death, known as donation after cardiac death donors. Once the patient's family and the attending physician have decided that life support will be discontinued, the patient is taken to the operating room, the ventilator is discontinued, and cardiac arrest occurs. The patient is pronounced dead only after all signs of respiration have ceased. Patient and graft survival rates are not statistically different from rates with traditional brain death donors.

Tissue Typing

A key element in the evaluation for transplantation is tissue typing. The recipient must receive a transplant from a blood group–compatible donor to avoid hyperacute rejection and immediate irreversible graft loss on the operating table. The donor and recipient need not share the same Rh factor.

HLA typing is performed on all potential recipients and donors. It is critical to determine the recipient's sensitization (i.e., the level of preformed HLA antibodies in the serum of the recipient). These antibodies typically result from previous transplantations, pregnancies, or blood transfusions. The critical test before renal transplantation is the final crossmatch: a complement-dependent cytotoxicity assay performed using the cells of the donor and serum of the recipient. If the crossmatch is positive, the transplantation should not be performed. Another option to increase the availability of organs is the donor exchange program, whereby an incompatible live donor-recipient pair in one institution finds a compatible match at another institution through computerized matching.

Rejection

Allograft rejection is initiated by the recipient's recognition of donor major histocompatibility complex antigens, thereby leading to activation of humoral and cellular immunity (Chapter 48). *Hyperacute humoral rejection*, which is rare, usually causes immediate irreversible necrosis of the allograft on the operating table. Hyperacute rejection is caused by preformed alloantibodies in the recipient directed against donor HLA or ABO antigens, and this form of antibody-mediated rejection can usually be prevented by careful crossmatching techniques.

The clinical manifestations of *acute cellular rejection* (Fig. 133-3), which can occur any time but are generally seen within the first 3 months, may be minimal with the use of newer immunosuppressive agents but may include fever, allograft swelling and tenderness, or oliguria. The BUN and creatinine concentrations are usually elevated. A Doppler ultrasound study should be performed to exclude obstruction or vascular thrombosis (Chapter 127). The diagnosis of acute rejection can be reliably made only with an allograft biopsy (Table 133-2).

Acute humoral rejection (see Fig. 133-3) usually occurs within the first 3 months but can occur at any time, particularly if the patient is noncompliant with medications. It occurs when the recipient develops de novo donor-reactive cytotoxic antibodies after transplantation (i.e., positive crossmatch after but negative before transplantation). These alloantibodies may be reactive with HLA class I or II antigens. Early detection and treatment of acute humoral rejection with plasmapheresis, pooled human immune globulin (e.g., 0.4 to 0.6 g/kg), and rituximab (e.g., 1 g) in addition to tacrolimus (to maintain a level of 8 to 10), mycophenolate mofetil (e.g., 750 to 1000 mg twice daily), and steroids has led to dramatic reversal of the acute allograft dysfunction in approximately 90% of cases. Protocols using plasma exchange, rituximab, and intravenous immune globulin also have been used before transplantation in an attempt to lower the levels of preformed HLA antibody

TABLE 133-2 DIFFERENTIAL DIAGNOSIS OF RENAL ALLOGRAFT DYSFUNCTION

IMMEDIATE/DELAYED GRAFT FUNCTION (1-3 DAYS)
Acute tubular necrosis
Hyperacute humoral rejection
Urinary leak or obstruction
Renal artery or vein thrombosis
Recurrence of disease (e.g., FSGS)
EARLY POST-TRANSPLANTATION PERIOD (FIRST MONTH)
Acute cellular rejection
Acute humoral rejection
Calcineurin inhibitor toxicity
Urinary tract obstruction
Volume depletion
Recurrence of disease
LATE ACUTE DYSFUNCTION
Acute rejection
Cyclosporine or tacrolimus toxicity
Recurrence of primary disease
Tubulointerstitial nephritis, drug-induced
Renal artery stenosis
Infection (bacterial UTI, cytomegalovirus, BK virus)
Hemodynamic (volume; use of ACEI, AIIRB)
CHRONIC DYSFUNCTION
Chronic rejection
Cyclosporine or tacrolimus toxicity
Recurrent renal disease
De novo renal disease
Urinary tract obstruction
Bacterial UTI
Hypertensive nephrosclerosis

ACEI = angiotensin-converting enzyme inhibitor; AIIRB = angiotensin II receptor blocker; FSGS = focal segmental glomerulosclerosis; UTI = urinary tract infection.

in highly sensitized patients. Such protocols often convert a previously positive crossmatch to a negative one, thus enabling transplantation from a living donor.

Another promising approach to the treatment of acute humoral rejection focuses on the depletion of plasma cells with the proteasome inhibitor bortezomib, which is also used in the treatment of multiple myeloma. Long-term studies are needed to determine whether the successful treatment of acute antibody-mediated rejection and chronic humoral rejection will improve long-term graft survival.

Induction Immunosuppression

The goal of immunosuppression therapy (Chapter 48) is to prevent allograft rejection but still allow the immune system to fight infection and malignancy. The multiagent strategy allows for a synergistic effect and reduction of specific drug toxicity (Fig. 133-4). Immunosuppression is initiated at high doses (induction) during the initial period after transplantation, when the risk of rejection is highest, and is reduced over time (maintenance immunosuppression). In recipients with a high risk of rejection (children, retransplant recipients, delayed graft function, multiparous women, and multitransfused patients), induction immunosuppression is often used, consisting of a course of polyclonal antilymphocyte-antithymocyte globulin (ATG) or antilymphocyte globulin; monoclonal anti-CD3 antibodies (OKT3); or anti-interleukin-2 (anti-IL-2) receptor monoclonal antibodies (basiliximab or daclizumab). Appropriate antiviral prophylaxis is essential to reduce the risk of severe cytomegalovirus (CMV) infection and Epstein-Barr virus (EBV)-associated post-transplantation lymphoproliferative disease (PTLD). Likewise, prophylaxis with trimethoprim-sulfamethoxazole has been effective in preventing urinary tract infections as well as *Pneumocystis jirovecii* infection in these highly immunosuppressed patients.

Polyclonal Antibodies

Polyclonal antibodies are raised in various animals (rabbits, goats, horses) using different antigenic preparations (thymocytes, lymphocytes). The polyclonal antilymphocyte antibodies (1.5 mg/kg for three doses) are used for

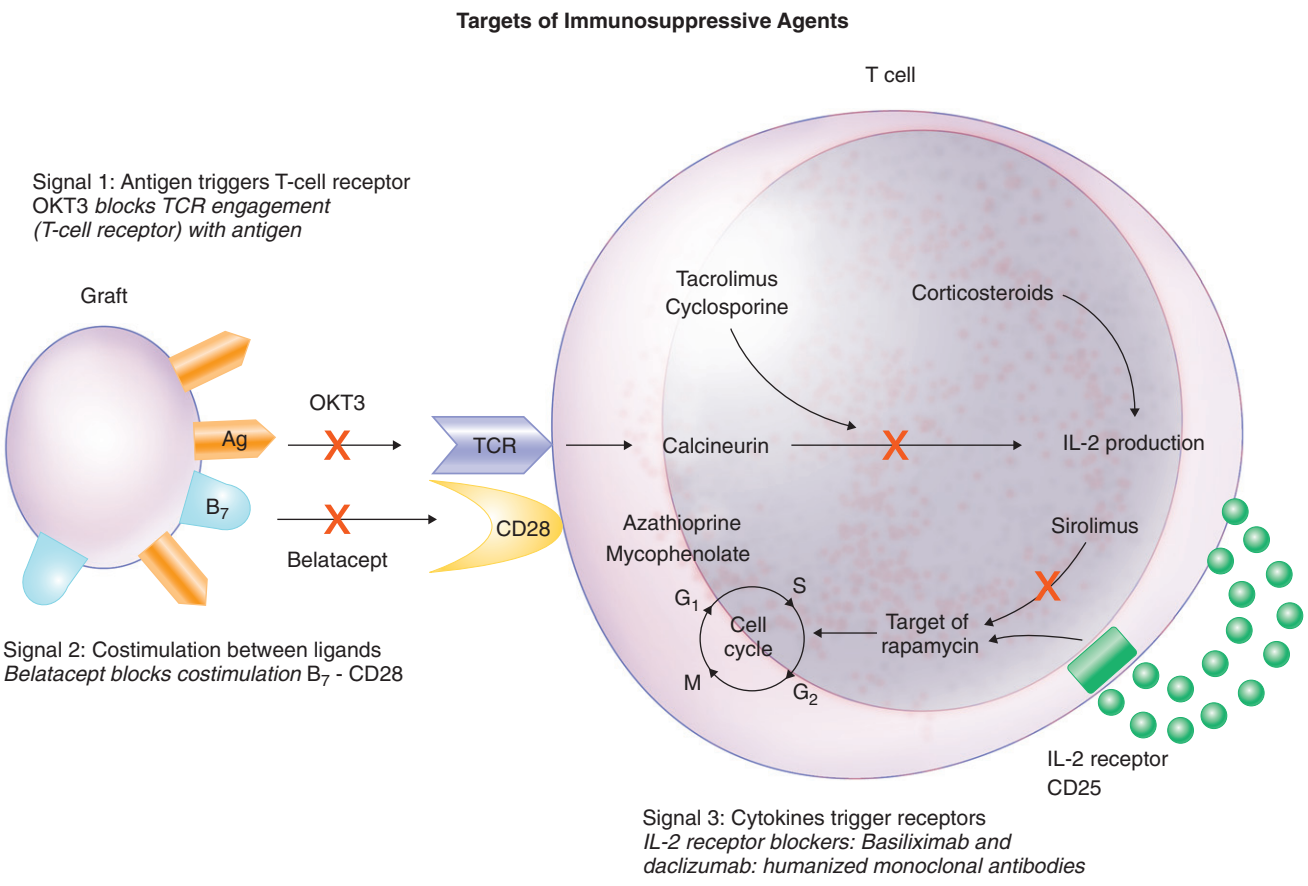

FIGURE 133-4. Targets of immunosuppressive agents. G_1, S, G_2, and M are stages of the cell cycle. Ag = antigen; AZA = azathioprine; B_7 = costimulatory molecule; CsA = cyclosporine; IL = interleukin; MMF = mycophenolate mofetil; SRL = sirolimus; TAC = tacrolimus; TCR = T-cell receptor; TOR = target of rapamycin.

induction therapy in high-risk recipients (i.e., those with high panel-reactive antibodies and those undergoing retransplantation) at the onset of transplantation, for treatment of steroid-resistant acute cellular rejection, and as a calcineurin inhibitor–sparing agent in recipients with delayed graft function. The polyclonal antibodies can cause serum sickness, bone marrow suppression, and hemolysis. The use of these agents also may trigger a potent cytokine response. Most side effects are related either to the degree of purity of the antigenic preparation used to immunize the animals or to the purification of the serum. Serum sickness (Chapter 46) and anaphylactic reactions (Chapter 261) are related to previous exposure to the animal species used to raise the antibody.

OKT3

OKT3, which is a mouse monoclonal antibody directed against the CD3 antigen, is used primarily for treatment of steroid-resistant acute cellular rejection and occasionally as an induction agent. OKT3 can cause myriad side effects, including fever, rigors, nausea, vomiting, diarrhea, severe headache (aseptic meningitis), hypotension, chest pain, dyspnea, wheezing, and, infrequently, pulmonary edema. These symptoms are secondary to massive cytokine release after OKT3 engages the TCR. OKT3 is associated with a higher incidence of severe CMV infections and PTLD, so CMV prophylaxis (Chapter 384) is essential.

Interleukin-2 Receptor Blockers

IL-2 receptor blockers are engineered monoclonal antibodies against the α-chain of the IL-2 receptor. Daclizumab is a humanized molecule consisting of a human IgG1 with antigen-binding regions from a mouse antibody. Basiliximab is a chimeric construct with a murine variable region and human constant regions. Daclizumab and basiliximab are used only as induction agents to prevent rather than treat rejection. They both have a safe side-effect profile, largely because of their human origin.

New Agents

Alemtuzumab is an anti-CD52 monoclonal antibody used as an induction agent at the time of transplantation. Alemtuzumab appears to facilitate minimization of maintenance immunosuppressive protocols (with either sirolimus or low-dose tacrolimus). The dose and frequency of administration remain to be determined.

Maintenance Immunosuppression

Many immunosuppressive agents are available for prevention of rejection in the maintenance phase (Table 133-3). Common regimens consist of low-dose steroids, mycophenolate mofetil, or azathioprine plus a calcineurin inhibitor (either cyclosporine or tacrolimus). Corticosteroids (Chapter 34), which have nonspecific immunosuppressive and anti-inflammatory actions, are used for induction therapy, for maintenance immunosuppression, and in high doses (pulse) for the treatment of acute cellular rejection. Corticosteroids cause many metabolic changes, including diabetes, hypercholesterolemia, osteoporosis, increased risk of cardiovascular events, obesity, and hypertension, and they can cause significant mood swings, irritability, and depression.

TABLE 133-3 IMMUNOSUPPRESSIVE AGENTS

AGENT	MECHANISM OF ACTION	SIDE EFFECTS
Corticosteroids	Multiple anti-inflammatory actions, blockade of IL-1, IL-6, TNF-α	Infection, hypertension, glucose resistance, osteoporosis, hyperlipidemia, glaucoma, adrenal suppression
Azathioprine	Blockade of purine synthesis, which affects DNA and RNA synthesis	Bone marrow suppression
Cyclosporine	Binds to cyclophilin, causing calcineurin inhibition, which prevents NFAT activity on IL-2 gene; stimulates production of TGF-β	Hypertension, glucose intolerance, nephrotoxicity, hirsutism, gingival hyperplasia
Tacrolimus	Binds to FKBP-12, causing calcineurin inhibition, which prevents NFAT activity on IL-2 gene	Neurotoxicity, increased incidence of diabetes mellitus (≈20%)
Mycophenolate mofetil	Blocks de novo pathway of purine synthesis by inhibition of IMPDH, selective for lymphocytes	Gastrointestinal symptoms (diarrhea), leukopenia
Sirolimus	Binds to FKBP-12 and mTOR, blocking cell cycle progression	Hyperlipidemia, leukopenia, thrombocytopenia, impaired wound healing

FKBP-12 = FK506-binding protein 12; IL = interleukin; IMPDH = inosine monophosphate dehydrogenase; NFAT = nuclear factor of activated T lymphocyte; TGF-β = transforming growth factor-β; TNF-α = tumor necrosis factor-α; mTOR = mammalian target of rapamycin.

The calcineurin inhibitors cyclosporine and tacrolimus inhibit the translocation of nuclear factor of activated T lymphocyte (NFAT) from the cytoplasm to the nucleus. Cyclosporine and tacrolimus levels must be closely monitored to avoid toxicity as well as rejection. The most important nonimmune toxicity of the calcineurin inhibitors is nephrotoxicity, with three distinct patterns. First is an acute hemodynamic effect, which is caused by afferent arteriolar constriction and which may exacerbate ischemic injury and delay graft function, with a reversible decrease in the glomerular filtration rate that improves when the dose of the drug is adjusted. Second is subacute to chronic nephrotoxicity, which may be evidenced by tubular lesions, hyalinosis of small arterioles, or striped fibrosis in the more chronic phase. Third is a thrombotic microangiopathy, which can present a picture similar to the hemolytic-uremic syndrome (Chapter 175) with intimal proliferation, fibrin deposition, and thrombotic occlusion of the arcuate and intralobular arteries. The peripheral smear may show evidence of schistocytes, and thrombocytopenia may or may not be present. Switching from cyclosporine to tacrolimus or vice versa sometimes may be beneficial. Other side effects of the calcineurin inhibitors include neurotoxicity (tremors, mental status changes, irritability, and seizures), hypertension, hyperglycemia, hyperkalemia, hyperuricemia, gout, and an increased incidence of EBV-related B-cell lymphomas (PTLD). Both cyclosporine and tacrolimus are metabolized by the cytochrome P-450 system and excreted by the liver. Therefore, drugs that interact with the P-450 system, such as macrolide antibiotics, diltiazem, imidazole, and triazole antifungals may raise the levels of calcineurin inhibitors. In contrast, agents such as rifampin, phenobarbital, and phenytoin that induce cytochrome P-450 enzymes increase the catabolism of calcineurin inhibitors. Many other significant interactions need to be recognized, including the risk of rhabdomyolysis with statins and interaction with most nephrotoxic agents.

Azathioprine, which was a cornerstone of transplant immunosuppression until the introduction of mycophenolate mofetil, is still useful. Azathioprine inhibits DNA synthesis; its main side effect is bone marrow suppression (see Table 133-3). Azathioprine has also been associated with malignancies, especially skin cancers, and papillomavirus infection. Azathioprine is metabolized by xanthine oxidase, so concomitant administration of allopurinol, a xanthine oxidase inhibitor, should be avoided because significant bone marrow toxicity may occur.

Mycophenolate mofetil, which selectively inhibits lymphocyte proliferation (see Table 133-3), reduces the incidence of acute cellular rejection by 50% and allows for a significant reduction in the use of OKT3/ATG. Gastrointestinal symptoms (e.g., nausea, epigastric discomfort, diarrhea) are the main side effects and usually can be improved by dose reduction. The effect of mycophenolate mofetil on the prevention of chronic rejection is currently under study.

Sirolimus binds to the same immunophilin as tacrolimus but does not affect calcineurin activity (see Table 133-3). Inhibition of mTOR by sirolimus suppresses alloantigen and cytokine-driven T-cell proliferation when it inhibits the cell cycle. Regimens using sirolimus have reduce the incidence of acute cellular rejection. Sirolimus causes hyperlipidemia and also is associated with thrombocytopenia. Sirolimus also interacts with calcineurin inhibitors and may cause an increase in calcineurin inhibitor toxicity.

PROGNOSIS

Since 1975, the 1-year deceased donor kidney survival rate has dramatically improved, from approximately 50% to 90% in 2010. The 1-year allograft survival for kidneys from living donors has increased from 88 to 93%. The acute rejection rates are only about 11% with new immunosuppressive regimens, and 1-year allograft survival rates have improved. However, the initial projected long-term improvement in the survival of grafts from living as well as deceased donors has not been realized.

Patients benefit from aggressive control of coronary risk factors because coronary disease is a major cause of death in these patients (Chapters 51 and 73). The ultimate goal of transplantation is tolerance to donor antigens while maintaining the ability to respond to third-party antigens in the absence of

ongoing immunosuppression. The induction of mixed hematopoietic chimerism, using nonmyeloablative conditioning, has been successfully accomplished in rodents, miniature swine, and nonhuman primates. These observations now are being extended to patients with multiple myeloma and ESRD.

134 APPROACH TO THE PATIENT WITH GASTROINTESTINAL DISEASE

KENNETH MCQUAID

The luminal gastrointestinal (GI) tract (esophagus, stomach, duodenum, small and large intestine, and anus) and pancreas are responsible for digestion, for the absorption of nutrients and fluids, and for the temporary storage and excretion of undigested waste. The GI tract has an epithelial lining with an enormous surface area that provides nutrient absorption and serves as a barrier to microorganisms. In addition, the GI tract has a large innate and adaptive immune system that interfaces with luminal food antigens, host proteins, commensal and pathogenic bacteria, and parasites and must decide which antigens to tolerate and which require immune activation. The GI tract also contains an extensive enteric endocrine system that regulates food intake, weight control, and glucose homeostasis, as well as secretions from the stomach, intestine, and pancreas. Finally, it has an enteric nervous system that is integrated with the autonomic and central nervous systems to control gastric emptying, intestinal motility, and defecation.

Numerous diseases within and outside the GI tract may alter normal function by causing structural damage (erosion, ulceration, perforation, stenosis, or obstruction), bleeding, inflammation, abnormal absorption or secretion of nutrients and electrolytes, or abnormal motility. Despite its anatomic and physiologic complexity, the GI system has only a limited repertoire of symptoms and signs to express conditions that may be either serious or clinically insignificant: abdominal pain, heartburn, regurgitation, dysphagia, odynophagia, dyspepsia, nausea and vomiting, gas and bloating, weight loss, diarrhea, constipation, overt or occult gastrointestinal bleeding, and incontinence.

GENERAL APPROACH TO PATIENTS WITH GASTROINTESTINAL SIGNS AND SYMPTOMS

An appropriate history and physical evaluation usually can narrow the differential diagnosis of GI complaints. A specific diagnosis can almost always be established thereafter by the judicious use of laboratory, endoscopic, or imaging studies (Table 134-1).

Clinical History

The clinician should elicit the nature of the complaint, including its acuity, severity, location, radiation, duration, pattern (steady vs. colicky; abrupt vs. gradual onset), and relationship to food, meals, and bowel movements. Symptoms that arise from the GI tract are almost always improved or worsened by eating or by bowel movements. For symptoms of recent onset, it is important to elicit recent dietary intake, a medication history, potential exposure to enteric infections or sexually transmitted diseases (Chapter 293), and recent travel. It is also useful to establish whether there are signs or symptoms that suggest a systemic illness, including fever, weight loss, arthralgias, fatigue, weakness, or skin rash.

Most nonsurgical GI diseases manifest with mild to moderate symptoms that develop gradually and do not require immediate attention. Acute symptoms that require urgent assessment are severe abdominal pain and overt GI bleeding (Chapter 137) that manifests by hematemesis, melena, or large-volume hematochezia. Severe or dramatic abdominal pain that develops acutely over minutes to hours requires urgent evaluation to determine whether surgical intervention is required. Severe vomiting or diarrhea with signs of dehydration also warrants urgent attention.

Mild to moderate chronic or intermittent symptoms that have been present for a long period can be evaluated in a deliberate fashion. A substantial proportion of chronic GI complaints have no obvious organic or biochemical basis and ultimately are classified as *functional* GI disorders (Chapter 139). Complaints that have been ongoing for years rarely are attributable to readily remedied structural disorders. In patients with chronic GI symptoms, it is important to elicit and address the current reason for seeking evaluation, which may include concern for underlying serious illness (especially cancer), a change in the character or severity of symptoms, life stressors, or depression. Asking the patient what he or she thinks or fears may provide insights into the proportion of the complaint attributable to these amplifying issues, regardless of whether the problem is functional or structural in origin.

A dietary history (Chapter 221) should be obtained. For acute symptoms of nausea, vomiting, diarrhea, or abdominal pain, intake over the previous 24 to 48 hours should be reviewed for clues to a food-borne illness, including possible exposure to a contaminated food or water source and similar symptoms in other people (Chapter 291). For chronic or intermittent complaints, a recall of meals and types of foods eaten over the previous 1 to 2 days provides insight into eating habits and the amounts and types of fruits and vegetables, whole grains, fiber, protein, fat, and dairy products ingested. A relationship between specific foods and symptoms may be found. For example, pain, flatulence, or diarrhea may be caused by dairy products (lactose intolerance), whole grains, legumes or cruciferous vegetables, or fatty meals (malabsorption), and chronic constipation may be due to a low-fiber diet. Recent and long-term changes in body weight should be elicited. Involuntary loss of greater than 5% of body weight over the prior 12 months is worrisome for serious disease and significant malnutrition (Chapter 222).

The number and consistency of bowel movements should be elicited, and any change in bowel habits must be explored. Signs of acute GI bleeding (melena or hematochezia) or inflammatory colitis (blood, mucus, or pus) should be elicited. Improvement in symptoms after passage of flatus or a bowel movement suggests a disorder of the colon or anorectum.

Past Medical History

The past medical history should be reviewed for conditions that may cause acute or chronic GI symptoms, including endocrine disorders such as diabetes (Chapter 237) or thyroid dysfunction (Chapter 233), cardiovascular diseases such as heart failure (Chapter 58) or peripheral vascular disease (Chapter 81), chronic liver disease and portal hypertension (Chapter 156), neurologic conditions such as Parkinson's disease (Chapter 416) or neuromuscular disorders (Chapter 403), and rheumatologic and collagen vascular disorders (Chapter 264). In addition to their impact on GI tract function, the severity of these conditions must be considered when weighing the risks of diagnostic studies, especially endoscopy. Patients with symptomatic or advanced respiratory insufficiency (Chapter 83), sleep apnea (Chapter 100), valvular heart disease (Chapter 75), coronary artery disease (Chapter 50), heart failure (Chapter 58), cirrhosis (Chapter 156), cerebrovascular disease (Chapter 413), neuromuscular disease (Chapter 430), or dementia (Chapter 409) have an increased risk of sedation-related complications during endoscopy.

A list of prescription and nonprescription medications, vitamins, minerals, and other nutritional supplements should be obtained, paying particular attention to any that were recently initiated or changed. Herbal supplements (Chapter 38) are commonly used but are seldom reported without direct questioning. Medications are potential causes of odynophagia, dyspepsia, nausea or vomiting, abdominal pain, diarrhea, and constipation. The use of antiplatelet agents, including aspirin and anticoagulants, should be determined. The risks of stopping versus continuing these medications must be weighed in patients who have acute or chronic GI bleeding or in whom a therapeutic procedure is to be performed.

Social History

The patient's personal relationships, employment history, quality of life, alcohol intake (Chapter 32), and smoking (Chapter 31) history should be determined. It can be very informative to observe both verbal and nonverbal interactions between the patient and a partner or caregiver during an interview. Alcohol may cause heartburn, dyspepsia, nausea, diarrhea, or chronic liver disease. Many patients are reluctant to disclose the full extent of their alcohol intake on direct questioning; therefore, in addition to asking how often they imbibe (days/week and drinks/day), it may be revealing to inquire about their preferred beverage and how it is purchased (location, volume, and frequency). Cigarette smoking is associated with an increased risk of heartburn, peptic ulcer disease, Crohn's disease, and GI malignancies.

Clinicians should inquire about the degree to which GI symptoms are disrupting a patient's life. GI illness may affect dietary and bowel habits, sleep, and sense of vitality. Concerns about dietary intolerances, inability to eat, inability to have comfortable bowel movements, uncontrolled diarrhea or gas, fecal urgency, or fecal incontinence may affect a patient's social life, personal and sexual relationships, employment, and sense of optimism.

The social history should also be reviewed for recent stressors that may precipitate or exacerbate GI symptoms, including marital or interpersonal

discord, personal or family illness, bereavement, financial pressures, job loss, or change in employment. To elicit such information, it may be helpful to tell the patient that stress worsens many conditions and to inquire whether they believe stress may be contributing to their problem.

For elderly, disabled, or marginally housed patients, it is important to elicit how they obtain and prepare their meals and how they access toilet facilities. For patients undergoing GI procedures, it is important to determine whether they have mental, physical, or social barriers that would make it difficult to comply with pre-procedure instructions (including bowel preparation) and whether they have an able-bodied adult who can accompany them to the procedure and observe them at home, if necessary, afterward.

Family History

The family history should be reviewed for GI disorders with a heritable component, especially celiac disease (Chapter 142), inflammatory bowel diseases (Chapter 143), and GI, gynecologic, and genitourinary neoplasms.

Physical Examination

Nonabdominal Examination

The nonabdominal examination should assess nutritional status (Chapter 221) and any signs of systemic conditions that may cause GI symptoms or that must be considered when weighing the risks and benefits of further testing, especially endoscopy. Vital signs should be obtained in all patients. Low-grade fever (<100.5° F) is common in inflammatory conditions, including gastroenteritis, inflammatory bowel disease, appendicitis, cholecystitis, and diverticulitis. High fever (>102° F) suggests sepsis, pelvic, or intra-abdominal infections (e.g., cholangitis, pelvic inflammatory disease, pyelonephritis) or peritonitis. Hemodynamic instability (hypotension or tachycardia) suggests intravascular depletion due to poor oral intake, acute GI or intra-abdominal bleeding, severe diarrhea, or peritonitis. A body mass index less than 18 suggests malnourishment.

A general survey should be performed to assess for signs of weight loss (fat and muscle wasting), malnutrition (dry or thin skin, hair loss, edema, anasarca), and vitamin deficiencies (pellagra, scurvy). Skin lesions may provide clues to systemic conditions such as liver disease (jaundice, spider telangiectasias, palmar erythema), inflammatory bowel disease (erythema nodosum, pyoderma gangrenosum), celiac disease (dermatitis herpetiformis), vasculitis, and rare gastrointestinal malignancies, polyposis syndromes, and pancreatic endocrine tumors (Chapters 198, 199, and 201). An oral examination looks for mucocutaneous candidiasis (which may reflect immunosuppression), ulcerations (which may reflect inflammatory bowel disease, vasculitis, viral infection, or vitamin deficiencies), and glossitis or angular cheilitis (which may reflect vitamin deficiencies). With the exception of supraclavicular lymph nodes, peripheral lymph nodes are uninvolved with GI diseases but should be examined when systemic infection or advanced malignancy is suspected (Chapter 171). Examination of the lungs and cardiovascular system should focus on evidence of conditions that might increase the risk of moderate sedation in the event endoscopy is required (respiratory insufficiency, heart failure) and for conditions that increase the risk of intestinal ischemia (atrial fibrillation, valvular heart disease, peripheral vascular disease) (Chapter 145). The extremities should be evaluated for edema and peripheral pulses. Finally, a brief neurologic assessment should be performed to screen for intracranial mass lesions or other neurologic disorders that may present with GI symptoms.

Abdominal Examination

The abdominal examination begins with a visual inspection of the abdomen and inguinal region for scars (due to prior surgeries or trauma), asymmetry (suggesting a mass or organomegaly), distention (due to obesity, ascites, or intestinal ileus or obstruction), prominent periumbilical veins (suggesting portal hypertension), or hernias (umbilical, ventral, inguinal). The examination proceeds with auscultation followed by percussion, and it ends with light and deep palpation.

In patients *without* abdominal pain, auscultation of bowel sounds to assess intestinal motility has limited usefulness and may be omitted. Percussion may be performed before or in conjunction with light and deep palpation. Initial cursory light percussion across the upper, mid-, and lower abdomen is useful to denote areas of dullness and tympany, as well as to elicit unanticipated areas of pain or tenderness before palpation. More extensive percussion provides limited but useful information about the size of the liver and spleen, gastric or intestinal distention, bladder distention, and ascites (Chapters 148 and 156). Gentle, light palpation promotes abdominal relaxation and allows the detection of muscular resistance (guarding), abdominal tenderness, and superficial masses of the abdominal wall or abdomen. Deeper palpation of the abdominal organs (liver, spleen, kidneys, aorta) and abdominal cavity may detect enlargement or abnormal masses. Superficial or deep masses should be assessed for size, location, mobility, content (solid, liquid, or air), and the presence or absence of tenderness. The consistency of a patient's response to palpation with and without distraction is particularly useful in those with suspected chronic functional abdominal discomfort. Superficial masses include hernias, lymph nodes, subcutaneous abscesses, lipomas, and hematomas. Deep abdominal masses may be caused by neoplasms (liver, gallbladder, pancreas, stomach, intestine, kidney), abscesses (appendicitis, diverticulitis, Crohn's disease), or aortic aneurysms.

Examination of the right upper quadrant should assess the liver size, contour, texture, and tenderness. Liver size is crudely estimated by percussion of the upper and lower borders of liver dullness in the midclavicular line. Liver contour and tenderness are best assessed during held inspiration by deep palpation along the costal margin. Examination of the left upper quadrant is useful to detect splenomegaly (Chapter 171), although a normal-sized or even an enlarged spleen often cannot be detected. Percussion in the left upper quadrant near the tenth rib (posterior to the midaxillary line) may detect splenic dullness that is distinct from gastric or colonic tympany. The tip of an enlarged spleen may be palpated during inspiration if the examiner supports the left costal margin with the left hand while palpating below the costal margin with the right hand. Ascites should be suspected in a patient with a protuberant abdomen and bulging flanks. To screen for ascites, percussion of the flanks should be performed to assess the level of dullness. If the level of flank dullness appears to be increased, the most sensitive test for ascites is to check for "shifting" dullness when the patient rolls from the supine to the lateral position.

Digital Rectal and Pelvic Examinations

The digital rectal examination is intrusive and uncomfortable and should be performed only when necessary, such as in patients with perianal or rectal symptoms, incontinence, difficult defecation, suspected inflammatory bowel disease, and acute abdominal pain. The digital examination, with or without fecal occult blood testing, is not a useful screening test for colorectal cancer (Chapter 199). However, in patients with acute or chronic GI bleeding (Chapter 137), it is a rapid means of assessing the stool for color and occult blood. The perianal area should be visually inspected for rashes, soilage (suggesting incontinence or fistula), fistulas, fissures, skin tags, external hemorrhoids, and prolapsed internal hemorrhoids (Chapter 147). After gentle digital insertion, the anal canal should be assessed for resting tone and voluntary squeeze. The distal rectal vault should be swept circumferentially to palpate for mass lesions, tenderness, or fluctuance.

Laboratory Studies

Blood Tests

Blood tests routinely obtained in the evaluation of patients with GI symptoms include a complete blood count, liver tests (Chapter 149), serum chemistries, and, in selected cases, pancreatic enzymes and markers of inflammation. GI causes of anemia include acute or chronic GI blood loss, inflammatory bowel disease, nutrient malabsorption (folate, iron, or vitamin B_{12}), and chronic liver disease. Microcytosis suggests iron deficiency due to chronic GI blood loss or malabsorption. Macrocytosis may be attributable to folate or B_{12} malabsorption, medications (e.g., immunomodulators used for inflammatory bowel disease), or chronic liver disease. An elevated platelet count suggests chronic inflammation (e.g., inflammatory bowel disease) or GI blood loss with compensatory marrow production. A low platelet count may be attributable to portal hypertension with splenic sequestration. Low serum albumin may be caused by chronic GI disorders that result in weight loss, nutrient malabsorption, chronic inflammation, loss of protein across abnormal GI mucosa (i.e., protein-losing enteropathy), or decreased hepatic synthesis (e.g., chronic liver disease). Abnormal liver tests may be due to acute or chronic liver diseases, disorders of the pancreas or biliary tract, and medications (Chapter 149). Serum amylase and lipase are obtained to screen for pancreatitis (Chapter 146) in patients with acute abdominal pain. Increased levels of inflammatory markers, such as an elevated erythrocyte sedimentation rate and C-reactive protein, are nonspecific but useful in the management of patients with inflammatory bowel disease (Chapter 143).

Serum ferritin reflects total body iron and may be decreased in patients with chronic GI blood loss or intestinal malabsorption (e.g., celiac disease).

TABLE 134-1 APPROACH TO COMMON GASTROINTESTINAL SIGNS AND SYMPTOMS

	ABDOMINAL PAIN	GI BLEEDING	DIARRHEA	STEATORRHEA	CONSTIPATION
History (ascertain the following)	Duration: acute vs. chronic Onset: sudden vs. 1-2 hr vs. gradual Character: visceral (vague or dull, steady or cramping, diffuse) or parietal (severe, well localized, worse with movement) Location: upper, middle, or lower; radiation Associated symptoms: vomiting, hematemesis, diarrhea, hematochezia, melena, constipation, obstipation, jaundice Previous episodes Other diseases	Acute vs. chronic (duration); intermittent vs. continuous; quantity; hematemesis, melena, or hematochezia; associated pain and location; symptoms of anemia (e.g., dyspnea, chest pain, lightheadedness); medication use (especially aspirin, NSAIDs, anticoagulants); previous episodes; risk factors for chronic liver disease (alcohol, hepatitis)	Acute (<2 wk) vs. chronic (duration); fever, weight loss, or abdominal pain; stool character: number per 24 hr, watery or bloody, large vs. small volume, change in volume with eating, greasy; dietary history (especially lactose); history of IBD, pancreatic disease, intestinal surgery, DM; recent change in medications or antibiotic use; community outbreak or similar symptoms in family members; potential exposure to contaminated food; elderly immunosuppressed host; risk of HIV or sexually transmitted disease	Duration; weight loss; stool number, consistency (greasy), presence of blood; abdominal pain; flatulence; history of excessive alcohol, chronic liver disease, pancreatitis, intestinal dysmotility, surgery, DM; history of easy bruising, night blindness, bone pain, osteoporosis, dermatitis herpetiformis	Acute vs. chronic (duration); age; number of stools per wk; difficulty with defecation (straining, incomplete evacuation, digital manipulation); bloating or discomfort; blood on stools, weight loss; dietary fiber and fluid intake; chronic illness (DM, neuromuscular, endocrine); abdominal surgeries; medications, impaired mobility
Physical findings (evaluate for the following)	Fever, HR, BP Appearance: calm, restless, motionless Inspect: skin, distention, hernias Bowel sounds: present, absent, roaring Percussion and palpation: organomegaly, mass (abscess), focal tenderness, guarding Peritoneal signs: sharp pain with cough, shaking, percussion, light palpation	HR, BP, orthostatic findings; abdominal pain present or absent; signs of chronic liver disease and portal hypertension (which may indicate varices); jaundice, spider angiomas, hepatosplenomegaly; ascites; examine nasogastric aspirate for blood ("coffee grounds" vs. bright red); examine stool for blood (Hemoccult) and color (melena, maroon, or bright red)	HR, BP, orthostatic findings; fever; wasting; presence of abdominal tenderness or mass; perianal disease; extraintestinal symptoms of IBD (e.g., oral ulcers, arthritis, erythema nodosum)	Wasting, presence or absence of abdominal mass or tenderness; rash (vitamin deficiencies) or excessive bruising (vitamin K deficiency); jaundice or signs of chronic liver disease	Assess mobility and chronic medical conditions; abdominal distention; palpable stool within bowel in left lower quadrant; rectal examination—impacted stool, anal fissure, rectal prolapse, pelvic floor descent with straining, rectocele
Laboratory tests	CBC, BUN, Cr, glucose, amylase, lipase, liver tests (ALT, AST, bilirubin, alkaline phosphatase), albumin, INR, U/A, urine β-HCG	CBC BUN, Cr, liver tests, INR, type and cross	CBC, BUN, Cr, glucose, electrolytes, liver tests, albumin, C-reactive protein Selected cases: consider serum chromogranin A, VIP, calcitonin, gastrin, glucagon, urinary 5-HIAA; stool for culture, ova, parasites; consider fecal weight, fat, electrolytes, laxative screen	CBC, glucose, liver tests, albumin, electrolytes, celiac disease antibodies (anti-tTG or antiendomysial); assessment of vitamin and mineral absorption (A, D) and INR (K is fat soluble), folate, iron, calcium, phosphate, B_{12}; qualitative or quantitative stool for fecal fat; H_2 breath test for bacterial overgrowth	CBC, Chem-7, calcium, magnesium, phosphate, TFTs; selected patients with severe constipation may undergo colonic transit studies and/or anal manometry with balloon expulsion

NAUSEA AND VOMITING	DYSPHAGIA	ODYNOPHAGIA	HEARTBURN AND REGURGITATION	ANOREXIA	WEIGHT LOSS
Nausea with or without emesis; acute vs. chronic (duration); intermittent vs. constant; presence or absence of severe abdominal pain, comorbid illnesses, especially peptic ulcer, endocrine (DM), cardiac, psychiatric; medications; history of excessive alcohol	Oropharyngeal vs. esophageal dysphagia; solids vs. liquids; acute vs. chronic (duration); intermittent vs. progressive; GERD symptoms present or absent; weight loss; history of food impactions, allergies, atopic conditions, skin changes, cold hands (Raynaud's phenomenon)	Duration of pain with swallowing; underlying immunosuppression (e.g., HIV infection, DM); caustic ingestion; use of medications that cause topical injury (especially NSAIDs, KCl, bisphosphonates, iron, antibiotics, zidovudine)	Duration of symptoms; location; relation to meals or specific foods; nocturnal symptoms; dysphagia or chest pain; extraesophageal manifestations: cough, hoarseness, asthma	Acute vs. chronic (duration); association with different foods; psychiatric disease (e.g., depression, dementia); chronic or undiagnosed medical conditions (e.g., DM, thyroid or adrenal disease, COPD, advanced heart failure, renal insufficiency, malignancy, HIV infection); medication use	Acute vs. chronic (duration); age; total amount (>5% is significant); intentional vs. unintentional; appetite increased or decreased; rapid vs. gradual; change in physical activity; documented vs. undocumented; fever or sweats; anorexia, nausea, vomiting; diarrhea, steatorrhea, blood in stool; abdominal pain; history or symptoms of chronic medical, neurologic, or psychiatric illness; medications; alcohol and substance abuse
Acute with severe abdominal pain: evaluate for GI obstruction, pancreatitis, mesenteric ischemia, biliary colic, appendicitis, or other conditions causing peritonitis Acute without abdominal pain: evaluate for pregnancy, medications, food poisoning, infectious gastroenteritis, hepatitis, CNS disease, postoperative ileus Chronic: evaluate for medications, chronic gastric outlet obstruction (due to ulcer disease or malignancy), impaired GI motility (gastroparesis), other chronic medical conditions, intracranial disorders, psychiatric disease (bulimia)	Usually normal; examine oropharynx and neck for lymphadenopathy and masses; evaluate the skin for sclerodermatous changes	Usually normal; evaluate oropharynx for thrush, herpetic lesions, caustic injury; general exam for signs of underlying immunosuppression	Usually normal, unless extraesophageal manifestations are present	Wasting; fever; signs of bulimia (e.g., loss of tooth enamel, knuckle ulcerations and calluses); abdominal masses; enlarged lymph nodes	Wasting; malnutrition; poor dentition or poorly fitting dentures; thyromegaly; COPD or heart failure; abdominal masses; enlarged lymph nodes; pelvic masses in women; diabetic neuropathy; signs of depression, dementia, or bulimia
β-HCG, CBC, serum electrolytes, BUN, Cr, glucose, HbA_{1c}, liver tests, albumin, TFTs, cortisol	CBC; eosinophilia or elevated IgE in some patients with eosinophilic esophagitis	CBC, HIV test, fasting glucose	Usually normal	CBC, Chem-7, liver tests, albumin, HIV test, TFTs	CBC, Chem-7, HbA_{1c}, TFTs, liver tests, C-reactive protein or ESR, calcium, phosphate, albumin, HIV test, morning cortisol

TABLE 134-1 APPROACH TO COMMON GASTROINTESTINAL SIGNS AND SYMPTOMS—cont'd

	ABDOMINAL PAIN	GI BLEEDING	DIARRHEA	STEATORRHEA	CONSTIPATION
Endoscopy	EGD, colonoscopy	EGD, colonoscopy, enteroscopy, wireless capsule study	Colonoscopy (including ileal inspection) with biopsies; EGD with duodenal biopsies; wireless capsule study	EGD with duodenal biopsies	Colonoscopy if recent change in bowel habits
Imaging	CT scan or ultrasound; angiography; small bowel enterography	Tagged RBC scan, angiography	Small bowel enterography: CT, MRI, or barium (Crohn's disease); somatostatin scintigraphy	CT of the abdomen (pancreatic calcifications; biliary dilation)	Usually not necessary; MRI or defecography

ALT = alanine transaminase; AST = aspartate transaminase; BP = blood pressure; BUN = blood urea nitrogen; CBC = complete blood count; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; Cr = creatinine; CT = computed tomography; DM = diabetes mellitus; EGD = esophagogastroduodenoscopy; ESR = erythrocyte sedimentation rate; GERD = gastroesophageal reflux disease; GI = gastrointestinal; HCG = human chorionic gonadotropin; 5-HIAA = 5-hydroxyindoleacetic acid; HIV = human immunodeficiency virus; HR = heart rate; IBD = inflammatory bowel disease; INR = international normalized ratio; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; RBC = red blood cell; TFTs = thyroid function tests; tTG = tissue transglutaminase; U/A = urinalysis; VIP = vasoactive intestinal polypeptide.
Adapted from Proctor DD. Approach to the patient with gastrointestinal disease. In: Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine*, 23rd ed. Philadelphia: Saunders-Elsevier; 2008.

Disorders of malabsorption that result in steatorrhea may lead to deficiencies in the fat-soluble vitamins (A, D, E, K) (Chapter 142). The serum international normalized ratio may be elevated in patients with cholestasis owing to malabsorption of vitamin K or in patients with chronic liver disease due to decreased hepatic synthetic function. Serum B_{12} may be decreased in patients with autoimmune gastritis (pernicious anemia), gastric bypass surgery, or malabsorption due to small bowel bacterial overgrowth or disease of the terminal ileum (e.g., Crohn's).

Specialized laboratory tests that are useful for the diagnosis of specific diseases include antibodies to *Helicobacter pylori* in patients with peptic ulcer disease or dyspepsia, antibodies to tissue transglutaminase in celiac disease, antibodies to microbial antigens or autoimmune markers in inflammatory bowel disease (anti–*Saccharomyces cerevisiae* [ASCA], perinuclear antineutrophil cytoplasmic antibody [pANCA]), and CA-19-9 in pancreaticobiliary malignancy. Owing to their limited sensitivity and specificity, these tests are not useful for screening but may be helpful in circumscribed situations in which the results may shift the diagnostic probability.

Stool Examination

Fecal occult blood testing is useful to evaluate iron deficiency anemia and acute or chronic GI blood loss. In patients with acute diarrhea, assessment of fecal leukocytes or culture of common pathogens is routine, and in selected patients, testing for parasites (*Giardia, Entamoeba histolytica*), *Clostridium difficile*, *Escherichia coli* O157:H7, or other specific organisms may be warranted. To distinguish among the causes of chronic diarrhea (Chapter 142), stool samples may be sent for assessment of electrolytes, leukocytes, and fecal fat.

Endoscopy and Radiology

Endoscopy (Chapter 136) and radiographic studies (Chapter 135) play a major role in the evaluation and management of many GI disorders. Esophageal manometry and esophageal pH and impedance monitoring can be useful for the evaluation of heartburn, reflux, and other esophageal symptoms (Chapter 140). Anorectal manometry may be useful in some patients with fecal incontinence and defecatory dysfunction (Chapter 147). Breath tests are commonly used to diagnose *H. pylori* infection (Chapter 141), lactose intolerance, and small bowel bacterial overgrowth (Chapter 142).

The diagnosis of a functional GI disorder is made after organic disorders have been excluded by clinical evaluation and limited, directed diagnostic testing. "Overtesting" should be avoided. Thereafter, the emphasis should switch from finding a "cause" of the symptoms to implementing successful coping and adaptive behaviors.

ABDOMINAL PAIN

Abdominal pain, which is a frequent complaint among outpatients in the office setting and emergency department, may be benign and self-limited or the presenting symptom of severe, life-threatening disease. Chronic abdominal pain that has been present for months or years in the absence of other organic illness is almost always functional in origin and does not require urgent evaluation. By contrast, most patients with severe acute abdominal pain require a thorough but emergent evaluation, which may quickly reveal an acute surgical illness.

PATHOBIOLOGY

Stimulation of hollow abdominal viscera is mediated by splanchnic afferent fibers within the muscle wall, visceral peritoneum, and mesentery that are sensitive to distention and contraction. Visceral afferent nerves are loosely organized, innervate several organs, and enter the spinal cord at several levels. Thus, visceral pain is vague or dull in character and diffuse; patients attempting to localize the pain often move their entire hand over the upper, middle, or lower abdomen. Most visceral pain is steady, but cramping, intermittent pain or "colic" results from peristaltic contractions caused by partial or complete obstruction of the small intestine, ureter, or uterine tubes. In contrast to visceral innervation, the parietal peritoneum is innervated unilaterally by a dense network of nerve fibers that follow a spinal T6 to L1 somatic distribution. Pain fibers of the parietal peritoneum are stimulated by stretch or distention of the abdominal cavity or retroperitoneum; direct irritation from infection, pus, or secretions (e.g., caused by a ruptured viscus); or inflammation caused by contact between the parietal peritoneum and an adjacent inflamed organ (e.g., appendicitis). Parietal pain is sharp, well characterized, and localized by the patient to a precise location on the abdomen, often by pointing with one finger.

The gastrointestinal viscera (liver, biliary system, pancreas, and GI tract) arise during embryology from midline structures that have bilateral innervation. Thus, GI visceral pain is typically localized to the abdominal midline.

Acute Abdominal Pain

CLINICAL MANIFESTATIONS

History

The history should determine the time course, character, and location and radiation pattern of the pain (Table 134-2). Severe abdominal pain that begins suddenly over seconds to minutes indicates a catastrophic event such as esophageal rupture, perforated peptic ulcer or viscus, ruptured ectopic pregnancy, ruptured aortic aneurysm, acute mesenteric ischemia, or myocardial infarction. Pain that progresses within 1 to 2 hours is consistent with a rapidly progressive inflammatory disorder (e.g., cholecystitis, appendicitis, pancreatitis), acute obstruction of a viscus (small intestinal obstruction, ureteral colic), or organ ischemia caused by a strangulated blood supply (volvulus, strangulated hernia, ovarian torsion). Pain that is less severe and develops over several hours is more commonly caused by a medical rather than a surgical condition, including upper GI disorders (dyspepsia), intestinal disorders (gastroenteritis, inflammatory bowel disease), liver disorders (hepatitis, abscess), urinary disorders (cystitis, pyelonephritis), or gynecologic infections; however, the slow evolution of surgical disorders such as cholecystitis (Chapter 158), appendicitis or diverticulitis (Chapter 144), and intra-abdominal abscesses must not be overlooked.

The character of the pain provides important information about whether the symptoms are due to visceral stimulation or parietal stimulation

NAUSEA AND VOMITING	DYSPHAGIA	ODYNOPHAGIA	HEARTBURN AND REGURGITATION	ANOREXIA	WEIGHT LOSS
EGD to exclude gastric outlet obstruction	EGD with biopsies and/or dilation, esophageal motility study, 24-hr pH probe	EGD with biopsies	EGD (to detect erosive esophagitis or Barrett's esophagus); 24-hr pH probe	Directed at detecting underlying disease, e.g., if a GI cause is suspected, EGD and/or colonoscopy with biopsies may be helpful	Directed at detecting underlying disease, e.g., if a GI cause is suspected, EGD and/or colonoscopy with biopsies may be helpful
CT of the abdomen; if chronic, also consider head CT, gastric emptying study, small bowel enterography	Esophagogram (barium swallow) will show stricture, Schatzki's ring, mass, etc.	Usually not necessary	Usually not necessary	Directed at detecting underlying disease, e.g., if a GI cause is suspected, abdominal CT may be helpful	Directed at detecting underlying disease, e.g., chest or abdominal CT may be helpful

(peritonitis). Patients with peritonitis may report severe localized pain or irritation with activities or maneuvers that stretch or move the parietal peritoneum, such as walking, moving in bed, and coughing; as a result, they tend to lie quietly to avoid painful stimulation. By contrast, patients with visceral pain may move or walk restlessly or attempt a bowel movement in an effort to relieve their symptoms.

The location of pain in the upper, middle, or lower abdomen is a crude but important indicator of the diagnosis (Fig. 134-1). Visceral pain arising from the foregut (esophagus, stomach, proximal duodenum, bile duct, gallbladder, pancreas) most often manifests in the epigastrium. Pain derived from the midgut (small intestine, appendix, ascending colon, proximal transverse colon) presents in a periumbilical location. Pain derived from the hindgut (distal transverse colon, left colon, rectum) localizes to the lower midline between the umbilicus and symphysis pubis. Paired intra-abdominal organs such as the kidneys, ureters, ovaries, and fallopian tubes have unilateral innervation that localizes pain to the side of the involved organ. As some surgical conditions progress, the character and location of the pain shift from a visceral to a parietal pain pattern. Thus, early cholecystitis (Chapter 158) may present with vague midline epigastric pain that progresses to sharp right upper quadrant pain as localized peritoneal irritation develops. Likewise, appendicitis (Chapter 144) commonly begins with vague, diffuse periumbilical pain that evolves to sharp, well-localized right lower quadrant pain as peritonitis ensues.

Anorexia, vomiting, diarrhea, distention, and constipation are commonly seen with abdominal pain caused by both medical and surgical disorders. Although nonspecific, the *absence* of any of these symptoms is evidence against an emergent surgical or medical disorder because severe illness usually leads to reflex stimulation or inhibition of gastric and intestinal peristalsis. Vomiting is common in medical and surgical disorders involving the upper GI tract, including acute gastroenteritis, pancreatitis, gastric and small intestinal obstruction, and biliary tract disease. Pain that precedes the onset of vomiting is typical of surgical conditions, whereas the reverse is true of medical conditions (e.g., food poisoning, gastroenteritis). Abdominal pain with prominent diarrhea is most commonly caused by a medical condition (e.g., gastroenteritis, inflammatory bowel disease). Although constipation alone is a nonspecific complaint, the absence of stool passage and flatus is consistent with complete bowel obstruction or paralytic ileus.

Jaundice accompanying acute abdominal pain virtually always indicates a hepatobiliary disorder (Chapter 149), including obstruction of the biliary duct (choledocholithiasis, pancreatic carcinoma, cholangiocarcinoma), complications of acute cholecystitis, acute hepatitis (viral, ischemic), or hepatic malignancies. The possibility of cholangitis should be considered and excluded in all patients with acute abdominal pain and jaundice, especially if the patient has fever, chills, hypotension, altered mental status, or leukocytosis. Hematemesis with upper abdominal pain suggests a Mallory-Weiss tear, alcoholic gastritis, or peptic ulcer disease. Hematochezia with abdominal pain is most commonly caused by medical conditions such as infectious gastroenteritis or inflammatory bowel disease, but it also may be caused by ischemic colitis or mesenteric ischemia. Gross hematuria may be due to cystitis (Chapter 292) or a ureteral stone (Chapter 125). Abdominal pain with weight loss may be due to inflammatory bowel disease, chronic mesenteric ischemia, or advanced GI malignancies. In women, a missed menstrual period, adnexal pain, spotting, or cramping may suggest pregnancy, ectopic pregnancy, or spontaneous abortion. Acute pain between cycles may be caused by ovarian follicles or ruptured corpus luteum cysts. Pelvic pain with fever, chills, or cervical discharge suggests pelvic inflammatory disease.

The past medical history and review of systems can provide clues about systemic and extra-abdominal conditions that may present with abdominal pain. Acute coronary syndromes (Chapter 72), heart failure (Chapter 58), pneumonia (Chapter 97), or empyema may cause dyspepsia, epigastric or right or left upper quadrant pain, nausea, and vomiting. Metabolic conditions such as uremia (Chapter 132), diabetes with hyperglycemia or ketoacidosis (Chapter 236), hypercalcemia (Chapter 253), or acute adrenocortical insufficiency (Chapter 234) may cause pain, nausea, vomiting, and diarrhea. Acute intermittent porphyria (Chapter 217) and familial Mediterranean fever (Chapter 283) may cause recurrent episodes of severe pain and peritonitis that may be misdiagnosed, leading to unnecessary surgeries. Other causes of acute abdominal pain include narcotic withdrawal (Chapter 33), insect or reptile bites (Chapter 113), and lead or arsenic poisoning (Chapter 21).

Physical Examination

The physical examination must identify life-threatening illnesses that require urgent surgical evaluation. Nevertheless, the examination must be orderly, careful, and complete. If the examiner immediately palpates the site of maximal pain, the patient is unlikely to relax and cooperate for the remainder of the examination.

First, the patient should be observed and the abdomen inspected. Most patients remain calm, cooperative, and freely capable of moving during the examination. Patients who are writhing or restless may have pain due to visceral distention (e.g., renal colic, intestinal obstruction), whereas patients who lie motionless may have peritonitis. Gentle shaking of the bed or having the patient cough may elicit sharp, well-localized pain in patients with parietal but not visceral pain. Auscultation should be performed before percussion or palpation so that intestinal activity is undisturbed. An abdomen that is quiet except for infrequent squeaks or tinkles suggests peritonitis or ileus. Loud peristaltic rushes that occur in synchrony with abdominal pain suggest small bowel obstruction. Light percussion across the upper, middle, and lower abdomen can determine any site of focal tenderness suggestive of peritonitis. Light palpation should be performed with one or two fingers (not the whole hand), beginning away from where the patient localizes the pain and gradually moving to the site of pain. Thereafter, gentle, deeper palpation of the entire abdomen is performed gradually, including the region of tenderness. An attempt should be made to palpate for an abdominal aortic aneurysm (Chapter 78). Examination also should include the inguinal and femoral canals, umbilicus, and surgical scars for evidence of incarcerating hernias. The presence of focal tenderness indicates parietal peritoneal irritation. Voluntary or involuntary tightening of the muscle wall ("guarding") may occur during

TABLE 134-2 TYPICAL MANIFESTATIONS OF KEY CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN

CONDITION	LOCATION	QUALITY	ONSET	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Peptic ulcer disease (Chapter 141)	Epigastric, occasionally RUQ, rarely LUQ	Dyspepsia: mild to moderate aching discomfort, pain, burning, gnawing, postprandial fullness	Days	Variable relief with antacids; may be relieved by, worsened by, or unrelated to meals	Recurrent; associated factors (e.g., *Helicobacter pylori*, aspirin, NSAIDs)	Anemia, upper endoscopy, *H. pylori* testing
Acute pancreatitis (Chapter 146)	Epigastric, radiates to midback (occasionally RUQ or LUQ)	Diffuse, steady, stabbing, penetrating	1-2 hr	Aggravated by food; better when lying still and with narcotics	Severe nausea and vomiting; reduced or absent bowel sounds; associated factors (e.g., alcohol, gallstones)	Elevated amylase and lipase, CT
Acute cholecystitis (Chapter 158)	Epigastric, then moves to RUQ; may radiate to right scapula	Gradual, steady increase, moderate to severe	Hours	May follow a fatty meal; better with narcotics and surgery	Nausea, some vomiting, fever	Elevated WBC count, US or CT
Acute appendicitis (Chapter 144)	Periumbilical, then moves to RLQ	Vague initially; gradual, steady increase to intense, localized, pain	Hours	Unprovoked; better with narcotics and surgery	Anorexia, nausea, obstipation; occasional vomiting, fever late	Elevated WBC count, US or CT
Diverticulitis (Chapter 144)	LLQ or suprapubic	Moderate to severe, steady or cramping, sharp or aching, localized	Hours to days	Unprovoked; better with narcotics and antibiotics or surgery	Anorexia, nausea, distention, constipation or loose stools; partial relief with passage of flatus or BM; fever late	Elevated WBC count, CT
Ruptured viscus and peritonitis (Chapter 144)	Diffuse	Intense	Minutes to hours	Worse with cough or movement; better when lying still or with narcotics or surgery	Fever, anorexia, nausea, vomiting; lack of bowel sounds; tenderness with percussion, light touch, rebound; guarding and rigidity (late); loath to move	Elevated WBC count, CT
Intestinal ischemia (Chapter 145)	Small intestine—periumbilical; proximal (right) colon—periumbilical or RLQ; distal colon—LLQ	Severe, stabbing pain out of proportion to physical findings	Minutes	Chronic ischemia—occurs after eating; acute ischemia—usually unprovoked; better with narcotics, thrombus dissolution, stenting, surgical resection	Nausea, bloody diarrhea; associated factors (e.g., hypotension, cardiac arrhythmias)	Elevated WBC count, angiography or colonoscopy (colonic ischemia)
Strangulated hernia (Chapter 144)	Localized	Sharp, localized, intense; crampy or steady	Minutes to hours	Previous hernia history; unprovoked; better with narcotics and decompression, including surgery	Anorexia, nausea, vomiting, no stool or flatus passage if obstruction; bowel sounds variable—hyperactive early if obstruction present, but absent bowel sounds late, especially with peritonitis	Elevated WBC count, CT, US
Small or large bowel obstruction (Chapter 144)	Small intestine—periumbilical; proximal (right) colon—periumbilical or right abdomen; distal (left) colon—LLQ	Early—diffuse, colicky, crampy; late—steady and better localized	Hours to days	Aggravated by food; better with narcotics, NGT decompression, and/or surgery	Distention, anorexia, nausea, vomiting; no stool or flatus passage; small intestine—increased hyperperistaltic (rushes) bowel sounds (early) or quiet abdomen (late); large intestine—bowel sounds variable; associated factors (e.g., hernia, previous surgery)	CT

TABLE 134-2 TYPICAL MANIFESTATIONS OF KEY CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN—cont'd

CONDITION	LOCATION	QUALITY	ONSET	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Abdominal abscess (Chapter 144)	Located over the abscess, usually LLQ or RLQ	Insidious, intense, constant	Days	May be aggravated by movement; better with abscess drainage	Fever, anorexia, nausea, abdominal mass	Elevated WBC count, CT
Acute hepatitis (Chapter 150)	RUQ	Dull or intense; localized	Days	Worse with deep inspiration	Jaundice, anorexia, nausea; liver enlarged and tender to palpation; associated factors (e.g., alcohol, infection)	Abnormal liver tests
GERD (Chapter 140)	Substernal or epigastric	Burning, gnawing	Days to years	Provoked by large or fatty meals or recumbency; relief with antacids	Recurrent; may have regurgitation, dysphagia, or extraesophageal manifestations (e.g., asthma, chronic cough, laryngitis)	Upper endoscopy (usually normal), 24-hr pH probe
Nonulcer (functional) dyspepsia (Chapter 139)	Epigastric	Mild to moderate discomfort, pain, burning, gnawing, postprandial fullness	Years	May be worsened by meals; cannot be reliably distinguished from ulcer disease by history alone	Other symptoms of functional disorders (IBS, fibromyalgia, pelvic pain)	Normal EGD
IBS (Chapter 139)	Variable; usually lower abdomen	Vague, crampy, sense of urgency	Years	Pain may be precipitated by dietary factors or stress; associated with change in bowel characteristics (e.g., frequency, form, difficulty with passage); relieved with stool passage	Bloating and abdominal distention	Normal sigmoidoscopy, colonoscopy, and CT, but these are usually not necessary for diagnosis
Chronic pancreatitis (Chapter 146)	Epigastric or periumbilical, radiates to midback	Intense, localized	Days to years	Aggravated by food; better with narcotics	Anorexia, nausea, vomiting; associated factors (e.g., alcohol)	Amylase and lipase may be normal; CT may show calcifications, dilated pancreatic duct, pseudocyst
Inflammatory or infectious enterocolitis (Chapters 142 and 291)	Small intestine—periumbilical; large intestine—right or left side of the abdomen over the colon; rectum—tenesmus	Crampy	Hours to days	Better with stool passage and treatment of underlying cause	Nausea, vomiting, bloody diarrhea; associated factors (e.g., infectious—food transmission, IBD—prolonged duration, family history)	Stool studies for culture, colonoscopy with biopsies
Malignancy (Chapter 199)	Variable, depending on cancer location	Variable; intense and crampy if bowel obstruction; steady and vague if local invasion	Days	Better with narcotics and cancer therapy	Primary vs. metastatic disease	CT and biopsies, PET
Pneumonia/pleurisy (Chapters 97 and 99)	Upper abdomen: epigastric, RUQ, or LUQ	Localized; worse with deep breathing	Hours to days	Painful breathing; better with antibiotics	Cough, fever, dyspnea	CXR
Angina and myocardial infarction (Chapters 71-73)	Retrosternal or epigastric	Pressure, squeezing, heaviness, or intense	Minutes	Worse with exertion; relief with nitroglycerin	Dyspnea, diaphoresis	ECG, cardiac enzymes, stress testing
Genitourinary disorders (Chapters 128 and 293)	Bladder—suprapubic; renal colic—abrupt, excruciating LLQ or RLQ pain radiating to the groin; prostate—dull, suprapubic; kidney—CVA	Constant or colicky; stone passage—restless, cannot find a comfortable position	Minutes to days	Better with antibiotics and pain medications (pyelonephritis or nephrolithiasis)	Hematuria, dysuria, prostate tenderness, fever	Urinalysis, urine culture, CT for stone disease

TABLE 134-2 TYPICAL MANIFESTATIONS OF KEY CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN—cont'd

CONDITION	LOCATION	QUALITY	ONSET	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Ovarian cysts or torsion (Chapters 205 and 243)	LLQ or RLQ	Constant, intense	Minutes	Better with NSAIDs or surgery (torsion)	Nausea, vomiting; may be recurrent	US
Ruptured ectopic pregnancy (Chapter 247)	LLQ or RLQ	Constant, intense, stabbing	Minutes	Better with surgery	Rebound and guarding present, abnormal menses or amenorrhea	Acute anemia, elevated β-HCG, US
Musculoskeletal disorders	Specific muscle groups	Aching	Days	Better with heat or NSAIDs; aggravated by movement	History of muscle injury or exertion	Normal laboratory results
Herpes zoster (Chapter 383)	Dermatomal distribution	Burning, itching, neuropathic, constant	Days	Aggravated by touching the dermatome; better with pain or antiviral medications	Recurrent; rash may or may not be present	Skin culture or biopsy
Metabolic disorders (e.g., DM; Chapter 236)	Epigastric or generalized	Intense, constant	Hours to days	Worse with poor metabolic control (e.g., poor glucose control)	Recurrent; nausea, vomiting, diabetic neuropathy	Specific metabolic parameters abnormal (e.g., elevated glucose in DM)
Abdominal epilepsy (Chapter 410)	Epigastric or umbilical	Constant	Hours to days	Unprovoked; better with antiseizure therapy	Recurrent; may have associated seizure disorder	EEG
Dissecting or leaking abdominal aortic aneurysm (Chapter 78)	Over the aneurysm, radiates to the back or groin	Severe, searing, constant	Minutes to hours to days	History of HTN or CAD	Shock, pulsatile mass; bruit *not* usually present	Acute anemia, CT, angiography

BM = bowel movement; CAD = coronary artery disease; CT = computed tomography; CVA = costovertebral angle; CXR = chest x-ray; DM = diabetes mellitus; ECG = electrocardiogram; EEG = electroencephalogram; EGD = esophagogastroduodenoscopy; GERD = gastroesophageal reflux disease; HCG = human chorionic gonadotropin; HTN = hypertension; IBD = irritable bowel disease; IBS = irritable bowel syndrome; LLQ = left lower quadrant; LUQ = left upper quadrant; NGT = nasogastric tube; NSAIDs = nonsteroidal anti-inflammatory drugs; PET = positron emission tomography; RLQ = right lower quadrant; RUQ = right upper quadrant; US = ultrasonography; WBC = white blood cell.

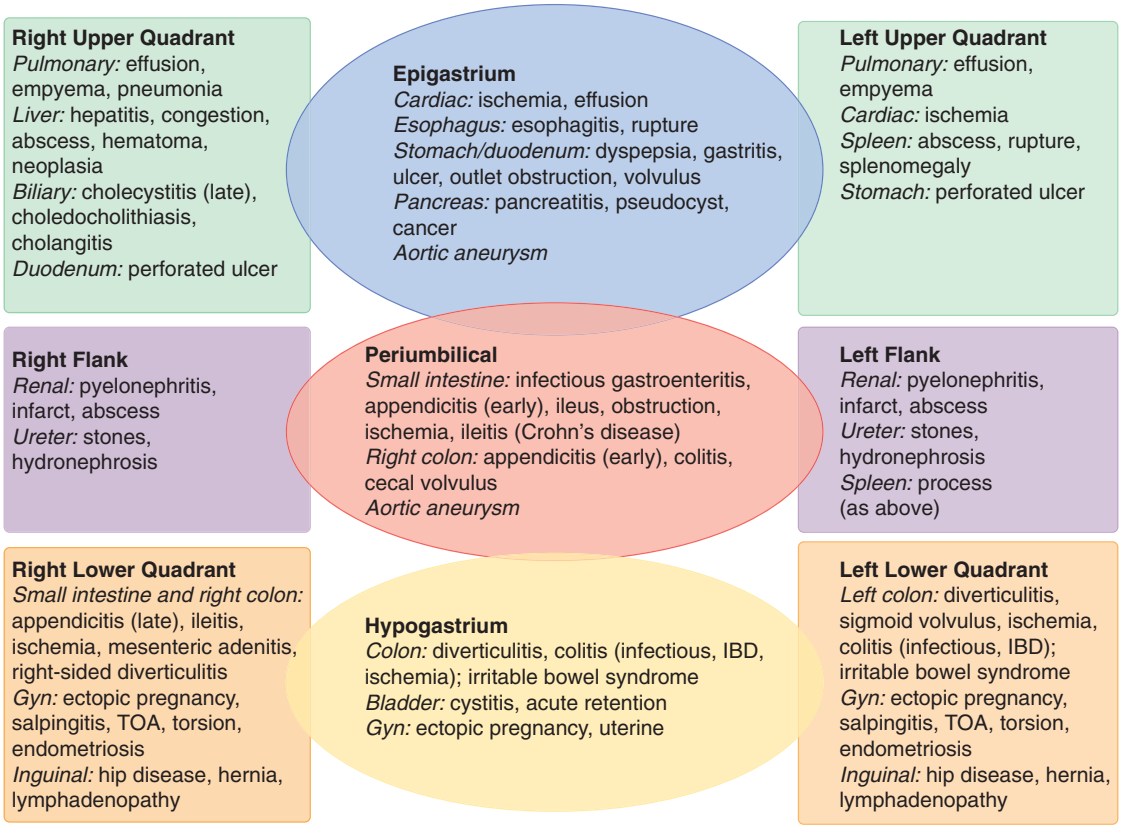

FIGURE 134-1. Differential diagnosis of abdominal pain by its initial location. IBD = inflammatory bowel disease; TOA = tubo-ovarian abscess.

palpation. With gentle, steady compression of the abdomen with one hand, voluntary guarding usually subsides, allowing the examination to proceed. Persistent involuntary guarding indicates peritonitis with reflex muscle wall contraction. Testing for "rebound tenderness" in patients with suspected peritonitis is not recommended because it causes significant pain and is usually not necessary to establish the diagnosis. When the presentation strongly suggests a nonserious GI disorder but the patient has significant tenderness with palpation, it is useful to use the stethoscope ostensibly to listen for bowel sounds but actually to reproduce the pressure of palpation. A significant discrepancy in the tenderness elicited by the stethoscope and by digital palpation may be seen in patients who are anxious, have functional complaints, or are seeking secondary gain. A digital rectal examination should be performed in most patients with acute abdominal pain to evaluate for tenderness or fluctuance that suggests a perirectal abscess and to assess the stool for signs of overt or occult blood. Women with lower abdominal pain should have a pelvic examination by a skilled examiner to evaluate for gynecologic pathology. Some specific and dramatic findings point to particular diagnoses (Table 134-3).

Special Populations

Increased diligence is required in the evaluation of patients in whom abdominal signs and symptoms may be minimal until the disease process is far advanced. Such patients include the elderly (Chapter 24) and patients who have dementia (Chapter 409), psychiatric disturbances (Chapter 404), or spinal cord injuries. An admitting diagnosis of "altered mental status," "failure to thrive," "obstipation," or "fever of unknown origin" may stem from serious intra-abdominal conditions. Disorders that may be overlooked in the elderly include bowel perforation, bowel obstruction, cholecystitis, diverticulitis, volvulus, mesenteric ischemia, and abdominal aortic aneurysm. In patients with chronic liver disease, the presence of ascites may mask the signs and symptoms of serious surgical conditions such as cholecystitis, appendicitis, and diverticulitis. Even in the presence of perforation, signs of peritonitis may be lacking because the ascites fluid separates the visceral peritoneum and parietal peritoneum. Likewise, immunocompromised populations, who are at risk for infectious, drug-related, and iatrogenic complications, may manifest few physical findings or laboratory abnormalities. Owing to the limitations of the clinical evaluation in these vulnerable populations, there should be a low threshold for the use of abdominal imaging.

Abdominal Pain Developing in the Hospital

When pain develops as a new problem in a hospitalized patient, it is usually caused by a limited number of conditions. Postprocedural complications may cause perforation, infection, or bleeding (intraperitoneal, retroperitoneal, or within solid organs). Shunting of splanchnic blood flow in severely ill medical or surgical patients may cause stress gastritis, nonocclusive mesenteric ischemia, or acalculous cholecystitis. Adynamic ileus or acute colonic pseudo-obstruction is common in critically ill or postoperative patients and manifests as diffuse abdominal pain and distention. *Clostridium difficile* (Chapter 304) colitis is a common cause of pain, diarrhea, and distention, especially in patients on antibiotics. Constipation (Chapter 138), which is a common problem in hospitalized patients, may go unnoticed until pain and distention develop. Finally, many medications can cause dyspepsia and abdominal pain.

TABLE 134-3 PHYSICAL SIGNS IN PATIENTS WITH ACUTE ABDOMINAL PAIN

SIGN	DESCRIPTION	DIAGNOSIS
Murphy's sign	Cessation of inspiration during right upper quadrant examination	Acute cholecystitis
McBurney's sign	Tenderness located midway between anterior superior iliac spine and umbilicus	Acute appendicitis
Cullen's sign	Periumbilical bluish discoloration	Retroperitoneal hemorrhage Pancreatic hemorrhage Ruptured abdominal aortic aneurysm
Grey Turner's sign	Bluish discoloration of flanks	Retroperitoneal hemorrhage Pancreatic hemorrhage Ruptured abdominal aortic aneurysm
Kehr's sign	Severe left shoulder pain	Splenic rupture Ectopic pregnancy rupture
Obturator sign	Pain with flexed right hip rotation	Appendicitis
Psoas sign	Pain with straight leg raising against resistance (right side)	Appendicitis

DIAGNOSIS

Patients with acute abdominal pain should have a complete blood count with differential; leukocytosis is present in most acute surgical conditions (Fig. 134-2). A pregnancy test is required in women of childbearing age. Serum electrolytes, glucose, blood urea nitrogen, and creatinine levels assess hydration, acid-base status, and renal function. Liver chemistries and pancreatic enzymes should be obtained in most patients, but especially in those with upper abdominal pain, jaundice, or vomiting. An elevation in aspartate or alanine aminotransferase levels may reflect choledocholithiasis with acute biliary obstruction (Chapter 158), acute gallstone pancreatitis (Chapter 146), or a hepatocellular process (Chapter 150). Painful jaundice with a significant rise in the alkaline phosphatase level usually reflects cholestasis caused by extrahepatic biliary obstruction (Chapter 158). Amylase and lipase levels are elevated in most patients with acute pancreatitis, but minor amylase elevations also occur with a perforated viscus or mesenteric ischemia (Chapter 145). Urinalysis may demonstrate pyuria, hematuria, or bacteriuria owing to ureteral calculi (Chapter 128) or urinary tract infection (Chapter 292).

Imaging

Ultrasound is preferred in suspected pregnancy and to evaluate for other acute gynecologic disorders such as tubo-ovarian abscess, ruptured corpus luteum cyst, or ovarian torsion; it is also preferred for the initial evaluation of suspected acute cholecystitis (Chapter 158) and ureteral stones with hydronephrosis (Chapter 125) and for the bedside evaluation of unstable patients. In most other settings, abdominal computed tomography (CT) with oral and intravenous contrast (when possible) is preferred and can provide a definitive diagnosis in up to 90% of patients with acute severe abdominal pain (Chapter 135). Abdominal CT may be falsely negative early in the course of acute pancreatitis, mesenteric ischemia, cholecystitis, appendicitis, and diverticulitis, especially if performed without contrast.

TREATMENT

Rx

Once the diagnosis is clear, treatment of the underlying condition is initiated. In patients with nonspecific acute abdominal pain and no clear diagnosis, early laparoscopy is useful for diagnosis, but outcomes such as complication rates, readmission rates, and length of hospitalization are no better than with a strategy of active observation.■

Chronic Abdominal Pain

Chronic or recurrent abdominal pain that has been present for months to years may be caused by structural (organic) disease, but the majority of patients have a functional disorder such as irritable bowel syndrome (Chapter 139). Common organic causes of chronic abdominal pain include medications with GI side effects, peptic ulcer disease (Chapter 141), inflammatory bowel disease (Chapter 143), chronic pancreatitis (Chapter 146), biliary tract disease (Chapter 158), GI cancers (Chapters 198 and 199), and endometriosis (Chapter 244). The clinician should attempt to distinguish patients with symptoms or signs of organic disease, in whom further diagnostic investigation is warranted, from those with probable functional disease (Fig. 134-3). Although functional disorders occur in all age groups, the symptoms usually begin before age 40. "Alarm" features that suggest a structural disorder and are inconsistent with a functional disorder are fever, severe pain, significant weight loss, jaundice, progressive dysphagia, recurrent vomiting, nocturnal pain or diarrhea, and stools that are bloody or positive for fecal occult blood. Laboratory studies should be normal with functional disorders; therefore, an unrevealing evaluation for anemia, leukocytosis, and levels of iron, albumin, C-reactive protein, and vitamins A, D, or B_{12} argues against structural or organic disease.

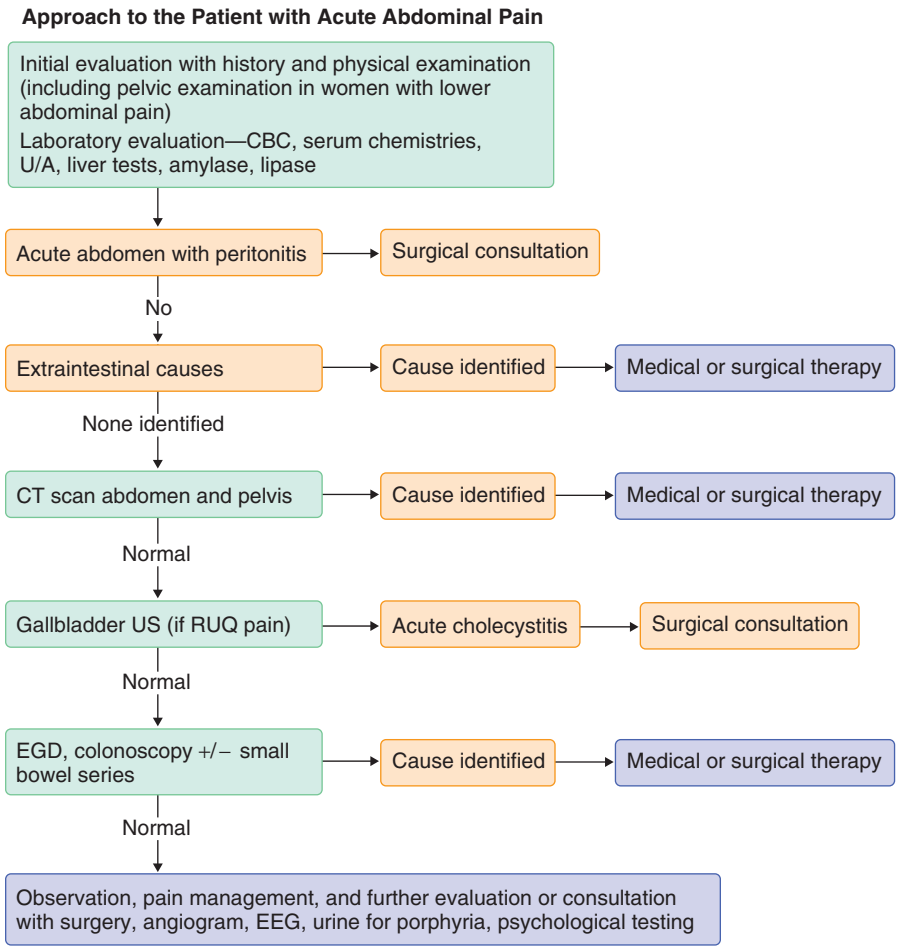

FIGURE 134-2. Approach to the patient with acute abdominal pain. CBC = complete blood count; CT = computed tomography; EEG = electroencephalography; EGD = esophagogastroduodenoscopy; RUQ = right upper quadrant; U/A = urinalysis; US = ultrasonography.

In patients younger than 50 years with a suspected functional disorder and no alarm features (e.g., family history of colon cancer or inflammatory bowel disease or abnormalities on screening blood tests), further testing should be minimized, and the emphasis should be shifted to managing symptoms, coping, and making lifestyle changes (Chapter 139). In patients who may have organic disease, testing often includes a combination of upper GI endoscopy, colonoscopy, and ultrasound or CT imaging.

GAS AND BLOATING

Belching

Belching (eructation), which is the involuntary or voluntary release of gas from the esophagus or stomach, commonly occurs during or after a meal. Virtually all belching is caused by swallowed air, which may be increased by eating quickly, drinking carbonated beverages, chewing gum, and smoking. Gas also may be produced within the stomach by antacids, especially sodium bicarbonate, which rapidly neutralize gastric acid and release carbon dioxide. Belching seldom reflects serious GI dysfunction but may be increased in patients with gastroesophageal reflux (Chapter 140), functional dyspepsia (Chapter 139), or gastroparesis (Chapter 138). Chronic, excessive, repetitive belching is a functional disorder caused by habitual aerophagia (air swallowing) and is treated with behavioral modification.

Flatus

Flatus or "gas" is a normal byproduct of digestion. Otherwise healthy adults pass flatus 10 to 20 times daily and excrete up to 1500 mL. Thus, it is difficult to distinguish patients with abnormal or excessive gas production from those with only a heightened awareness of or sensitivity to normal production. Increased flatulence with diarrhea may be symptomatic of disorders of malabsorption, including celiac disease (Chapter 142), pancreatic insufficiency (Chapter 146), and small intestinal bacterial overgrowth (Chapter 142).

In normal adults, flatus is derived from two sources: swallowed air and colonic bacterial fermentation of carbohydrates that results in the production of carbon dioxide or methane. Carbohydrates that may be incompletely absorbed in the small intestine and pass into the colon include lactose (dairy products), fructose, sorbitol, trehalose (mushrooms), and the α-galactosyl oligosaccharides raffinose, stachyose, and verbascose. The latter are found in increased amounts in cruciferous vegetables (cabbage, broccoli, cauliflower, brussels sprouts, turnips, rutabagas), legumes (beans, soy, lentils, peas), pasta, and whole grains. Fructose is present in fruits, especially apples and pears, and is a major component of corn syrups that are used widely as sweeteners. Sorbitol is a natural sugar in stone fruits (peaches, apricots, plums, prunes) and is a common sweetener in sugar-free candies.

TREATMENT Rx

Patients with long-standing flatulence in the absence of other symptoms or signs of GI disease can be treated conservatively. Avoidance of carbonated beverages, chewing gum, sorbitol- and fructose-containing sweeteners, and gas-producing vegetables improves symptoms in most patients. Lactase deficiency may be confirmed by a lactose breath test. Underlying GI illness is suggested by the recent onset of flatulence with other symptoms of organic disease, including weight loss, abdominal pain, diarrhea, distention, and abnormal laboratory studies (Chapter 142). A positive fecal fat analysis confirms malabsorption and merits further investigation (see Table 142-4 in Chapter 142). Suspected small bowel bacterial overgrowth may be confirmed by carbohydrate breath tests or treated empirically with antibiotics.

Bloating and Distention

Bloating and distention are common complaints among patients with functional GI disorders (Chapter 139). As chronic, isolated symptoms, they are almost never caused by serious structural disease. Functional bloating may be caused by heightened sensitivity to minor increases in intestinal gas or impaired transit of gas, even though the total volume of intestinal gas is within normal limits. The acute onset of distention in conjunction with alarm symptoms such as cramping pain, weight loss, nausea, vomiting, obstipation, or diarrhea warrants further evaluation for disorders that cause intestinal

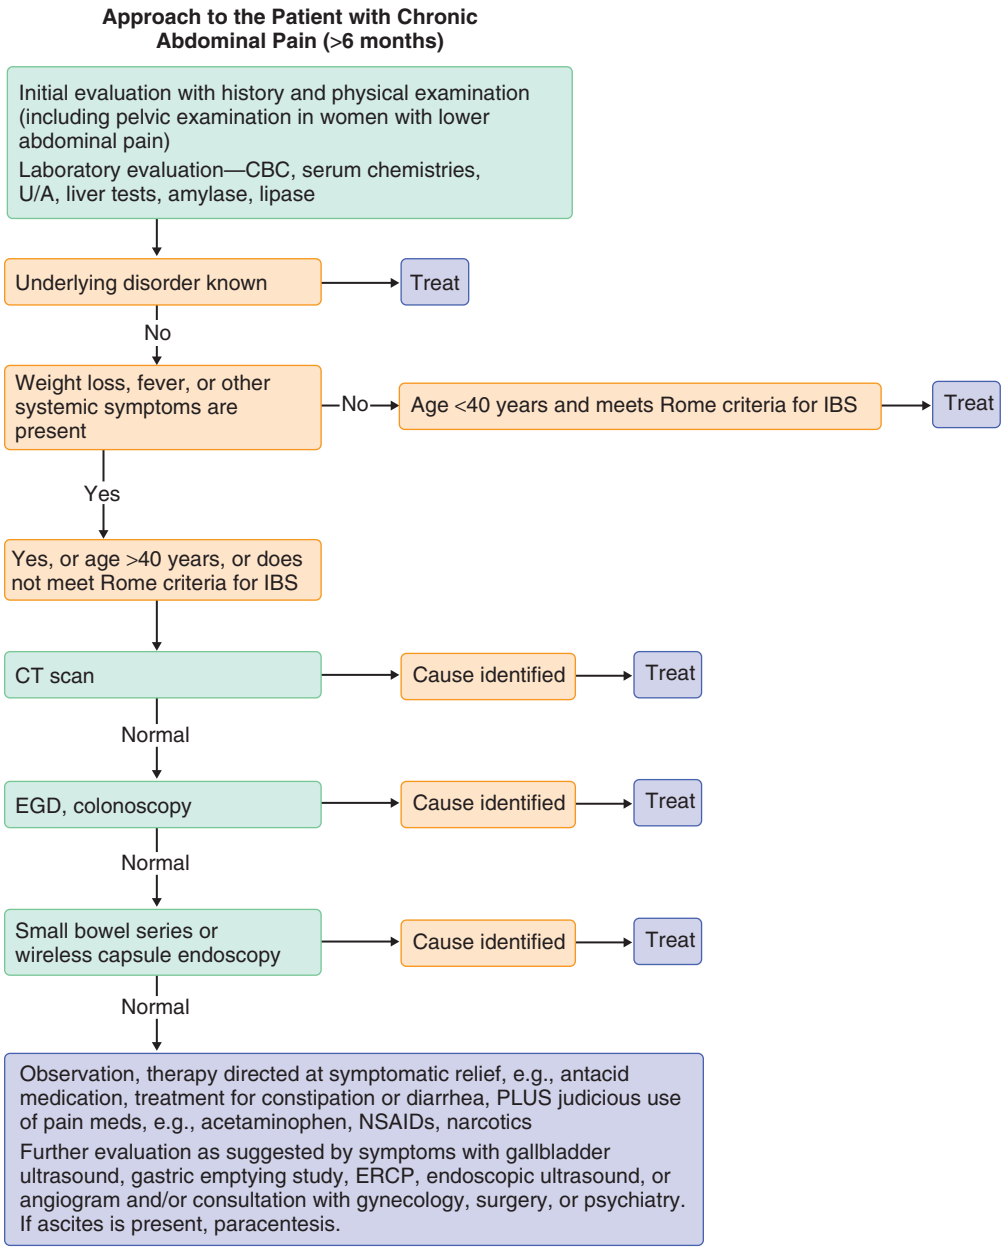

FIGURE 134-3. Approach to the patient with chronic abdominal pain. CBC = complete blood count; CT = computed tomography; EGD = esophagogastroduodenoscopy; ERCP = endoscopic retrograde cholangiopancreatography; IBS = irritable bowel syndrome; NSAIDs = nonsteroidal anti-inflammatory drugs; U/A = urinalysis.

obstruction (Chapter 144) or malabsorption (Chapter 142). Rifaximin (550 mg three times daily for 2 weeks) is effective for functional bloating, pain, and loose or watery stools;■ but dietary and behavioral changes and reassurance may also be useful.

INVOLUNTARY WEIGHT LOSS

The unintentional loss of more than 5% of baseline weight within a 12-month period is frequently due to a serious underlying medical or psychiatric illness. Weight loss is seldom the sole presenting sign of medical disorders, but it is often revealed during the clinical evaluation of other complaints. Chronic weight loss in the elderly is commonly caused by depression, dementia, difficulty chewing or swallowing, malignancy, medications, alcoholism, or physical and social limitations to procuring, preparing, and eating meals (Table 134-4) (Chapter 23). Gradual, mild weight loss occurs in some elderly patients owing to the loss of lean body mass. In young patients, weight loss is more commonly caused by eating disorders (Chapter 226), endocrine disorders (Chapters 233 and 234), or chronic GI conditions such as inflammatory bowel disease (Chapter 143) or celiac disease (Chapter 142). In chronic medical conditions, involuntary weight loss is usually caused by a combination of decreased appetite (anorexia) and varying degrees of cachexia; examples include advanced malignancy, chronic infections (HIV, tuberculosis), heart failure, chronic kidney or liver disease, end-stage lung disease, and adrenal insufficiency. Weight loss that occurs in the presence of normal or increased appetite suggests increased metabolism and energy expenditure caused by endocrine disorders such as poorly controlled diabetes (Chapter 236) or hyperthyroidism (Chapter 233) or GI disorders that result in food malabsorption (Chapter 142). Chronic GI disorders that cause progressive narrowing or obstruction of the esophagus (cancer, achalasia), stomach (cancer, peptic ulcer disease with gastric outlet obstruction), small intestine (Crohn's disease), or arterial circulation (chronic mesenteric ischemia) may cause weight loss owing to dysphagia, vomiting, or postprandial pain that limits the ability to ingest sufficient calories.

DIAGNOSIS

The cause of weight loss (see Table 134-4) is usually evident from the history, physical examination, and routine laboratory studies, including complete blood count, electrolytes, liver chemistries, thyroid-stimulating hormone, urinalysis, and, when appropriate, HIV serology (Fig. 134-4). A chest radiograph should be obtained in patients who smoke, have any respiratory symptoms, or are older than 40 years. Signs of dehydration or severe malnutrition may require an assessment for nutritional deficiencies (Chapter 221) and nutritional support (Chapters 223 and 224).

The need for further diagnostic testing is determined by other symptoms and signs. Weight loss with increased appetite merits an assessment of thyroid function (Chapter 233), glucose intolerance (Chapter 237), and malabsorption (Chapter 142). Suspected malabsorption may be confirmed by a positive fecal fat analysis. GI symptoms suggesting obstruction or occult GI malignancy can be evaluated with upper GI endoscopy, upper GI radiographic series, colonoscopy, or abdominal CT. Psychiatric evaluation may be

TABLE 134-4 CAUSES OF INVOLUNTARY WEIGHT LOSS

CONDITION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
WEIGHT LOSS SECONDARY TO GASTROINTESTINAL CAUSES					
GI, pancreatic, or hepatobiliary malignancy (Chapters 198-202)	Progressive, fast	Months	Better with cancer therapy (e.g., surgery, XRT, chemotherapy)	Dysphagia (esophageal); anorexia, nausea, vomiting (gastric, small or large bowel obstruction); visible or occult blood in stool; altered bowel habits; jaundice or hepatomegaly (biliary obstruction, hepatic tumor, metastatic disease); iron deficiency anemia	CBC, FOBT, ferritin, CEA, CA19-9, AFP, EGD, colonoscopy, abdominal CT, PET
Malabsorption (Chapter 142) (poor absorption of nutrients due to pancreatic insufficiency, small intestinal mucosal disorders, or bacterial overgrowth)	Progressive, slow	Months to years	Diarrhea or steatorrhea, excessive flatulence; worse with eating and resolves with NPO status	Usually associated with increased appetite; may have anemia (iron, B_{12}, folate), osteoporosis, or osteomalacia (vitamin D, calcium, phosphorus); easy bruising (vitamin K), night blindness (vitamin A)	72-hr stool for fecal fat; vitamins A and D and INR; calcium, ferritin, B_{12}, albumin; celiac disease antibodies (e.g., anti-tTG, antiendomysial antibodies); EGD with small bowel biopsy; breath test for bacterial overgrowth
Inflammatory bowel disease (especially Crohn's disease) (Chapter 143)	Progressive, slow	Months	Eating causes pain, cramps, increased diarrhea and urgency; improved by low-residue diet or NPO status	Bloody stools, abdominal cramps and pain, perianal disease, extraintestinal manifestations (e.g., oral ulcers, uveitis, erythema nodosum, arthralgias)	CBC, albumin, ESR, CRP, colonoscopy with biopsies, CT or MR enterography, wireless capsule study
GI motility disorders (Chapter 138)	Intermittent, slow	Years	Worse with eating	Nausea, vomiting, distention, diarrhea, or constipation may be present	EGD and colonoscopy, gastric emptying study, CT or MR enterography, surgical full-thickness intestinal biopsies
Cirrhosis (Chapter 156)	Muscle wasting with edema, so weight may increase	Months to years	Worse with salt or fluid intake	Ascites, peripheral edema	Liver biopsy
Chronic intestinal ischemia (Chapter 145)	Progressive	Months to years	Worse with eating	Afraid to eat; postprandial abdominal pain, nausea; associated atherosclerotic disease	CT or MR angiography
WEIGHT LOSS SECONDARY TO NONGASTROINTESTINAL CAUSES					
Poor or inadequate caloric intake due to social factors	Intermittent or progressive, acute (hospitalized) or chronic	Days to months to years	Common in elderly, teenagers; exacerbated by poor dentition or poorly fitting dentures	Will eat if food is made available	Review dietary log and how food is obtained and prepared
Medications	Intermittent or progressive	Months	Worse with medication; resolves with discontinuation of offending drug	Anorexia, nausea, vomiting	Review drug profile
Non-GI malignancy	Progressive	Months	Better with cancer therapy (e.g., surgery, XRT, chemotherapy)	Anorexia, nausea, vomiting; pain; metastatic disease	Calcium, cortisol; CT for underlying disease, PET
Endocrine disorders: DM, hyperthyroidism, adrenal insufficiency (Chapters 233-237)	DM—appetite increased or decreased, early satiety; hyperthyroidism—increased appetite	Months to years	Worse with disease chronicity	DM: gastroparesis, neuropathy, retinopathy, nephropathy Adrenal insufficiency: nausea, vomiting, diarrhea, abdominal pain	Serum glucose, TFT, cortisol
Chronic infections, including HIV and TB (Chapters 332 and 397)	Progressive, fast	Months	Better with directed therapy, megestrol acetate (Megace)	Nausea, anorexia, other infections	HIV test, PPD, cultures, biopsies if necessary
Systemic inflammatory disorders	Progressive, moderate	Months to years	Better with directed therapy, megestrol acetate (Megace)	Arthritis, rash, vasculitis	ANA, RF, ESR, CRP
Chronic renal failure (Chapter 132)	Progressive, slow; edema may increase weight	Months to years	Better with dialysis, megestrol acetate (Megace)	Nausea, anorexia, weight gain	BUN, Cr, 24-hr creatinine clearance
Advanced COPD or heart failure (Chapters 58 and 88)	Progressive, slow	Months to years	Better with oxygen and specific treatment	Fatigue, dyspnea, edema, wasting	Pulmonary function testing or two-dimensional echocardiography
Psychiatric illness: depression, manic-depressive illness (Chapter 404)	Progressive, slow	Months to years		Depression common in elderly; flat affect; manic phase associated with hyperactivity and decreased intake	Psychological testing

TABLE 134-4 CAUSES OF INVOLUNTARY WEIGHT LOSS—cont'd

CONDITION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Psychogenic eating disorders—anorexia nervosa, bulimia (Chapter 226)	Intermittent or progressive	Months to years	Worse with stressors	Refusal to eat, loss of tooth enamel, calluses and healing ulcerations of hand	Psychiatric testing
Substance abuse (alcohol, opiates, CNS stimulants)	Intermittent or progressive	Months	Resolves with discontinuation	Anorexia, nausea, vomiting	Careful interview; patients may deny or minimize

warranted in patients with signs of depression, early dementia, or eating disorders. In up to 25% of patients, no cause of weight loss is found.

NAUSEA AND VOMITING

Nausea is an unpleasant feeling of the impending need to vomit. *Vomiting* is the forceful oral expulsion of gastric contents as a result of retrograde contraction of the duodenum and antrum with compression of the thoracoabdominal musculature. Nausea and vomiting may be caused by a number GI and non-GI disorders, but they are best categorized according to chronicity and the presence of abdominal pain. The acute onset of vomiting *with* severe abdominal pain suggests a serious illness potentially requiring surgical intervention, including GI obstruction (Chapter 144), mesenteric ischemia (Chapter 145), pancreatitis (Chapter 146), biliary colic (Chapter 158), or conditions causing peritonitis (Chapter 144), such as appendicitis

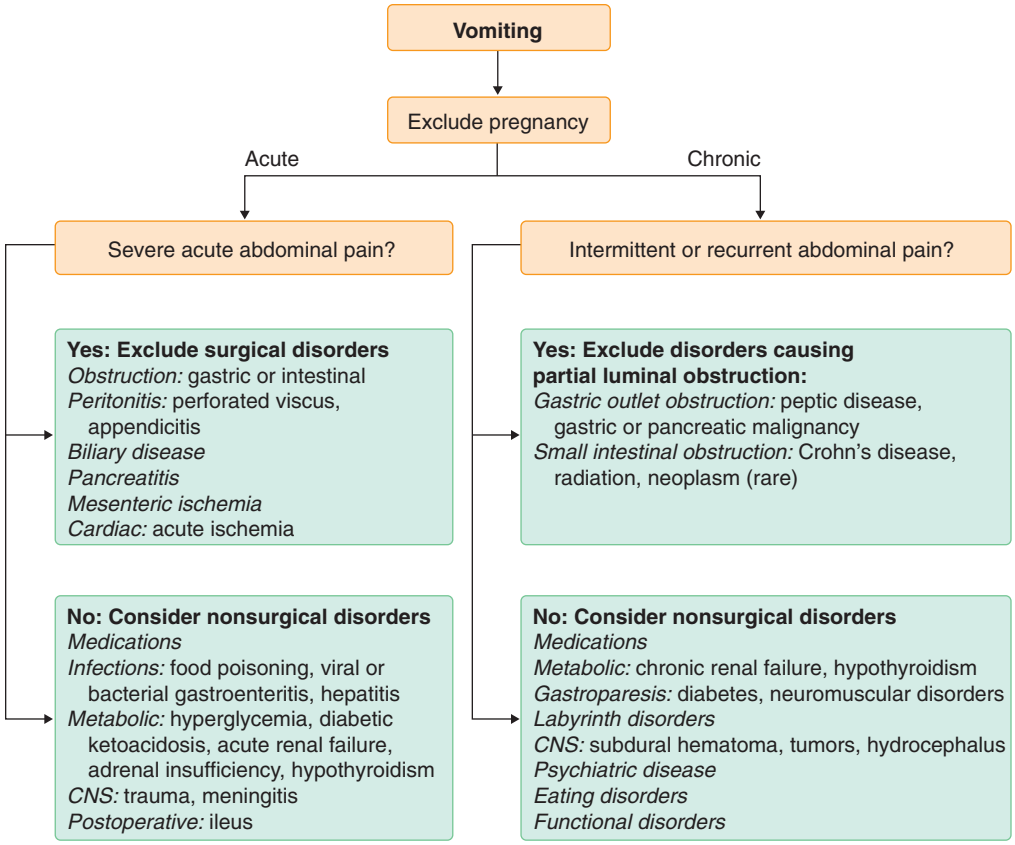

FIGURE 134-5. Approach to the patient with vomiting. CNS = central nervous system.

or a perforated viscus. Acute vomiting *without* abdominal pain is most commonly caused by medications (including chemotherapy), motion sickness (Chapter 436), food poisoning (Chapter 291), infectious gastroenteritis (Chapter 291), hepatitis (Chapters 150 and 151), upper GI bleeding, postoperative ileus, or acute central nervous system disease. Chronic or recurrent nausea and vomiting *with* abdominal pain are commonly caused by GI disorders that result in the partial or intermittent obstruction of the stomach or small intestine. Chronic nausea and vomiting *without* abdominal pain may be caused by disorders that impair gastric emptying or small intestine motility and by non-GI causes including medications, pregnancy, intracerebral disorders, cardiac disease, endocrine disease, labyrinth disorders, psychiatric disease (including bulimia), and functional disorders. Vomiting of undigested food eaten hours earlier suggests gastric obstruction or gastroparesis. Abdominal distention or feculent emesis suggests obstruction of the small intestine.

DIAGNOSIS

Most cases of acute vomiting without abdominal pain are self-limited and require no evaluation (Fig. 134-5). Medication-related symptoms and pregnancy should be excluded. With severe vomiting, serum electrolytes should be obtained. Hyperglycemia may cause acute gastroparesis. Increased liver chemistries or pancreatic enzymes suggest hepatobiliary or pancreatic disease. In patients with acute abdominal pain and vomiting, abdominal plain radiographs or CT is obtained to look for evidence of GI obstruction, a perforated viscus, or pancreaticobiliary disease. In patients with chronic vomiting of uncertain cause, the goal is to distinguish structural GI disorders, GI motility disorders, and non-GI disorders. Esophagogastroduodenoscopy, enterography, abdominal cross-sectional imaging, GI motility studies, and head CT or magnetic resonance imaging may all be indicated.

TREATMENT

Rx

The approach to the medical treatment of nausea and vomiting depends on the cause (Table 134-5). Patients who are receiving moderately emetogenic chemotherapy are frequently managed with a 5-HT_3-receptor antagonist and dexamethasone; aprepitant is added for highly emetogenic regimens. For patients with mildly emetogenic regimens or vomiting from other causes, treatment with single or combinations of anti-cholinergic agents, dopamine-receptor antagonists, or 5-HT_3-receptor antagonists usually provides symptomatic relief.

OTHER GASTROINTESTINAL COMPLAINTS

Heartburn, esophageal regurgitation, dysphagia, odynophagia, and noncardiac chest pain suggest esophageal disease (Chapter 140). *Dyspepsia*, which refers to bothersome, intermittent, mild to moderate upper abdominal or epigastric symptoms, can be caused by peptic ulcer disease (Chapter 141) or esophageal disease (Chapter 140), or it can be functional in origin (Chapter 139). An orderly diagnostic approach (Fig. 134-6) can help distinguish among the various causes, avoid unnecessary testing, and minimize symptoms.

Diarrhea, which is defined pathophysiologically as an increase in stool weight to greater than 200 g/day, can be caused by malabsorption of osmotically active substances or by increased intestinal secretion of electrolytes and water. In clinical practice, however, stool weight is seldom quantified, and the term *diarrhea* refers to an increase in stool liquidity and/or frequency (more than three bowel movements/day). Acute and chronic diarrhea should be distinguished because the evaluation and treatment are different (Chapter 142).

Constipation (Chapter 138), which is the most common digestive symptom, occurs in 15% of the population. Constipation may refer to fewer than three bowel movements per week; hard or lumpy stools; or difficulty during defecation, characterized by straining, a sensation of obstruction or incomplete evacuation, or the need to engage in manual manipulations to promote evacuation. Constipation may be caused by systemic conditions that slow colonic transit, including neuromuscular disease, endocrine disorders, and electrolyte abnormalities, or by lesions that obstruct the passage of stool through the distal colon or anorectum, such as neoplasms, strictures, prolapse, and agangliosis (Hirschsprung's disease). Most patients, however, do not have an apparent cause and are deemed to have functional constipation.

GI bleeding (Chapter 137) may be acute and clinically apparent (overt) or chronic, slow, and clinically inapparent (occult). The location of acute GI bleeding is described as either upper or lower, according to whether the source is proximal or distal to the ligament of Treitz (distal duodenum). Upper GI bleeding, which is three times more common than lower GI bleeding, is manifested by bloody emesis (hematemesis), coffee ground emesis, and, in most cases, black stools (melena). Common causes of significant bleeding are peptic ulcer disease, esophageal varices, Mallory-Weiss tears, erosive gastritis or esophagitis, and vascular ectasias. Major lower GI bleeding

TABLE 134-5 MEDICAL TREATMENT OF NAUSEA AND VOMITING

DRUG	USUAL INDICATIONS	USUAL DOSE (RANGE)	ROUTE	COMMENTS
ANTICHOLINERGIC-ANTIHISTAMINE AGENTS				Side effects: sedation, dizziness, delirium, blurred vision, glaucoma, bronchospasm, tachycardia, urinary retention Avoid concomitant alcohol or CNS depressants; use with caution in elderly patients
Scopolamine patch	MS	1.5 mg/72 hr	Patch	
Dimenhydrinate	MS	50 mg (50-100 mg) q4-6h	PO, IM, IV	Maximum 400 mg/24 hr
Cyclizine	MS, GIDz	50 mg q8h	PO, IM	Maximum 200 mg/24 hr
Meclizine	MS, V	25-50 mg q24h	PO	
Diphenhydramine	GIDz	25-50 mg q6h 50-100 mg q6h	PO, IV IM	
Promethazine	GIDz, PONV, MS	25 mg (12.5-25 mg) q6-12h 25 mg (12.5-50 mg) q4-6h	PO, PR IV, IM	Phenothiazine derivative, but lacks significant antidopaminergic effects Avoid perivascular extravasation or subcutaneous injection (severe tissue necrosis)
Trimethobenzamide	GIDz, PONV	200 mg q6-8h	IM	
DOPAMINE RECEPTOR ANTAGONISTS				Side effects: neuromuscular (extrapyramidal) symptoms—agitation, restlessness, involuntary movements, dystonia, torticollis, laryngospasm, Parkinson-like features
Prochlorperazine	GIDz, PONV, CTX	5-10 mg q6-8h 25 mg q12h	PO, IV, IM PR	Maximum dose 20-40 mg/24 hr; avoid subcutaneous injection (irritation)
Metoclopramide	GIDz CTX	10 mg (10-20 mg) q6-8h 1-2 mg/kg before and 2 hr after CTX	PO, IV, IM IV	Modest efficacy at these doses High doses infrequently used owing to availability of safer, more effective CTX regimens; use with diphenhydramine to reduce adverse side effects
Droperidol	PONV	2.5 mg (1.25-5 mg) pre-induction and q4-6h as needed	IV, IM	May cause QTc prolongation and torsades de pointes; use is restricted to patients who fail to respond to other agents
CORTICOSTEROIDS				
Dexamethasone	PONV CTX	4-8 mg once pre-induction 8-20 mg on day 1; 8 mg on days 2-4	PO, IV PO, IV	Most beneficial when used with other agents (e.g., 5-HT_3 RA, neurokinin-1 RA)
BENZODIAZEPINES				Used to reduce anxiety and anticipatory vomiting
Lorazepam	CTX	1-2 mg q4-6h	PO, IV	
CANNABINOIDS				May stimulate appetite; adverse side effects (sedation, dizziness, dysphoria, dry mouth) limit use
Dronabinol	GIDz, CTX	5-10 mg q6-8h	PO	
Nabilone	GIDz, CTX	1-2 mg q12h	PO	
5-HT_3 RECEPTOR ANTAGONISTS	PONV, CTX			PONV prevention: give IV immediately before anesthesia induction Prevention of CTX-induced vomiting: give 30 min (IV) to 1 hr (PO) before chemotherapy
Ondansetron	PONV CTX, RadTx	4 mg once 4-8 mg Moderately emetogenic CTX: 8 mg twice daily Highly emetogenic CTX: 24 mg once	IV PO IV or PO IV or PO	
Granisetron	CTX, RadTx	1-2 mg once daily 1 mg once daily	PO IV	
Dolasetron	CTX, PONV	100 mg once daily	PO, IV	
Palonosetron	CTX PONV	0.25 mg 0.5 mg 0.075 mg	IV PO IV	
NEUROKININ-1 RECEPTOR ANTAGONISTS	Highly emetogenic CTX			Used exclusively in combination with a 5-HT_3 RA and/or dexamethasone
Aprepitant		125 mg on day 1 80 mg on days 2-3	PO	
Fosaprepitant		115 mg on day 1	IV	Aprepitant 80 mg PO on days 2-3
ANTIEMETIC REGIMENS FOR CHEMOTHERAPY				
Mildly emetogenic CTX	Option 1 Option 2	Dexamethasone 8 mg Dopamine receptor antagonist	IV or PO	One dose only One dose only

TABLE 134-5 MEDICAL TREATMENT OF NAUSEA AND VOMITING—cont'd

DRUG	USUAL INDICATIONS	USUAL DOSE (RANGE)	ROUTE	COMMENTS
Moderately emetogenic CTX		Day 1: 5-HT_3 RA plus dexamethasone 8 mg	IV or PO	Days 2-3: continue oral 5-HT_3 RA or dexamethasone 8 mg to reduce delayed emesis
Highly emetogenic CTX		Day 1: 5-HT_3 RA plus dexamethasone 12 mg plus neurokinin-1 RA	IV or PO	Give aprepitant 80 mg PO days 2-3 and dexamethasone 8 mg PO days 2-4 to reduce delayed emesis

CNS = central nervous system; CTX = chemotherapy; GIDz = gastrointestinal disorders associated with nausea and vomiting; 5-HT_3 = serotonin 5-hydroxytryptamine$_3$; MS = motion sickness; PONV = postoperative nausea and vomiting; RA = receptor antagonist; RadTx = radiation therapy–induced nausea and vomiting; V = vertigo.

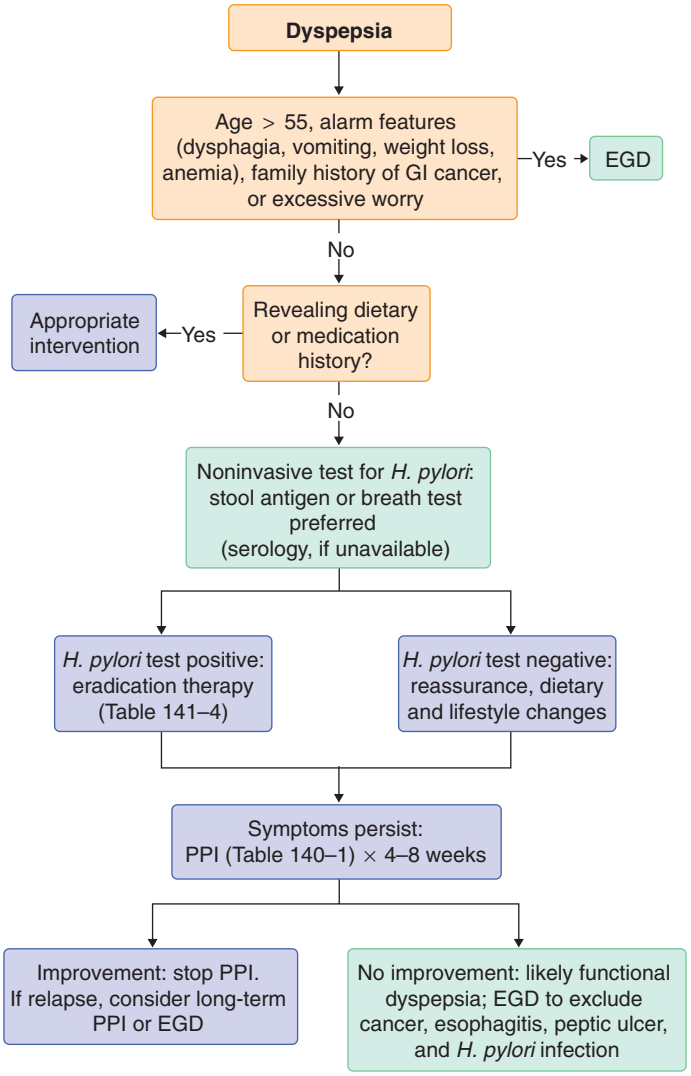

FIGURE 134-6. Approach to the patient with dyspepsia. EGD = esophagogastroduodenoscopy; GI = gastrointestinal; PPI = proton pump inhibitor.

is manifested by large-volume maroon or bright red bloody stools (hematochezia). Although 80 to 90% of patients with hematochezia have a lower source of bleeding, massive upper GI bleeding also may cause hematochezia. Approximately 95% of major lower GI bleeding arises from the colon and 5% from the small intestine. Lower GI bleeding is increased in patients older than 50 years, in whom diverticulosis accounts for 60% of cases; the remainder are due to ischemia, neoplasms, ulcers, vascular ectasias, or hemorrhoids. In patients younger than 50, bleeding is more commonly attributable to inflammatory bowel disease, hemorrhoids, or infectious colitis.

Occult GI bleeding refers to GI blood loss that is small in volume and not apparent to the patient but is detectable by tests for fecal occult blood. Chronic occult bleeding may result in iron deficiency anemia. Both upper endoscopy and colonoscopy should be performed to look for a source of occult bleeding, most commonly gastroesophageal or colonic neoplasia, erosive esophagitis or gastritis, ulcer disease, or vascular ectasia. In patients with recurrent iron deficiency and occult blood loss in whom no source is found on upper and lower endoscopy, video capsule endoscopy or enteroscopy is performed to look for a small bowel source (vascular ectasia, ulcer, or neoplasm).

Fecal incontinence (Chapter 147) is dependent on a number of factors, including a solid or semisolid stool, a compliant and distensible rectal reservoir, the ability to sense rectal fullness, an intact internal anal sphincter (an involuntary muscle innervated by the enteric nervous system), an intact external anal sphincter and puborectalis (voluntary muscles innervated by the pudendal nerve), and the mental and physical ability to reach a toilet facility when needed. Minor incontinence, which occurs in 10% of people older than 70 years, is characterized by the inability to control flatus or by the seepage of fecal matter that results in soiling of the perianal area and undergarments. It tends to be intermittent, occurring after bowel movements; when coughing, lifting, or passing flatus; or when stools are loose. Major incontinence is characterized by the partial or complete inability to reliably control bowel movements, resulting in gross, involuntary loss of feces and the need to wear a diaper. It occurs in less than 1% of the population and is virtually always caused by a central nervous system disorder that results in diminished awareness of bowel needs, neuropathy, or damage to the anal sphincters.

135 DIAGNOSTIC IMAGING PROCEDURES IN GASTROENTEROLOGY

DAVID H. KIM AND PERRY J. PICKHARDT

A wide range of diagnostic imaging modalities is available for evaluating diseases of the gastrointestinal (GI) tract and the hepatopancreaticobiliary system. Once the workhorse of GI radiology, conventional radiography and fluoroscopy are still relevant but have largely given way to more advanced cross-sectional imaging studies such as ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Many of the visceral vascular evaluations undertaken by conventional angiography have been replaced by these noninvasive modalities as well. These cross-sectional technologies have become the preferred methods of evaluation, allowing more precise and accurate diagnoses. In addition, cross-sectional techniques can be used to guide a wide variety of interventional procedures. With the emergence of molecular imaging, there has been renewed interest in nuclear medicine, most notably positron emission tomography (PET).

CONVENTIONAL RADIOGRAPHY

Conventional radiographs, often referred to as "plain films," remain useful for a limited number of abdominal indications but are generally much less sensitive and specific for pathology compared with techniques such as CT. Advantages of radiography include its wide availability, low cost, and portability, allowing the acquisition of images in acute clinical situations. Supine and upright frontal abdominal radiographs can assess rapidly for bowel obstruction or perforation in the setting of an acute abdomen (Fig. 135-1). Serial abdominal radiographs remain a practical approach for following patients with an abnormal bowel gas pattern suggestive of either evolving small bowel obstruction or adynamic ileus. Conventional radiographs can demonstrate abnormal abdominal calcifications and radiopaque foreign bodies. In each of these cases, however, cross-sectional modalities such as CT have increased sensitivity and provide better delineation of disease processes. CT is often undertaken when the initial plain film evaluation is negative or to provide better information when conventional radiography is positive.

FLUOROSCOPIC PROCEDURES

Standard double-contrast barium examinations that depict the mucosa, particularly of the stomach, duodenum, and colon, have largely been supplanted by endoscopy (Chapter 136) and advanced radiologic techniques. However, a variety of single-column fluoroscopic contrast studies remain quite useful because of their relatively noninvasive nature and their low cost. Real-time fluoroscopic contrast studies can provide a valuable physiologic evaluation, serve as a problem-solving tool when endoscopy is equivocal or contraindicated, and evaluate for suspected leaks, perforations, or fistulas. Depending on the specific indication, either barium or water-soluble iodinated contrast material may be used.

The videofluoroscopic swallowing study and barium esophagram are effective noninvasive means of excluding significant pathology in patients with dysphagia. Endoscopy is generally indicated when an esophageal stricture or mass is encountered on fluoroscopic examination, but it can be avoided in many cases that lack concerning findings. Fluoroscopic contrast evaluation may also avoid the need for endoscopy in symptomatic patients with suspected esophagitis from *Candida* or herpes infection. In the setting of gastroesophageal reflux disease, the barium esophagram is effective for excluding significant complications such as peptic stricture and adenocarcinoma, but it is insensitive to the changes of Barrett's esophagus (Chapter 140).

Although the double-contrast barium upper GI series can identify mucosal abnormalities of the stomach and duodenum, such as erosions, ulcers, polyps, and masses (Fig. 135-2), this function is now largely the domain of esophagogastroduodenoscopy (EGD). Gastroduodenal barium studies still play an important diagnostic role in evaluating for sliding hiatal and/or paraesophageal hernias and in pediatric evaluations for malrotation and hypertrophic pyloric stenosis.

For evaluation of the mesenteric small bowel, capsule endoscopy, CT enterography, and magnetic resonance (MR) enterography have largely replaced barium studies. Although fluoroscopic studies can still provide an anatomic roadmap, assess transit time, and detect fold thickening, the evaluation of unexplained GI bleeding (Chapter 137) or possible Crohn's disease (Chapter 143) is better performed using CT, MRI, or capsule endoscopy.

The single-contrast barium enema remains an important diagnostic tool in such settings as suspected sigmoid volvulus, colonic obstruction, postoperative leak or fistula, and ileocolic intussusception in children (Chapter 144). Many practices continue to perform fluoroscopic defecography to help delineate functional abnormalities in patients with evacuation disorders (Chapter 147), although dynamic MR cine series have replaced defecography at some institutions.

ULTRASONOGRAPHY

The introduction of harmonic and compound imaging, advances in high-resolution transducers, and improvements in color Doppler evaluation have all combined to enhance the diagnostic capabilities of portable ultrasound.

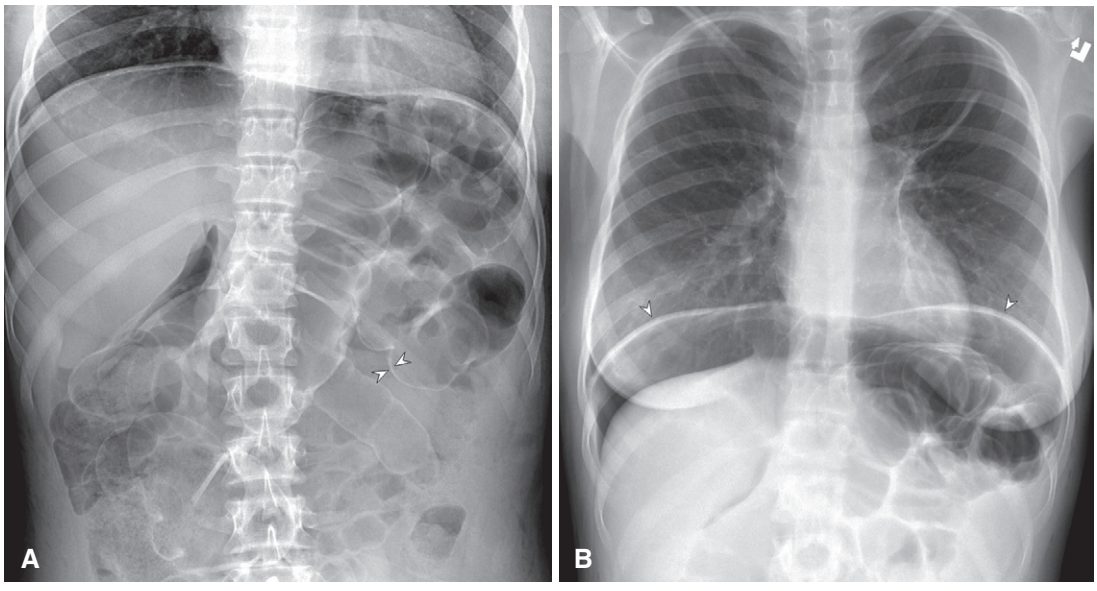

FIGURE 135-1. Pneumoperitoneum from bowel perforation on conventional radiographs. A, Supine abdominal radiograph shows abnormal lucency surrounding multiple bowel loops and the liver. Both sides of the bowel wall *(arrowheads)* are outlined by gas in areas (Rigler's sign), which typically requires a large amount of free peritoneal air to be visible on supine films. **B,** Upright radiograph centered over the diaphragm *(arrowheads)* shows the large amount of free intraperitoneal air (lucent area just inferior to the diaphragm) to better advantage. This view is more sensitive for the detection of pneumoperitoneum.

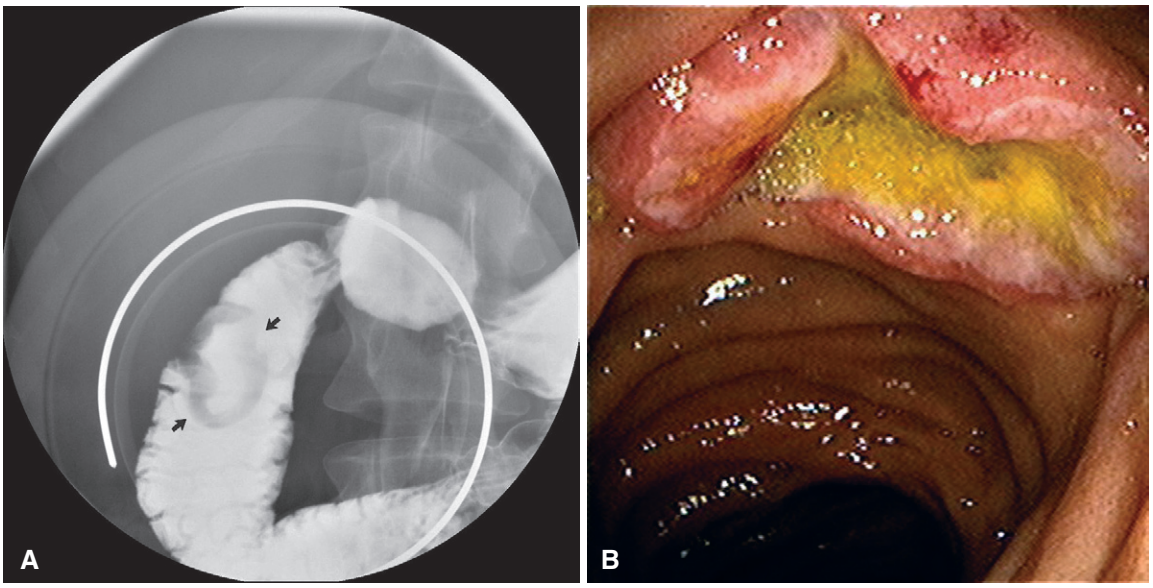

FIGURE 135-2. Metastatic melanoma on barium upper GI study. A, Fluoroscopic spot film image shows a filling defect *(arrows)* within the second portion of the duodenum that has a "bull's-eye" or "target" appearance due to the collection of barium in the center of the lesion. This appearance is characteristic of a submucosal mass with central ulceration and is typical of hematogenous metastatic disease from melanoma. **B,** Digital photograph from EGD confirms the presence of an ulcerated submucosal mass within the duodenum.

In general, ultrasound is useful for imaging solid organs and fluid-filled structures, but it is unable to penetrate gas-filled structures. For example, overlying bowel gas often precludes a complete sonographic evaluation of the pancreas. Ultrasound is a relatively versatile imaging technique, in that it can be performed via many different routes, including transabdominal, endoscopic (as part of EGD), transrectal, intravascular, and endovaginal approaches. In addition, it is excellent for many image-guided interventions because of its real-time evaluation.

With regard to GI pathology, ultrasonography is used most frequently to evaluate the liver and biliary system. Suspected acute cholecystitis (Chapter 158) is a common indication for right upper quadrant sonography; classic findings include cholelithiasis, gallbladder wall thickening, and a sonographic Murphy's sign (reproducible pain when the transducer is pressed over the gallbladder) (Fig. 135-3). The sensitivity for detecting gallstones with ultrasonography exceeds 95%. Acalculous cholelithiasis can be a more challenging diagnosis because the findings overlap with nonspecific gallbladder wall thickening in critically ill patients. Ultrasound is typically the first imaging test obtained in patients with new-onset jaundice or cholestatic laboratory findings because it offers a rapid, noninvasive evaluation of the biliary tree to differentiate obstruction from other causes. If biliary ductal dilation is present, the level and cause of the obstruction can sometimes be demonstrated on ultrasound; common causes include choledocholithiasis and pancreatic head masses. In most cases of biliary obstruction, additional imaging tests will be necessary, consisting of CT, MR cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), or percutaneous transhepatic cholangiography (PTC), depending on the specific circumstances.

Ultrasonography can be used to detect or further characterize focal liver lesions (Chapter 154), although it is typically less sensitive and specific than CT or MRI. Ultrasound is quite capable of distinguishing cystic from solid lesions. Although not approved for use in the United States, intravenous contrast agents for ultrasound have been studied fairly extensively in other countries and appear to offer similar advantages seen with CT and MRI contrast agents.

In diffuse disease, ultrasound is being used with increased frequency to screen patients with viral hepatitis for cirrhosis and hepatocellular carcinoma (Chapters 156 and 202). Sonographic findings in cirrhosis include a heterogeneously coarsened parenchymal echotexture, nodular surface contour, predominantly right-sided volume loss, and evidence of portal hypertension, including ascites, splenomegaly, and portosystemic collaterals. Focal hepatic lesions in the setting of cirrhosis are concerning for hepatocellular carcinoma, but they may also represent regenerative or dysplastic nodules. In noncirrhotic patients with elevated liver enzymes, ultrasonography can often suggest the diagnosis of hepatic steatosis (fatty liver; Chapter 155) when the parenchyma demonstrates increased echogenicity and decreased penetration of the sound beam. The findings of steatosis can be focal, multifocal, or diffuse; MRI is more specific and can confirm the diagnosis.

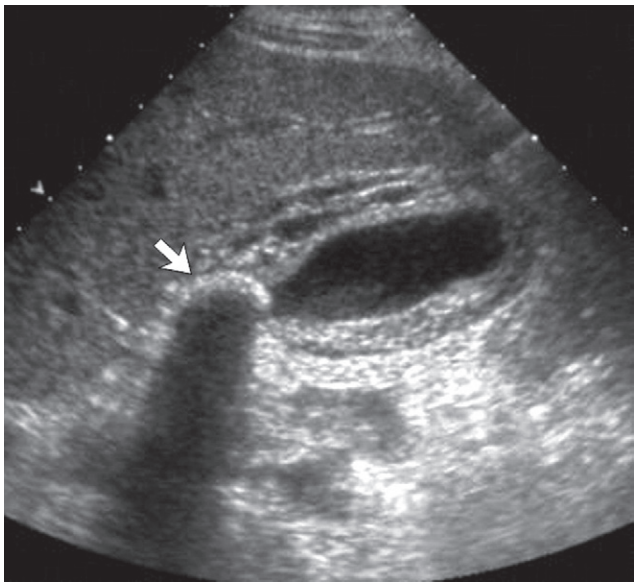

FIGURE 135-3. Acute cholecystitis on ultrasound. Image from right upper quadrant sonography shows diffuse gallbladder wall thickening and a shadowing impacted gallstone *(arrow)*. A sonographic Murphy's sign was present. These findings are diagnostic for acute calculous cholecystitis.

Color and power Doppler evaluation allows the noninvasive sonographic assessment of vascular patency. Doppler evaluation of the liver is commonly performed in patients with end-stage liver disease (Chapter 157) to evaluate the portal system and search for portosystemic collaterals. Abnormal portal vein findings include hepatofugal flow and thrombosis (Fig. 135-4). Doppler ultrasound is also used for the evaluation of transjugular intrahepatic portosystemic shunts (TIPS), both before and after stent placement. In orthotopic liver transplant recipients, Doppler evaluation is frequently performed to assess the hepatic vasculature, with particular attention to the hepatic arterial supply.

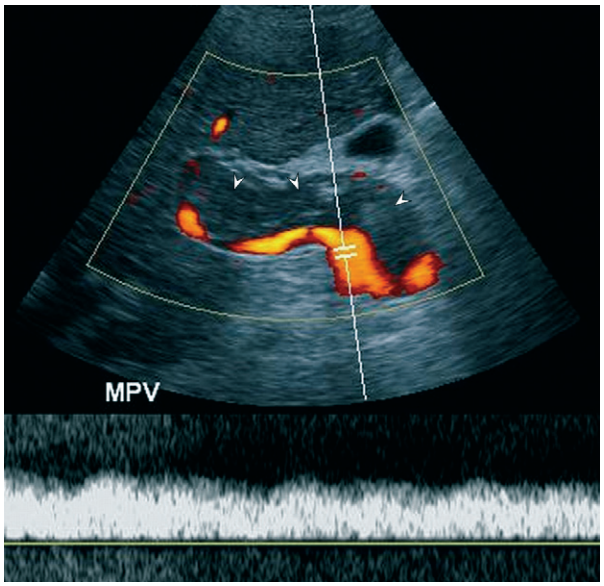

FIGURE 135-4. Portal vein thrombosis on ultrasound. Ultrasound gray-scale image with both power color Doppler and spectral Doppler interrogation shows a tubular hypoechoic structure *(arrowheads)* consistent with nonocclusive thrombus filling the majority of the main portal vein (MPV). Flow patency is seen in the deep peripheral aspect of the vessel.

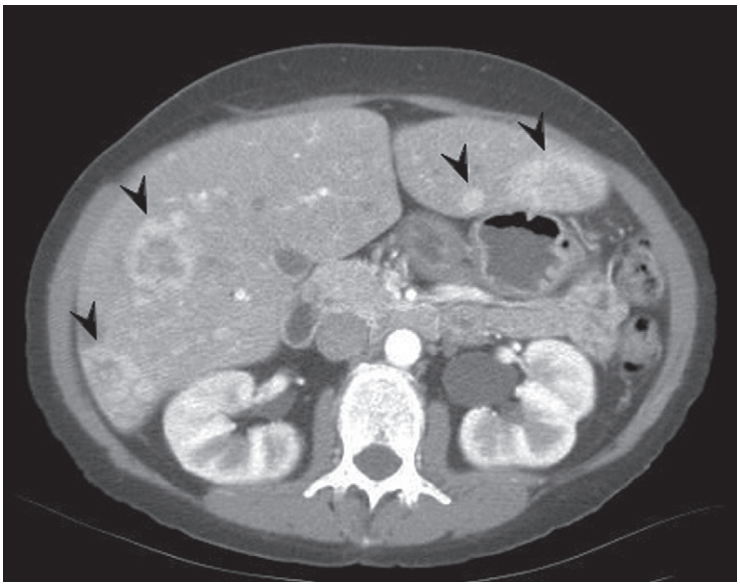

FIGURE 135-5. Multiple hypervascular liver lesions on CT. Dynamic contrast-enhanced CT image obtained during the arterial phase shows multiple hypervascular liver lesions *(arrowheads)*, which proved to be hepatic adenomas in a patient with von Gierke's disease.

COMPUTED TOMOGRAPHY

CT has revolutionized the imaging of abdominal pathology, providing a rapid, reproducible, and comprehensive evaluation. The introduction of single-detector helical or spiral CT, followed by multidetector scanners, has resulted in improved resolution and faster acquisition of true volumetric data. High-resolution scans of the entire abdomen and pelvis can now be easily acquired in a single short breath-hold. With the automated, high-rate injection of intravenous contrast materials and advanced processing, specialized CT examinations are replacing many traditional modalities. A major challenge, however, is to minimize radiation doses as CT use increases. The clinical indications for abdominal CT are very broad. One common use is the diagnostic evaluation of a nontraumatic acute abdomen (Chapter 144). Common inflammatory conditions such as appendicitis and diverticulitis are readily diagnosed by CT. Other common indications include evaluation for intra-abdominal abscess, pancreatitis, and small bowel obstruction. In cases of relatively high-grade bowel obstruction, CT can often localize the transition point, elucidate the underlying cause, and evaluate for vascular compromise. In the setting of an acute abdomen due to blunt trauma (Chapter 112), CT has become invaluable for the prompt detection of significant abdominal injury.

In the nonacute setting, multiphase CT with intravenous contrast can characterize lesions and often results in a noninvasive diagnosis, particularly in combination with the clinical history (Fig. 135-5). Primary abdominal malignancies, such as pancreatic cancer and hepatocellular carcinoma, are often first detected on CT. Abdominal staging for metastatic disease, including hematogenous, lymphatic, peritoneal, and local spread, is commonly performed with CT, as is assessing the response to various therapies.

CT is increasingly being used for primary bowel evaluation, often replacing traditional fluoroscopy because of its increased sensitivity and specificity. CT enterography protocols often combine neutral (i.e., water density) oral contrast with dynamic, high-resolution imaging that provides detailed multiplanar evaluation of the small bowel. Dedicated CT enterography and capsule endoscopy yield a complementary and comprehensive evaluation of the small bowel. CT colonography, also referred to as virtual colonoscopy, combines two- and three-dimensional evaluation of the prepared and distended colon for the detection of colorectal polyps and masses (Fig. 135-6). CT colonography is a promising tool for colorectal evaluation, particularly if it can improve adherence rates associated with screening. Optical colonoscopy is still required for polypectomy.

Visceral CT angiography is largely replacing conventional diagnostic angiography. For example, in many institutions, evaluation of the vascular anatomy before hepatic transplantation (Chapter 157) is now undertaken by CT rather than by catheter angiography (Fig. 135-7).

MAGNETIC RESONANCE IMAGING

The advantages of MRI over CT for abdominal evaluation include superior soft tissue contrast resolution and lack of ionizing radiation. However, for many institutions, MRI remains primarily a problem-solving tool for the abdomen because of several drawbacks, including decreased spatial resolution, longer examination times, increased expense, decreased availability, and inability to scan some patients owing to claustrophobia or implanted devices such as cardiac pacemakers. Imaging artifacts can also make MRI interpretation more difficult and less uniform across different readers.

Contrast-enhanced MRI offers a dynamic evaluation comparable to CT for the solid abdominal organs. In addition, intravenous gadolinium-based agents with hepatocyte-specific uptake increase MRI's diagnostic capabilities in evaluating focal hepatic lesions (Fig. 135-8). The high accuracy of MRI in diagnosing hepatic steatosis (Chapter 155) can sometimes prevent unnecessary biopsy, particularly in cases of nodular focal fatty infiltration that simulates metastatic disease. MRI is also sensitive for detecting iron overload within the liver and other organs related to primary hemochromatosis (Chapter 219) and secondary hemosiderosis (most often due to multiple transfusions). Similar to CT, MRI can provide quality arterial and venous angiographic imaging, such that conventional angiography is generally reserved for therapeutic interventions.

In the past, contrast MRI was considered an alternative to CT in patients with decreased renal function. However, the newly recognized condition of nephrogenic systemic fibrosis (Fig. 135-9) argues against this strategy. Nephrogenic systemic fibrosis, characterized by involvement of the skin, eyes, joints, and internal organs, is associated with intravenous gadolinium administration. Patients with impaired renal function are at risk of developing this rare but often fatal condition related to heavy metal toxicity from free gadolinium that has been dissociated from its chelate. Currently, there is no curative treatment.

Two specialized MR examinations have significantly changed practice patterns in recent years. MRCP, a heavily T2-weighted imaging technique for the noninvasive diagnostic evaluation of the biliary and pancreatic ductal systems, relies not on contrast administration but on the presence of static fluid. MRCP can be a useful screening tool to select appropriate candidates for more invasive therapeutic procedures such as ERCP and PTC. MRCP is useful for diagnosing biliary and pancreatic ductal obstruction, choledocholithiasis, primary sclerosing cholangitis, and cystic conditions such as Caroli's disease (Fig. 135-10). T1-weighted MR cholangiography with intravenous contrast agents that undergo biliary excretion can be useful in evaluating for bile leaks, analogous to hepatobiliary scintigraphy.

MR enterography is increasingly used to monitor patients with Crohn's disease (Chapter 143). Given the lack of ionizing radiation, it is particularly

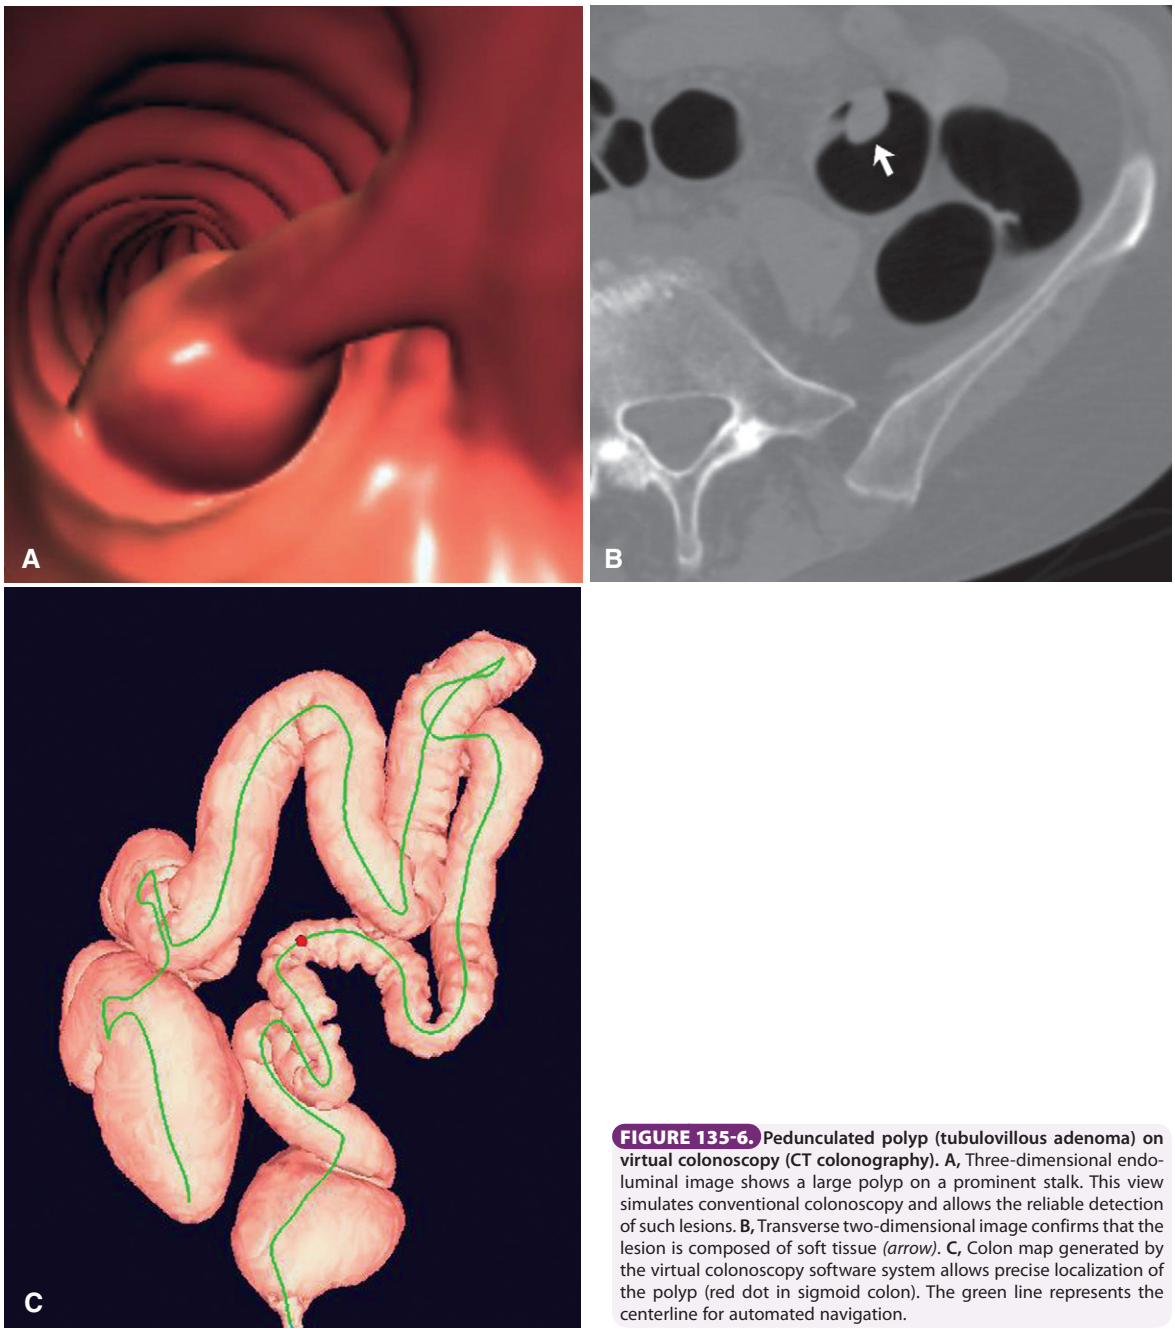

FIGURE 135-6. Pedunculated polyp (tubulovillous adenoma) on virtual colonoscopy (CT colonography). A, Three-dimensional endoluminal image shows a large polyp on a prominent stalk. This view simulates conventional colonoscopy and allows the reliable detection of such lesions. **B,** Transverse two-dimensional image confirms that the lesion is composed of soft tissue *(arrow)*. **C,** Colon map generated by the virtual colonoscopy software system allows precise localization of the polyp (red dot in sigmoid colon). The green line represents the centerline for automated navigation.

advantageous in young patients who require multiple examinations over a lifetime. Oral contrast agents such as polyethylene glycol are given to distend the small bowel; spasmolytics are typically administered to decrease bowel peristalsis. Similar to CT, fast breath-held imaging with intravenous contrast administration allows the evaluation of mucosal and wall enhancement or thickening, suggesting active disease. Unlike CT, MRI can assess intrinsic signal characteristics on T2-weighted images to improve specificity and distinguish active inflammation from chronic fibrostenotic disease (Fig. 135-11). Other emerging applications include MR staging for rectal cancer to assess the need for neoadjuvant chemoradiation.

INTERVENTIONAL PROCEDURES

Ultrasound, CT, fluoroscopy, and even MR techniques have been used for guidance when performing a wide variety of abdominal interventional procedures. Percutaneous image-guided biopsy, whether by fine-needle aspiration or core biopsy, is a relatively safe procedure that is commonly performed for tissue diagnosis and has drastically reduced the need for open surgical biopsy. Other common nonvascular procedures that use image guidance include abscess drainage, biliary interventions, gastrostomy, and tumor ablation. In the case of peridiverticular and periappendiceal abscesses, CT-guided drainage can often simplify the ultimate operative approach and turn high-risk emergent surgery into a safer elective procedure. Biliary interventions include transhepatic access of an obstructed system for stenting or external drainage, as well as cholecystostomy tube placement. Percutaneous CT- or ultrasound-guided tumor ablation is a rapidly evolving technique that is particularly useful in poor operative candidates or in conjunction with surgical resection of other lesions. A variety of ablation methods have been employed, including radio frequency, alcohol, microwave, and cryoablation.

Diagnostic conventional angiography has been largely replaced by noninvasive CT and MR techniques, but direct catheter angiography remains an important procedure for directing various therapies. Vascular interventions include angioplasty, stenting, embolization, and thrombolysis. TIPS placement (Chapter 157) is a commonly performed angiographic procedure in patients with portal hypertension complicated by variceal bleeding or intractable ascites. Placement of a TIPS stent creates a low-pressure communication between the portal and hepatic venous systems. Chemoembolization can provide palliation for those with advanced hepatic malignancy, whether primary or metastatic.

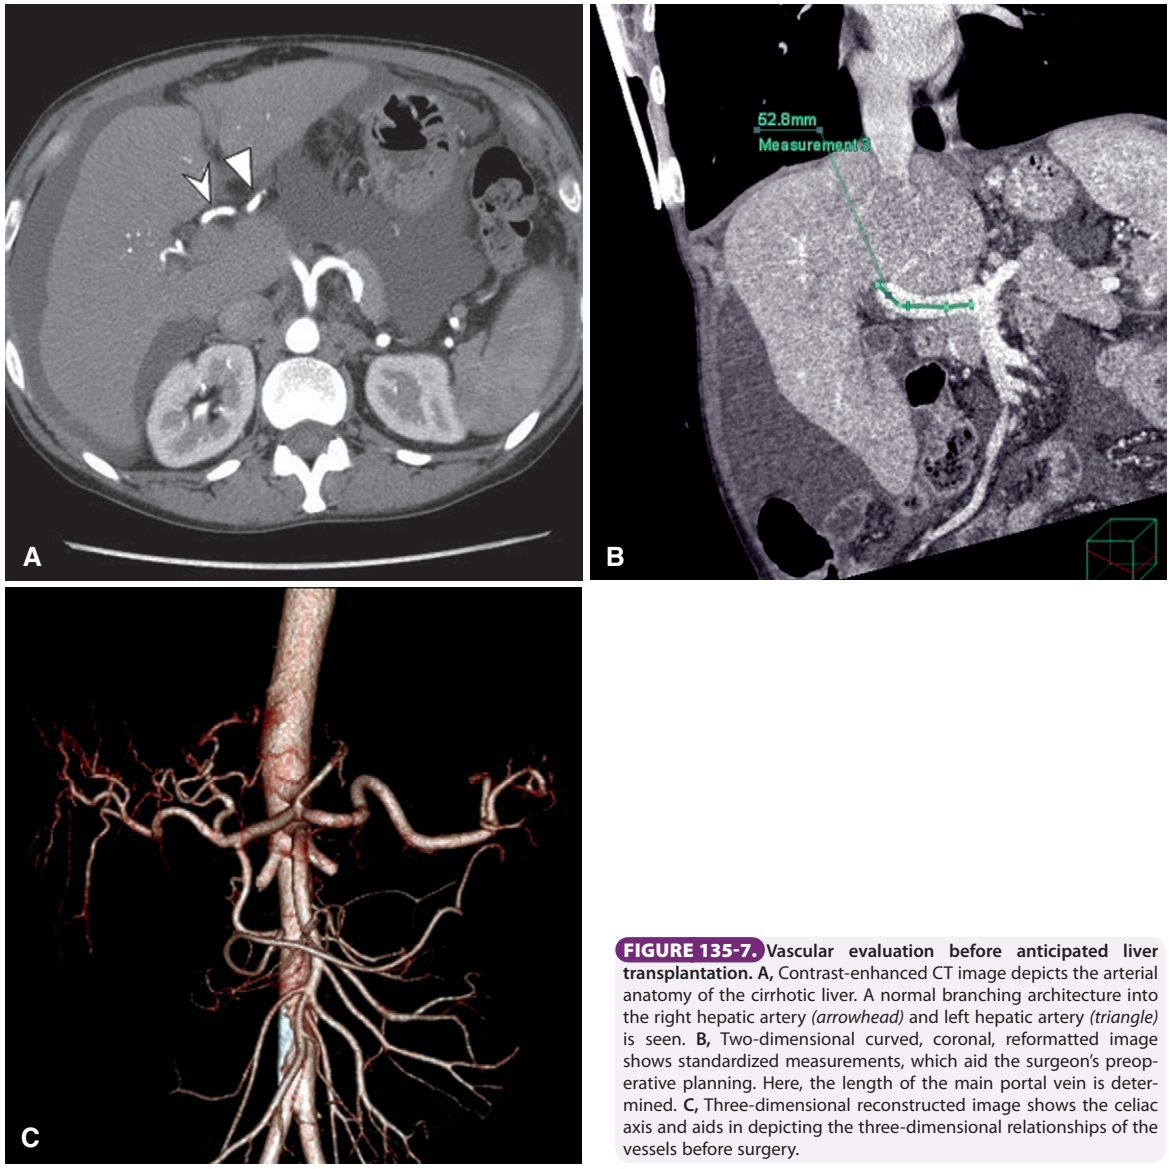

FIGURE 135-7. Vascular evaluation before anticipated liver transplantation. A, Contrast-enhanced CT image depicts the arterial anatomy of the cirrhotic liver. A normal branching architecture into the right hepatic artery *(arrowhead)* and left hepatic artery *(triangle)* is seen. **B,** Two-dimensional curved, coronal, reformatted image shows standardized measurements, which aid the surgeon's preoperative planning. Here, the length of the main portal vein is determined. **C,** Three-dimensional reconstructed image shows the celiac axis and aids in depicting the three-dimensional relationships of the vessels before surgery.

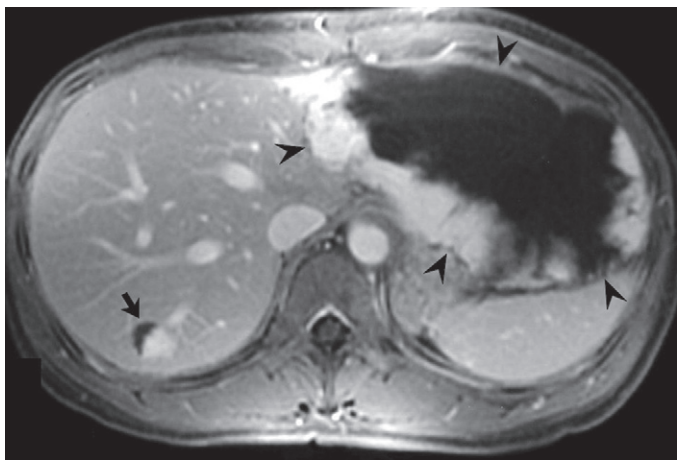

FIGURE 135-8. Hepatic cavernous hemangiomas on MRI. Contrast-enhanced fat-suppressed gradient echo MRI shows the characteristic findings of cavernous hemangiomas, including a giant left hepatic lobe lesion *(arrowheads)* and a smaller right hepatic lobe lesion *(arrow)*. Note the peripheral enhancement of the lesions, which matches the signal intensity of the aortic blood pool. These findings are diagnostic, and tissue biopsy is unnecessary.

NUCLEAR MEDICINE (RADIONUCLIDE SCINTIGRAPHY)

Owing to the emergence of PET-CT for oncologic evaluation, nuclear medicine is more relevant now than ever before in abdominal imaging. PET-CT is a powerful diagnostic tool that combines functional and anatomic imaging. PET is useful for both initial staging and evaluating the response to therapy for a wide range of primary malignant tumors, especially when combined with CT (Fig. 135-12). Currently, clinical PET imaging most often utilizes F^{18}-fluorodeoxyglucose, but other positron-emitting agents may be used for specific purposes.

Several other nuclear medicine studies are used to evaluate GI and hepatobiliary diseases. Injection of red blood cells labeled with technetium-99m provides a useful test for GI bleeding. Advantages of performing this as the initial diagnostic imaging study include its noninvasive nature, high sensitivity for active bleeding, and ability to rescan the patient hours later without the need for repeat injection. Disadvantages include relatively poor anatomic localization and lack of therapeutic ability. The use of tagged red blood cell scintigraphy for the diagnosis of hepatic cavernous hemangioma has decreased significantly owing to advances in CT and MRI. Hepatobiliary scintigraphy remains a useful tool in equivocal cases of cholecystitis, particularly acalculous disease, and it can confirm suspected biliary leaks. Scintigraphic imaging with In^{111}-octreotide is valuable for the diagnosis, staging,

FIGURE 135-9. Nephrogenic systemic fibrosis (NSF). Digital photograph of the upper extremities in a patient with NSF shows vague fibrotic plaques that are difficult to visualize but easily palpated. In the skin, NSF presents as bilateral, symmetrical, and variably erythematous fibrotic plaques beginning distally and progressing proximally, often with a reticulated advancing edge. (Courtesy of Dr. Molly A. Hinshaw.)

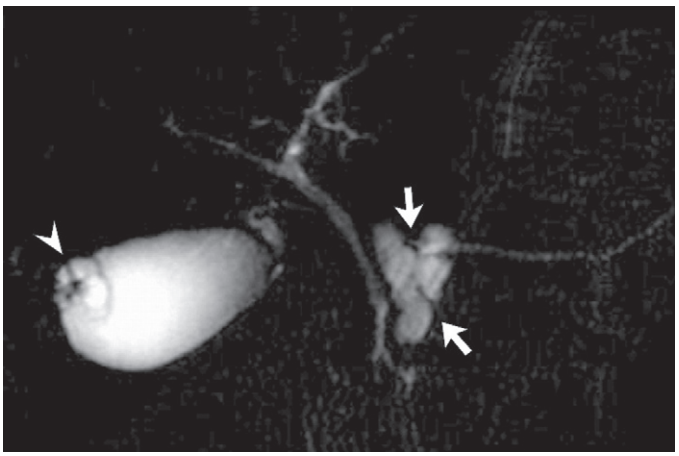

FIGURE 135-10. Pancreatic intraductal papillary mucinous neoplasm on MRCP. Heavily T2-weighted MR image shows a lobulated cystic lesion in the pancreatic head region *(arrows)* that represents a side branch intraductal papillary mucinous neoplasm. Note the mild focal irregularity of the gallbladder *(arrowhead)*, consistent with the fundal form of adenomyomatosis. The intra- and extrahepatic biliary ducts are normal.

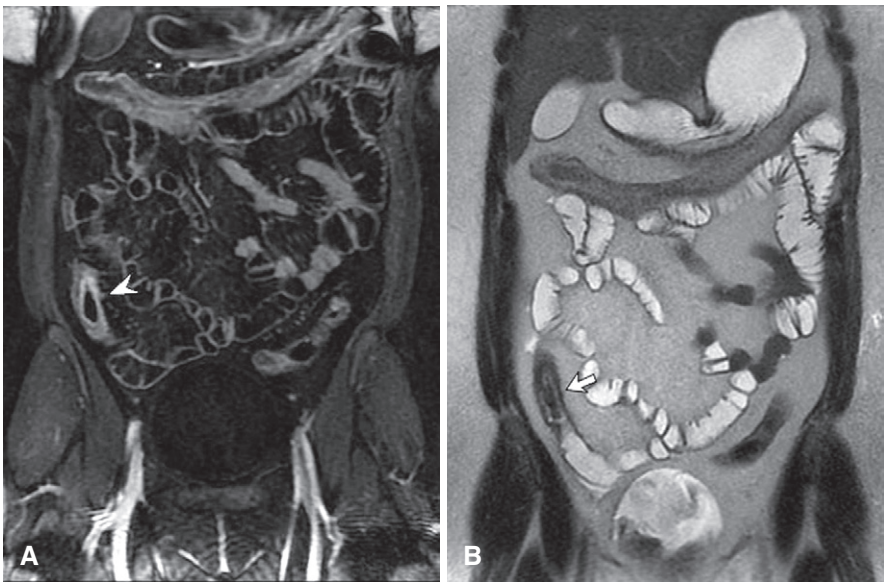

FIGURE 135-11. Active Crohn's disease on MR enterography. **A,** Coronal three-dimensional volume-acquired breath-hold, T1-weighted, gradient-echo image with dynamic gadolinium administration and fat saturation shows wall thickening and enhancement *(arrowhead)* of an abnormal segment of terminal ileum. **B,** Coronal two-dimensional single-shot, fast spin-echo, T2-weighted image shows increased signal in this area *(arrow)*, signifying edema and active disease.

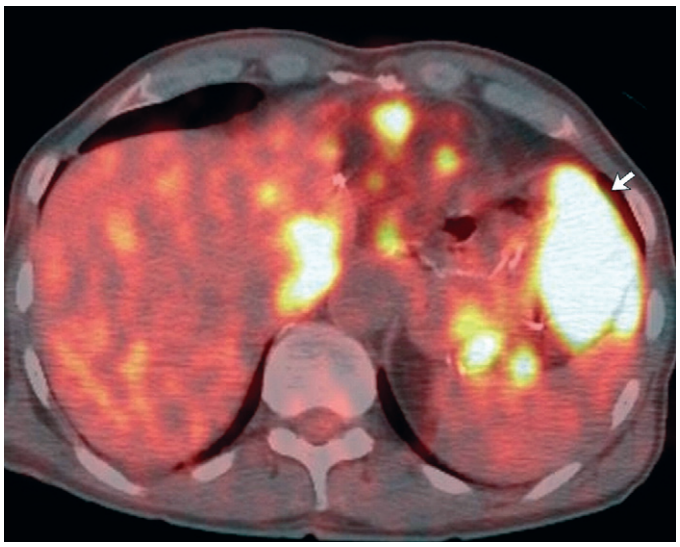

FIGURE 135-12. Metastatic gastrointestinal stromal tumor (GIST) on fused PET-CT. Transverse fused PET-CT image shows a dominant hypermetabolic mass *(arrow)* representing a gastric GIST. Multiple smaller peritoneal and hepatic hypermetabolic foci are consistent with metastatic deposits. Note the utility of combining the functional information from PET with the anatomic localization provided by CT.

and follow-up of GI neuroendocrine tumors, such as carcinoid and pancreatic islet cell tumors.

136 GASTROINTESTINAL ENDOSCOPY

PANKAJ JAY PASRICHA

IMPORTANCE AND USE OF ENDOSCOPY

Technologic advances in radiologic and endoscopic imaging have transformed medicine in the past few decades. With its remarkable accessibility, the gastrointestinal tract has benefited from the endoscopic approach perhaps more than any other organ system. The major advantages of endoscopy over contrast radiography in evaluating diseases of the alimentary tract include direct visualization, resulting in a more accurate and sensitive evaluation of mucosal lesions; the ability to obtain biopsy specimens from superficial lesions; and the ability to perform therapeutic interventions. These advantages make endoscopy the procedure of choice in most cases in which mucosal lesions or growths are suspected. Conversely, computed tomography (CT) or, occasionally, contrast radiography may be indicated when extrinsic or intrinsic distortions of anatomy are suspected, such as volvulus, intussusceptions, subtle strictures, or complicated postsurgical changes (Chapter 135).

INSTRUMENTS AND PROCEDURES (TABLE 136-1)

Luminal Endoscopy: Conventional and Wireless

The vast majority of endoscopic procedures are intraluminal in nature. The endoscopic shaft not only carries the optical elements for imaging but also contains channels that enable various functions such as air insufflation, water irrigation, suction, and passage of diagnostic and therapeutic devices.

A relatively recent innovation is capsule endoscopy, with a disposable plastic capsule that measures 11 mm by 26 mm and contains a chip camera, batteries, and a radio transmitter that wirelessly sends images to a device that the patient wears as a belt. At the end of the procedure, the information is downloaded to a computer, and the capsule itself passes harmlessly in the stool. Variations of this instrument have been developed for esophageal and colonic imaging, but these are not yet recommended for routine clinical use.

Ancillary Organ Imaging: Endoscopic Retrograde Cholangiography and Pancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) uses a side-viewing endoscope that accesses the second part of the duodenum, where a small catheter is introduced into the bile or pancreatic duct to inject radiographic contrast medium under fluoroscopic monitoring. Successful cannulation and imaging can be achieved in up to 95% of cases. In some instances, a fine-caliber endoscope can also be introduced into the duct of interest (cholangioscopy or pancreaticoscopy) for direct visualization of intraductal disease.

Mural and Transmural Imaging: Endoscopic Ultrasound

An ultrasonic transducer in the tip of a flexible endoscope or a stand-alone ultrasound probe inserted through the channel of a regular endoscope can image lesions within the wall of the gut and beyond. Endoscopic ultrasonography (EUS) can guide fine-needle aspiration more accurately than abdominal ultrasonography or CT.

COMPLICATIONS AND PRE-ENDOSCOPY PREPARATION

Diagnostic endoscopy is usually a remarkably safe and well-tolerated procedure. It can be performed under conscious sedation with a combination of benzodiazepines and narcotics or with propofol, which provides faster and deeper sedation with rapid recovery (Chapter 440). However, potential complications (Table 136-2) must be carefully explained to the patient as part of the informed consent process. In general, routine blood tests, radiographs, or electrocardiograms are not necessary before endoscopy unless a careful history and physical examination suggest possible hematologic, cardiovascular, or pulmonary or airway problems. Women of childbearing age should be questioned about the possibility of pregnancy and tested if there is any doubt.

Diagnostic endoscopies, including those with mucosal biopsies, are considered low risk and do not warrant discontinuation of anticoagulant medication. Similarly, aspirin or other nonsteroidal anti-inflammatory agents can be continued by patients undergoing screening colonoscopy. In high-risk elective procedures, anticoagulants and antiplatelet agents may be discontinued,

TABLE 136-1 ENDOSCOPIC PROCEDURES AND GENERAL APPLICATIONS

ENDOSCOPIC PROCEDURES	THERAPEUTIC APPLICATIONS
LUMINAL ENDOSCOPY	
Common procedures Esophagogastroduodenoscopy Colonoscopy Flexible sigmoidoscopy	Hemostasis Luminal restoration (dilation, ablation, stenting) Lesion removal (e.g., polypectomy, mucosal ablation) Provision of access (percutaneous endoscopic gastrostomy and jejunostomy)
Less common procedures Enteroscopy Capsule endoscopy	Barrier strengthening (antireflux procedures)
PANCREATOBILIARY IMAGING	
Endoscopic retrograde cholangiopancreatography	Lesion (stone) removal Luminal restoration (dilation, stenting) Provision of access (sphincterotomy) Drainage (bile, pancreatic pseudocyst)
TRANSLUMINAL IMAGING	
Endoscopic ultrasonography	Analgesic block Delivery of therapeutic agents (experimental)

TABLE 136-2 COMPLICATIONS OF ENDOSCOPY

ENDOSCOPIC COMPLICATIONS	INCIDENCE (%)	SPECIFIC PROPHYLAXIS
GENERAL COMPLICATIONS		
Complications related primarily to sedation (cardiovascular and respiratory depression, aspiration)	0.6-0.7	Airway protection with massive upper gastrointestinal bleeding Preprocedure medical evaluation, intraprocedure and postprocedure monitoring Anesthesiology consultation for high-risk patients
Perforation	0.14-0.25 (colonoscopy) 0.1-0.3 (upper endoscopy)	None (except careful technique)
Bleeding	0.7-2.5 (polypectomy) 0.3 (upper endoscopy)	Carefully balance risk and benefits Discontinue or reduce anticoagulant use before high-risk procedures
Bacteremia and infectious complications (endocarditis, bacterial ascites)	<0.1	Antibiotics for patients at risk for endocarditis (patients with artificial valves, pulmonary-systemic shunts, previous history of endocarditis), with synthetic vascular grafts, and with bacterial ascites (cirrhotics)
Death	0.2 (colonoscopy) 0.6 (upper endoscopy)	
COMPLICATIONS ASSOCIATED WITH SPECIALIZED PROCEDURES		
Pancreatitis (ERCP)	3-20	Not well established; experimental
Cholangitis (ERCP)	0.1-2	Preprocedure antibiotics
Wound infections (PEG)	3-4	Preprocedure antibiotics

ERCP = endoscopic retrograde cholangiopancreatography; PEG = percutaneous endoscopic gastrostomy.

in consultation with both the prescribing specialist and the gastroenterologist (Chapter 439). For patients with acute bleeding, reversal therapy or platelet replacement may be considered (Chapters 174 through 178).

ERCP is associated with the highest risk of serious complications, and about 1 to 5% of patients develop pancreatitis. Risk factors include young age, female gender, underlying sphincter of Oddi dysfunction, and previous history of pancreatitis. Despite a variety of trials, no pharmacologic prophylaxis has been unequivocally successful. However, most experts place a short-term pancreatic stent in high-risk cases as a reasonable preventive measure.

SPECIFIC INDICATIONS

Most indications for gastrointestinal endoscopy are based on the patient's presenting symptoms (e.g., dysphagia, bleeding, diarrhea). In other instances, endoscopy is required to evaluate specific lesions found by other diagnostic imaging, such as a gastric ulcer or colon polyp discovered by barium radiography. Finally, screening endoscopy is often performed in asymptomatic individuals on the basis of their risk for commonly occurring and preventable conditions, such as colon cancer (see later).

Implicit in the decision to perform endoscopy is the assumption that it will have a bearing on future management strategy. When evaluating gastrointestinal symptoms, several questions need to be addressed by the referring physician and the endoscopist: Which patients need endoscopy? When should the endoscopy be done? What is the endoscopist looking for? What endoscopic therapy, if any, should be planned?

Gastroesophageal Reflux and Heartburn (Chapters 140 and 141)

Gastroesophageal reflux disease (GERD) is an extremely common condition in the general population. The fact that its cardinal symptom, heartburn, is relatively specific for this condition justifies an empirical approach to treatment by a combination of lifestyle modifications and over-the-counter or even prescription drugs. Endoscopy is therefore not necessary to make the diagnosis of GERD. Indeed, normal findings on endoscopy do not rule out the diagnosis because the overall sensitivity of endoscopy in GERD is only about 70%. If necessary, further evaluation with ambulatory esophageal manometry and pH monitoring can establish the diagnosis. However, there are several circumstances in which endoscopy should be considered for patients with reflux, including those with warning symptoms ("red flags") such as dysphagia, odynophagia, regurgitation, weight loss, gastrointestinal bleeding, or frequent vomiting (Fig. 136-1). These symptoms imply either the development of a GERD-related complication (erosive esophagitis, stricture, or adenocarcinoma) or another disorder masquerading as GERD (esophageal cancer or a gastric-duodenal lesion such as cancer or peptic ulcer). Other candidates for endoscopy are those with severe, persistent, or frequently recurrent symptoms that suggest significant esophagitis and hence a risk for complications, such as stricture or Barrett's esophagus, which is intestinal metaplasia of the esophageal epithelium.

If a significant length of Barrett's esophagus (especially >3 cm) is discovered (see Fig. 136-1), most experts recommend some form of periodic surveillance endoscopy because of the increased risk for the development of adenocarcinoma. Control of reflux by either pharmacologic or surgical means does not generally lead to regression of established Barrett's esophagus (Chapter 140). Furthermore, endoscopic techniques to reduce reflux have not resulted in long-term benefits, despite promising initial results.

For patients in whom high-grade dysplasia associated with Barrett's esophagus poses a serious risk for cancer, endoscopic ablation or resection provides a potentially curative alternative to surgical esophagectomy. Ablation can be achieved by a variety of modalities, including radio frequency, cryotherapy, electrical cautery, argon plasma coagulation, and photodynamic therapy. An alternative to ablation is endoscopic mucosal resection, which is en bloc resection of the mucosa to allow complete pathologic analysis and minimize the risk for regrowth of the abnormal mucosal lining.

Heartburn in immunocompromised patients often indicates an esophageal infection. The most common causes in patients with human immunodeficiency virus (HIV) infection are *Candida albicans,* cytomegalovirus, herpesvirus, and idiopathic esophageal ulcers. Because most patients with acquired immunodeficiency syndrome (AIDS) and esophagitis have candidiasis, an empirical 1- to 2-week course of antifungal therapy may be justified. Patients who do not respond to this approach should almost always have endoscopy and biopsy so that more specific therapy can be instituted.

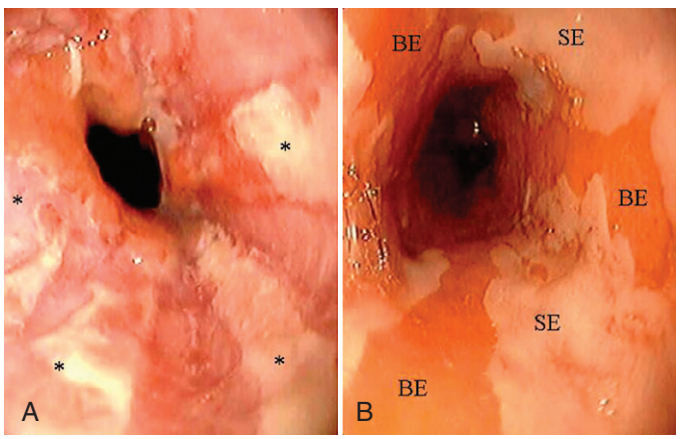

FIGURE 136-1. Severe reflux esophagitis. A, Mucosal erythema and linear ulcers with yellow exudates (asterisks). **B,** It is thought that such changes eventually lead to Barrett's esophagus, in which the normal white squamous epithelium *(SE)* is replaced by red columnar epithelium *(BE)*. These examples are from different patients.

Dysphagia (Chapter 140)

Dysphagia can often be categorized as oropharyngeal on the basis of the clinical features of nasal regurgitation, laryngeal aspiration, or difficulty moving the bolus out of the mouth. These symptoms are usually associated with a lesion in the central or peripheral nervous system. Although endoscopy is often performed in these patients, videofluoroesophagography (modified barium swallow or cine-esophagogram) is the procedure of choice because it allows a frame-by-frame evaluation of the rapid sequence of events involved in transfer of the bolus from the mouth to the esophagus. Common causes of esophageal dysphagia include malignant as well as benign processes (peptic strictures secondary to reflux, Schatzki's rings) and motility disturbances of the esophageal body or the lower esophageal sphincter. Endoscopic examination is considered mandatory in all patients with esophageal dysphagia. However, contrast esophagography may also be helpful; it can provide guidance in cases in which endoscopy is anticipated to be difficult (e.g., a patient with a complex stricture), suggest a disturbance in motility, and occasionally detect subtle stenoses that are not appreciated on endoscopy (the scope diameter is typically ≤10 mm, whereas some symptomatic strictures can be considerably wider).

Endoscopic treatment options are available for many causes of esophageal dysphagia. Tumors may be dilated mechanically, ablated by thermal means (cautery or laser), or stented with prosthetic devices. Metallic expandable stents have become the palliative procedure of choice for most patients with symptomatic esophageal cancer. Benign lesions of the esophagus, such as strictures or rings, can also be dilated endoscopically, usually with excellent results. Finally, some motility disturbances, such as achalasia, are best approached endoscopically with the use of large balloon dilators for the lower esophageal sphincter or the local injection of botulinum toxin.

Dyspepsia (Chapter 139)

Dyspepsia, which is chronic or recurring pain or discomfort centered in the upper abdomen, is a common condition that can be caused by a variety of disorders, including peptic ulcer, reflux esophagitis, gallstones, gastric dysmotility, and, rarely, gastric or esophageal cancer. However, up to 60% of patients with chronic (>3 months) dyspepsia have a so-called functional disorder in which there is no definite structural or biochemical explanation for the symptoms. Although *Helicobacter pylori* gastritis is found frequently in these patients, there is no evidence of a cause-and-effect relationship between these two findings. If a diagnostic test is to be performed, endoscopy, sometimes with biopsies to detect *H. pylori,* is clearly the procedure of choice (see Fig. 141-2 in Chapter 141); it has an accuracy of about 90%, compared with about 65% for double-contrast radiography. Because dyspepsia is a recurrent condition and patients who do not respond to empirical therapy almost always undergo endoscopy, many gastroenterologists opt for early endoscopy, if only for the reassurance that a normal examination provides.

Upper Gastrointestinal Bleeding (Chapter 137)

Acid peptic disease (including ulcers, erosions, and gastritis), variceal bleeding, and Mallory-Weiss tears account for most cases of upper gastrointestinal bleeding. Other less common but important lesions are angioma, gastric vascular ectasia ("watermelon" stomach), and the rarer Dieulafoy's lesion (a

superficial artery that erodes through the gut mucosa). Finally, upper gastrointestinal cancers are occasionally associated with significant bleeding. Endoscopy is mandatory in all patients with upper gastrointestinal bleeding, with the rare exception being a terminally ill patient in whom the outcome is unlikely to be affected. Endoscopy can detect and localize the site of bleeding in 95% of cases and is clearly superior to contrast radiography (with an accuracy of only 75 to 80%). The endoscopic appearance of bleeding lesions can also help predict the risk of rebleeding, thus facilitating the triage and treatment process. Bleeding can be effectively controlled during the initial endoscopic examination itself in the majority of cases. The risk of recurrent bleeding is diminished, resulting in a shorter hospital stay as well as a reduction in the need for surgery.

In general, endoscopy should be performed only after adequate stabilization of hemodynamic and respiratory parameters. The role of gastric lavage before endoscopy is controversial; some endoscopists prefer that it be done, occasionally even with a large-bore tube, whereas others avoid such preparation for fear of producing artifact. The timing of subsequent endoscopy depends on two factors: the severity of the hemorrhage, and the risk status of the patient. Patients with active, persistent, or severe bleeding (>3 units of blood) require urgent endoscopy. In these patients, endoscopy is best performed in the intensive care unit because of the risk for aspiration and the occasional need for emergent intubation to provide respiratory protection and ventilation. Patients with slower or inactive bleeding can be evaluated by endoscopy in a "semielective" manner (usually within 12 to 20 hours), but a case can be made for early endoscopy even in these stable patients (perhaps in the emergency department itself) to allow more confident triage and more efficient resource management.

Most bleeding from upper gastrointestinal lesions can be effectively controlled endoscopically. The endoscopist considers factors such as age (older patients have a higher risk of rebleeding), severity of the initial hemorrhage (which has a direct correlation to the risk of rebleeding), and appearance of the lesion in determining the need for endoscopic therapy. Nonvariceal bleeding vessels can be treated by a variety of means, including injections of various substances (epinephrine, saline, sclerosants), thermal coagulation (laser or electrocautery), and mechanical means (clipping). In the United States, the most popular approach to a bleeding peptic ulcer lesion is a combination of injection with dilute epinephrine and electrocoagulation. Initial hemostasis can be achieved in 90% or more of cases; rebleeding, which may occur in up to 20% of cases, responds about half the time to a second endoscopic procedure. Patients who continue to bleed (typically those with large ulcers in the posterior wall of the duodenal bulb) are usually managed angiographically (with embolization of the bleeding vessel) or surgically.

Variceal bleeding can also be effectively managed endoscopically, with a success rate similar to that for bleeding ulcers (Fig. 136-2) (Chapter 156). Hemostasis is achieved by band ligation (Fig. 136-3), sclerotherapy, or a combination of both. Increasingly, patients who do not respond to endoscopic treatment are considered candidates for a transjugular intrahepatic portosystemic shunt (TIPS); traditional shunt surgery for bleeding varices is rarely performed. Even if initial endoscopic hemostasis is successful, long-term prevention of rebleeding requires a program of ongoing endoscopic sessions until variceal obliteration is complete. Ligation is the preferred approach in this setting because it is associated with fewer side effects. In patients whose large esophageal varices have never bled, β-blockers are considered first-line treatment, but endoscopic band ligation may be useful in selected patients.

Acute Lower Gastrointestinal Bleeding (Chapter 137)

The most common cause of acute lower gastrointestinal bleeding is angiodysplasia, followed by diverticulosis, neoplasm, and colitis. In about 10% of patients presenting with hematochezia, a small bowel lesion may be responsible. In contrast to upper gastrointestinal bleeding, there is no single best test for acute lower gastrointestinal bleeding. In patients younger than 40 years with minor bleeding, findings that are highly suggestive of anorectal origin (e.g., blood on the surface of the stool or on the wipe) may warrant only flexible sigmoidoscopy. Conversely, patients presenting with hemodynamic compromise may need upper endoscopy first to exclude a lesion in the upper gastrointestinal tract (typically postpyloric) that is bleeding so briskly it presents as hematochezia. Colonoscopy was traditionally recommended after bleeding slowed or stopped and the patient had been given an adequate bowel purge. However, a disadvantage of delaying endoscopy is that when a

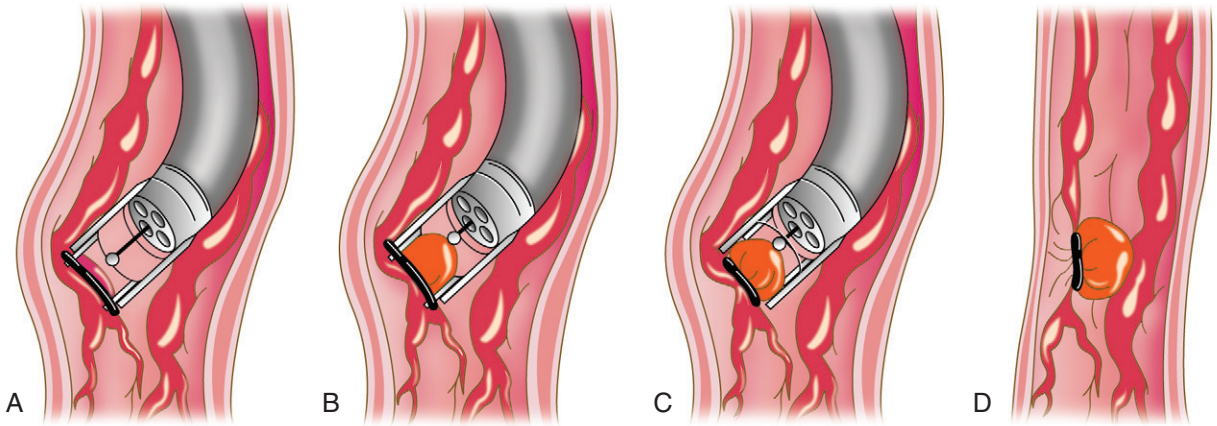

FIGURE 136-3. Endoscopic variceal ligation technique. A, The endoscope, with an attached ligating device, is brought into contact with a varix just above the gastroesophageal junction. **B,** Suction is applied, drawing the varix-containing mucosa into the dead space created at the end of the endoscope by the ligating device. **C,** The trip wire is pulled, releasing the band around the aspirated tissue. **D,** Completed ligation.

FIGURE 136-4. Mucosal telangiectasia (arteriovenous malformation) in the colon. The patient presented with hematochezia. The lesion was subsequently cauterized endoscopically.

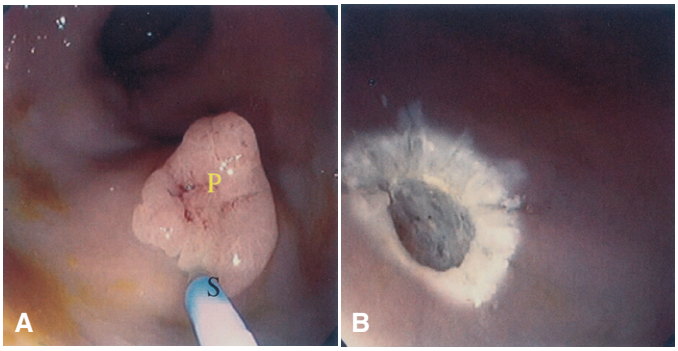

FIGURE 136-5. Endoscopic polypectomy. A, A snare *(S)* has been passed through the endoscope and positioned around the polyp *(P)*. **B,** Cautery was applied, and the polyp was guillotined, leaving behind a clean mucosal defect.

pathologic lesion such as an arteriovenous malformation (Fig. 136-4) or diverticulum is found, it may be impossible to implicate it confidently as the site of bleeding (complementary information by radiography or scintigraphy becomes particularly important in this situation). Some experts therefore recommend urgent diagnostic endoscopy with little or no preparation for acute lower gastrointestinal hemorrhages and have reported significant diagnostic as well as therapeutic success rates. However, such recommendations have not been universally accepted and remain logistically difficult to implement in most hospital settings.

It is not uncommon for gastrointestinal bleeding to develop or to be discovered in hospitalized patients who have had a recent myocardial infarction. In many cases, the bleeding is of a microscopic nature, and endoscopic evaluation can be deferred until the patient has fully recovered from the cardiac event. In other cases, however, the bleeding is more significant, and its risks outweigh the potential adverse effects of endoscopic intervention. In patients with recent myocardial infarction, upper endoscopy and colonoscopy are associated with a higher risk of cardiovascular complications, but they are usually transient and minor.

Occult Gastrointestinal Bleeding or Iron Deficiency Anemia (Chapter 137)

Normal fecal blood loss is usually less than 2 to 3 mL/day. Most standard fecal occult blood tests detect only blood loss of 10 mL/day or more. Therefore, even if this test result is negative, patients with iron deficiency anemia and no other obvious source of blood loss should always undergo aggressive gastrointestinal evaluation, which uncovers a gastrointestinal lesion in the majority of cases. Although most lesions that cause overt gastrointestinal bleeding can also cause occult blood loss, occult bleeding should almost never be ascribed to diverticulosis or hemorrhoids. Endoscopy is always preferable to radiographic studies for the evaluation of occult blood loss or iron deficiency anemia because of its ability to detect flat lesions, particularly vascular malformations, which may be found in 6% or more of patients. If the findings on both upper and lower endoscopy are normal, the next test is capsule endoscopy, which may be helpful to detect small bowel lesions such as erosions, tumors, or angiomas. Although it is relatively contraindicated in patients with suspected narrowing or strictures of the small bowel, capsule endoscopy has become the diagnostic procedure of choice in patients with obscure gastrointestinal bleeding (with normal findings on upper and lower endoscopies) and when mucosal lesions of the small bowel are suspected. Findings on capsule endoscopy may prompt the consideration of enteroscopy (using specialized double- or single-balloon endoscopes), which can theoretically access the entire small bowel and permit biopsy and/or therapy of suspected lesions.

Colorectal Neoplasms (Chapter 199)

Colonoscopy is the most accurate test for detecting mass lesions of the large bowel or colon that are suspected on clinical or radiologic grounds. However, endoscopy's greatest impact on colorectal neoplasia may be in the area of screening and prevention. The adenoma to carcinoma sequence of progression in colorectal cancer provides a unique opportunity for prophylaxis. Thus, if screening programs can identify patients with polyps, and if these polyps are removed, cancer can largely be prevented. Various techniques are available for safe and effective polypectomy, depending on the size, presence of a stalk, and location (Fig. 136-5). Colonoscopy is currently recommended for screening patients at average risk—that is, anyone older than 50 years. Adenomatous polyps should be removed, and patients should then enter a surveillance program with follow-up colonoscopies every 3 to 10 years, depending on the nature and number of initial lesions. Patients with no polyps generally do not require follow-up colonoscopies more than every 10 years.

More aggressive screening strategies are required for patients considered at high risk for colorectal cancer, including patients with well-defined hereditary syndromes as well as those with a history of colorectal cancer in a first-degree relative. In addition, patients with ulcerative colitis (Chapter 143) with long-standing (>8 years) disease affecting the entire colon have an increased risk for the development of colon cancer, about 0.5 to 3% after 20 years. Periodic colonoscopic surveillance (every 1 to 2 years with biopsies) is recommended for patients with long-standing disease (8 years with pancolitis, 12 to 15 years with left-sided colitis); the discovery of high-grade dysplasia or cancer is an indication for colectomy.

"Virtual colonoscopy" (Chapter 135), which involves the digital construction of an endoluminal view of the colon on the basis of data from abdominal CT, is fast emerging as a viable alternative to colonoscopy, particularly in patients who have failed previous endoscopic attempts or for whom colonoscopy is a high-risk procedure. Alternative screening techniques, including devices that can be used by nonphysicians, electronically mapped and driven instruments, and even completely self-propelled devices, are currently undergoing clinical trials.

Chronic Diarrhea (Chapter 142)

Endoscopy may be a valuable aid in the evaluation of patients with persistent diarrhea. The timing of the endoscopy in these patients often depends on the clinical features of the illness. Patients with bloody diarrhea should have lower endoscopy as part of an initial evaluation to determine whether inflammatory bowel disease is present (Chapter 143). In most patients with chronic diarrhea, endoscopy is often done when routine testing does not yield a specific diagnosis. Both upper and lower endoscopies may be performed, depending on the clinical presentation. Thus, a patient suspected of having a malabsorptive process may require upper endoscopy with jejunal or duodenal biopsies to look for celiac sprue or rarer lesions such as lymphoma or Whipple's disease; endoscopic biopsy has largely replaced blind intestinal biopsy for these conditions. Conversely, a patient thought to have a secretory cause of diarrhea requires a colonoscopy with biopsies to look for overt inflammatory bowel disease or more subtle variants such as microscopic or lymphocytic colitis, in which case the diagnosis requires careful examination of the biopsy specimens.

The endoscopic approach to diarrhea in immunocompromised patients, such as those with HIV infection, is guided by the degree of immunosuppression and the need to find treatable infections. When the results of routine stool tests are negative, patients with CD4 counts less than 100/mm^3 should undergo endoscopic evaluation to detect pathogens such as cytomegalovirus, *Mycobacterium avium* complex, and microsporidia. Small-volume stools with tenesmus suggest proctocolitis, for which sigmoidoscopy (rather than full colonoscopy) with biopsies is usually adequate. In patients with upper gastrointestinal symptoms (large-volume diarrhea, bloating, and dyspepsia), upper endoscopy with small bowel biopsy may be attempted first.

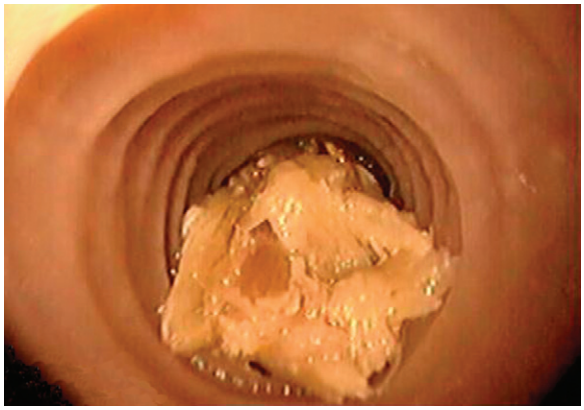

FIGURE 136-6. Impacted food bolus in a young male patient who was found to have a ringed esophagus on endoscopy. This presentation is characteristic and may be either congenital or acquired secondary to reflux-induced or eosinophilic esophagitis.

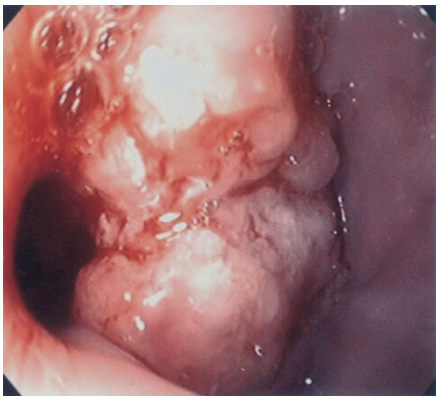

FIGURE 136-7. Large malignant mass at the gastroesophageal junction, as seen endoscopically.

Miscellaneous Indications

The upper endoscope has provided a relatively quick and noninvasive means of removing accidentally or deliberately ingested foreign bodies. Timing is critical for removal, however, because objects are usually beyond endoscopic retrieval when they reach the small bowel. Any foreign object that is causing symptoms should be removed, as should all potentially dangerous devices such as batteries and sharp objects. In general, objects larger than 2.5 cm wide or 13 cm long are unlikely to leave the stomach and should be removed. On occasion, patients with food impacted in the esophagus require endoscopic removal (Fig. 136-6). This condition almost always indicates an underlying functional or structural problem (Chapter 140) and should prompt a thorough diagnostic evaluation after the acute problem has been addressed.

Because of the relatively poor correlation between oropharyngeal lesions and more distal visceral injury, upper endoscopy is usually recommended urgently in patients with corrosive ingestion (Chapter 110). Endoscopy allows patients to be divided into high- or low-risk groups with regard to complications, with the institution of appropriate monitoring and therapy. Among the myriad causes of nausea and vomiting, a few, such as mucosal lesions and unsuspected reflux disease, are amenable to endoscopic diagnosis.

Malignant obstruction of the gastrointestinal lumen, including the esophagus (Fig. 136-7), pylorus or duodenum, and colon, can now be safely and effectively palliated endoscopically by expandable metal stents, thereby avoiding surgery. Colonoscopy is also useful in patients with pseudoobstructive (nonobstructive) colonic dilation or Ogilvie's syndrome (Chapter 138); such patients are at risk for colonic rupture at diameters greater than 9 to 12 cm, and colonoscopic decompression is often required, sometimes on an emergent basis.

A major advance in enteral feeding has been the introduction of percutaneous endoscopic gastrostomy (PEG), a relatively quick, simple, and safe endoscopic procedure that has virtually eliminated the surgical placement of gastric tubes. A variation of PEG is percutaneous endoscopic jejunostomy (PEJ), in which a long tube is passed through the gastric tube, past the pylorus, and into the jejunum. PEJ does not prevent aspiration, but it is effective in patients with a significant impairment of gastric emptying. Retrograde tube migration with PEJ is common, however, and PEJ may require frequent replacement. The most common indication for these procedures is the need for sustained nutrition in patients with neurologic impairment of swallowing or with head and neck cancers. Patients with a short life expectancy are not suitable candidates for PEG and can be managed by nasoenteral tubes. Further, despite its intuitive appeal, there is little or no evidence that PEG feeding alters clinical or nutritional outcomes or significantly improves quality of life.

PANCREATOBILIARY ENDOSCOPY

Suspected Biliary Disease (Chapters 148 and 158)

The diagnostic approach to patients with cholestasis begins with an attempt to differentiate obstructive from hepatocellular causes. The most common causes of obstructive jaundice are common bile duct stones and tumors of the pancreatic and bile ducts. Less invasive conventional imaging with ultrasonography, CT, or magnetic resonance imaging (MRI) demonstrates dilated bile ducts and mass lesions; however, it is not sensitive or specific in the detection or delineation of pathologic change in the distal common bile duct and pancreas, two regions where the majority of obstructing lesions are found. Furthermore, some biliary diseases, such as sclerosing cholangitis, do not result in dilated ducts but have a characteristic appearance on cholangiography. Finally, the ability to use devices such as cytology brushes and biopsy forceps during cholangiography provides an additional aid in the diagnosis of biliary lesions. Both percutaneous and endoscopic cholangiographic techniques are associated with a high rate of success in experienced hands, but the endoscopic approach allows visualization of the ampullary region and the performance of sphincterotomy; it also avoids the small risk of a biliary leak associated with puncture of the liver capsule.

In the past few years, magnetic resonance cholangiopancreatography (MRCP), a digital reconstruction technique based on an abdominal MRI scan, has become a popular imaging modality for the pancreatobiliary system, with excellent sensitivity and specificity. Because of its relative safety, many experts now advocate this procedure for screening patients with a low likelihood of disease. In those with a higher probability, ERCP is still the procedure of choice because of its therapeutic options.

Of the approximately 600,000 patients undergoing cholecystectomy in the United States, 5 to 10% may present with bile duct stones before or after surgery. Endoscopic stone removal is successful in 90% or more of these cases and usually requires a sphincterotomy (Fig. 136-8). The sphincter of Oddi is a band of muscle that encircles the distal common bile duct and pancreatic duct in the region of the ampulla of Vater; cutting of this muscle, or sphincterotomy, is one of the mainstays of endoscopic biliary treatment and is accomplished with a special tool called a papillotome or sphincterotome. This procedure is often sufficient for the treatment of small stones in the bile ducts, but larger stones may require additional procedures such as mechanical, electrohydraulic, or laser lithotripsy, which can be performed endoscopically. In addition, sphincterotomy may be curative for patients with papillary stenosis or muscle spasm (sphincter of Oddi dysfunction). Finally, by enlarging the access to the bile duct, sphincterotomy facilitates the passage of stents and other devices into the bile duct. Sphincterotomy carries an additional small risk of bleeding, but its associated morbidity is about one third that of surgical exploration.

Endoscopic therapy has also revolutionized the palliative approach to malignant biliary obstruction. This technique, which requires the placement of indwelling stents, is superior to both radiologic and surgical techniques. Plastic stents have been the mainstay of treatment, but metal stents last longer and may be preferred in patients with longer life expectancies.

Pancreatic Neoplasms

EUS is probably the single best test for the diagnosis of pancreatic tumors (Chapter 201), particularly the small endocrine varieties, with a sensitivity approaching 95% (Fig. 136-9). It is also the procedure of choice for imaging submucosal and other mural lesions of the gastrointestinal tract (overall accuracy of 65 to 70%) as well as for staging a variety of gastrointestinal tumors (overall accuracy of 90% or more), especially esophageal and pancreatic cancer.

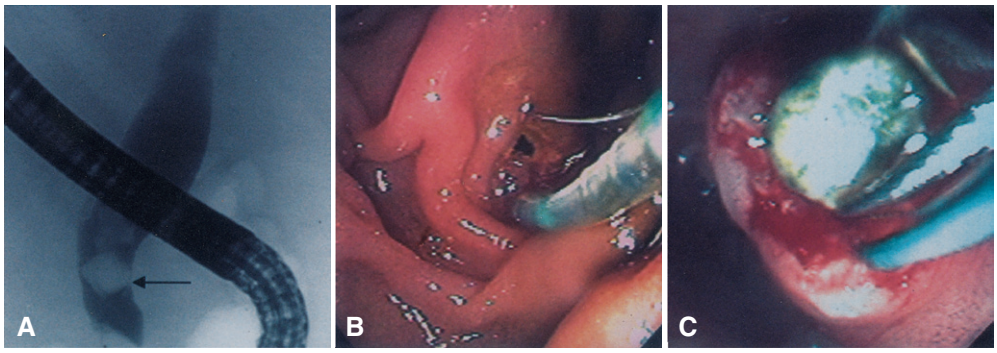

FIGURE 136-8. Biliary sphincterotomy and stone removal from the bile duct. (Courtesy of Dr. Ralph Kiesselich, University of Mainz.)

EUS-directed celiac plexus neurolysis appears to be effective for the treatment of pain in patients with pancreatic cancer, although it does not work as well in patients with chronic pancreatitis.

Nonmalignant Pancreatic Disease (Chapter 146)

ERCP is indicated for patients with acute or recurrent pancreatitis without any obvious risk factors based on history or routine laboratory evaluation. Imaging of the pancreatic duct may delineate anatomic abnormalities responsible for the pancreatitis, such as congenital variants (pancreas divisum, annular pancreas), intraductal tumors, or possibly sphincter of Oddi dysfunction. In such cases, bile can be collected from the bile duct for microscopic examination for crystals (so-called microlithiasis) that can cause pancreatitis in some patients even in the absence of macroscopic stones. In patients with chronic pancreatitis, which is most often due to excessive alcohol intake, pancreatography can confirm the diagnosis, provide useful information about disease severity, and identify ductal lesions that may be amenable to therapy by either endoscopic or surgical means. In more subtle cases, collection and analysis of pancreatic juice after stimulation with secretin may be useful in establishing exocrine impairment and hence confirming chronic pancreatic injury.

ERCP also has a role in some patients with acute pancreatitis caused by obstructing biliary stones. Patients presenting with severe biliary pancreatitis may benefit from urgent ERCP early in the course of the disease, with the intention being to detect and remove stones from the common bile duct. Similarly, patients with smoldering acute pancreatitis that is not improving satisfactorily with conservative treatment may require ERCP for the identification and treatment of any obstructing lesions in the pancreatic or distal biliary duct.

Therapeutic endoscopy for chronic pancreatic disease is still evolving. Relief of ductal obstruction (e.g., by endoscopic removal of pancreatic stones or dilation of strictures) can provide short- to intermediate-term pain relief in some patients with chronic pancreatitis, although it is probably not as effective as surgery in the long term. Endoscopic pseudocyst drainage by a variety of techniques is now technically feasible, with results that appear to be comparable to those of surgical or radiologic techniques. Patients with ductal disruptions (e.g., pancreatic ascites) can often be treated successfully

with endoscopic stent placement. Pancreatic papillotomy may also be useful in some patients with recurrent pancreatitis, such as when pancreas divisum is thought to play a role. Although the ability to approach these difficult clinical entities by less invasive endoscopic techniques represents a major accomplishment, the treatment of pancreatic diseases remains a multidisciplinary effort, with important and in some cases dominant roles played by surgeons and interventional radiologists.

EVOLVING TECHNIQUES AND FUTURE DIRECTIONS

Promising innovations include endoscopic optical coherence tomography, different forms of spectroscopy, and confocal microscopy (Fig. 136-10). These and a variety of other so-called optical biopsy techniques have the ability to provide microscopic images of cells at the surface as well as within deeper layers, thereby providing virtual real-time histology. Further, using targeted probes, it is possible to image function as well as form (E-Fig. 136-1). Innovations in endoscopic therapy include natural orifice transluminal endoscopic surgery (NOTES), by which the endoscopist or surgeon introduces an endoscope through a natural orifice (mouth, vagina, anal canal), traverses the wall of the viscus, and accesses the peritoneal cavity to perform diagnostic and therapeutic procedures.

material) or melena (black, tarry stool), but about 15 to 20% of patients who present with hematochezia, which is passage of red blood or clots per rectum, have an upper GI source of brisk bleeding. The most common causes are peptic ulcer disease , esophageal or gastric varices (Fig. 137-1), and erosive esophagitis (see Fig. 136-1 in Chapter 136). Variceal bleeding, which occurs in the setting of portal hypertension, is discussed in Chapter 156. Other causes of severe upper GI bleeding include tumors, vascular ectasias, Mallory-Weiss tears (Fig. 137-2), and erosions (Table 137-1). Depending on the severity of bleeding, patients may otherwise be asymptomatic, may present with fatigue or dizziness, or may have hypovolemic shock (Chapter 106).

DIAGNOSIS

Initial assessment includes a medical history, vital signs, and a comprehensive physical examination, including a digital rectal examination. Patients should be asked questions that may help determine the source of the bleeding. For example, peptic ulcer bleeding (Chapter 141) should be suspected in patients taking daily aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). For patients with known or suspected liver disease, bleeding from varices or gastropathy related to portal hypertension (Chapter 156) should be strongly considered. Heavy alcohol intake or vomiting should suggest a Mallory-Weiss tear (Chapter 140). The presence of a feeding tube or a chronic nasogastric

GASTROINTESTINAL HEMORRHAGE AND OCCULT GASTROINTESTINAL BLEEDING

DENNIS M. JENSEN

GASTROINTESTINAL HEMORRHAGE

Background

Gastrointestinal (GI) hemorrhage, which is a common clinical problem, has an annual hospitalization rate of 350 per 100,000 population in the United States, thereby resulting in more than 1 million hospitalizations annually. It can manifest clinically as overt bleeding from the upper GI tract (esophagus, stomach, and duodenum) or lower GI tract (colon), or it can emanate from obscure locations, usually in the small intestine. Alternatively, it can present as occult bleeding that is detected by the presence of iron deficiency anemia (Chapter 162) or a positive fecal occult blood test (Chapter 199).

Upper Gastrointestinal Bleeding

CLINICAL MANIFESTATIONS

Upper GI bleeding, which occurs proximal to the ligament of Treitz, accounts for approximately 50% of hospitalizations for GI bleeding. Upper GI bleeding usually presents as either hematemesis (vomiting of blood or coffee-ground

tube or a history of gastroesophageal reflux disease raises the suspicion for erosive esophagitis.

On the vital signs, special attention should be paid to signs of hypovolemia such as hypotension and tachycardia. Evidence of postural tachycardia or hypotension may reveal severe volume depletion that is not appreciated on a supine examination. It is important to examine the skin for petechiae, purpura, spider angiomas, and palmar erythema (see Fig. 148-2 in Chapter 148), and the abdomen for ascites (see Fig. 148-5 in Chapter 148), hepatomegaly, or splenomegaly, which may indicate portal hypertension. Tenderness or a mass may indicate an intra-abdominal tumor.

Placement of a nasogastric or orogastric tube can help localize bleeding to the upper GI tract, determine whether red blood or coffee-ground material is present, and assess how brisk, persistent, and recurrent the bleeding is. However, the sensitivity of nasogastric aspiration for upper GI bleeding is only about 80%, usually because blood in the duodenum is not refluxed into the stomach. Guaiac testing of nasogastric tube aspirates for unseen blood is not useful because the trauma of tube placement often may cause scant bleeding and false-positive results. Patients who have witnessed coffee-ground emesis or fresh bloody emesis do not require a nasogastric tube for diagnostic purposes but may need one to help clear the gastric blood for better endoscopic visualization and to minimize the risk of aspiration.

Blood should be sent for standard hematology, chemistry, liver, and coagulation studies, and the patient should be typed and crossmatched for the potential infusion of packed red blood cells (Chapter 180). The hemoglobin concentration and the hematocrit level may not accurately reflect blood loss because equilibration with extravascular fluid requires 24 to 72 hours. A low platelet count suggests chronic liver disease, dilution, drug reaction, or a hematologic disorder. In upper GI bleeding, the blood urea nitrogen level typically increases to a greater extent than the creatinine level because of increased intestinal absorption of urea after breakdown of blood proteins, but this phenomenon may not be seen in the setting of renal insufficiency or rapid transit of blood. An elevated international normalized ratio (INR) can be seen in chronic liver disease or with the use of warfarin.

Endoscopy

Patients with evidence of active bleeding (red blood by nasogastric lavage or hypotension) should undergo emergency endoscopy as soon as possible after medical resuscitation. Other patients should have endoscopic evaluation within 24 hours of their presentation (Chapter 136). Endoscopy can identify the site of bleeding with a sensitivity of about 92% and a specificity of nearly 100%, and it also can provide therapeutic hemostasis in most patients. An intravenous prokinetic agent (either erythromycin, 250 mg, or metoclopramide, 10 mg) 30 to 60 minutes before endoscopy may help move blood out of the stomach and into the small intestine, thereby improving endoscopic visualization.

In addition to localizing and treating the bleeding source, endoscopic evaluation can provide prognostic information and stratification for the risk of rebleeding, based on the presence or absence of stigmata of recent hemorrhage (Table 137-2). Other poor prognostic factors include older age, bleeding onset in the hospital, medical comorbidities, shock, coagulopathy, fresh blood in the nasogastric lavage, and the need for multiple blood transfusions. Clinical scoring systems, such as the Rockall score (Table 137-3), use clinical information and endoscopic findings to predict clinical outcomes. Similarly a Glasgow-Blatchford bleeding score of zero (urea < 6.5 mmol/L [18.3 g/dL], hemoglobin > 13 g/dL in men or >12 g/dL in women, systolic blood pressure ≥ 110 mm Hg, pulse < 100/minute, and no melena, syncope, heart failure, or liver disease) can identify patients whose upper GI hemorrhage can be treated on an outpatient basis.

Pre-endoscopic proton pump inhibitor therapy has not been shown to alter clinical outcomes, but it may downstage the severity of the lesion and decrease the need for endoscopic intervention. Therefore, in patients with suspected ulcer bleeding, intravenous proton pump inhibitors (e.g., pantoprazole, 80 mg bolus, followed by 8 mg/hour for 72 hours) may be considered while waiting for the endoscopy, but this therapy is no substitute for endoscopy and should not delay it.■

TREATMENT Rx

Resuscitation efforts should be initiated simultaneously with the initial assessment. Large-bore (14- or 16-gauge) intravenous catheters are recommended for essentially all patients so that normal saline can be infused as fast as necessary to maintain hemodynamic stability (Chapter 106). Blood products should be considered as needed to keep the hemoglobin above 8 g/dL, the platelet count above 50,000/mm^3, and the INR below 2. Endotracheal intubation should be considered in patients with active hematemesis or with altered mental status to prevent aspiration, which can cause considerable morbidity and mortality.

The goal of endoscopic therapy is to stop acute bleeding and reduce the risk of recurrent bleeding. Most endoscopic therapies were designed for peptic ulcer hemorrhage, but they can be used for other causes of nonvariceal upper GI bleeding, in which underlying arteries are the source of bleeding. Available treatments include injection (epinephrine or sclerosant), thermal coagulation (with multipolar, bipolar, or heater probe), and mechanical compression (hemostatic clips). Epinephrine injection therapy is effective, safe, and inexpensive, but it should be combined with either thermal coagulation or hemoclips to achieve hemostasis in more than 95% of patients with active bleeding and to reduce the risk of rebleeding. Endoscopic therapy is reserved for lesions that have high-risk stigmata for rebleeding (e.g., active arterial bleeding, nonbleeding visible vessel, or adherent clot) or moderate-risk stigmata, such as oozing blood without associated clot or a nonbleeding visible vessel; it is not warranted for low-risk stigmata (clean-based ulcer or flat pigmented spot), which have the lowest risk of rebleeding (Fig. 137-3). Repeat or "second-look" endoscopy, usually about 24 hours after the initial endoscopy, may occasionally be useful to confirm adequate hemostasis in high-risk patients but is not generally recommended. Some causes of upper GI bleeding, such as gastric or duodenal erosions and neoplasms, generally are not amenable to endoscopic treatment and require appropriate medical or surgical therapy, or both.

TABLE 137-1 CAUSES OF SEVERE UPPER GASTROINTESTINAL BLEEDING IN A LARGE SERIES

DIAGNOSIS	%
Gastric or duodenal ulcer	38
Gastric or esophageal varices	16
Erosive esophagitis	13
No UGI cause found*	8
UGI tumor	7
UGI angioma†	6
Mallory-Weiss tear	4
Gastric or duodenal erosions	4
Dieulafoy's lesion	2
Other‡	2

*No cause found in esophagus, stomach, or duodenum, but 25% of these patients (2% of all patients) had mouth, nose, or pharyngeal bleeding sites.
†Upper gastrointestinal (UGI) angiomas include single or multiple angiectasias, watermelon stomach, or Osler-Weber-Rendu telangiectasia.
‡Other lesions were surgical anastomoses, Cameron ulcers, aortoenteric fistulas, and hemobilia.

TABLE 137-2 ENDOSCOPIC STIGMATA OF RECENT ULCER HEMORRHAGE AND THEIR ASSOCIATED FREQUENCIES, RISKS OF REBLEEDING, AND REDUCTION IN BLEEDING RISKS AFTER SUCCESSFUL ENDOSCOPIC HEMOSTASIS

ENDOSCOPIC APPEARANCE	FREQUENCY (%)	RISK OF REBLEEDING (%)	REBLEEDING RISK AFTER ENDOSCOPIC HEMOSTASIS (%)*
Active arterial bleeding	12	80-90	15-30
Nonbleeding visible vessel	22	40-50	15-30

Medical Therapy

The most common cause of upper GI bleeding is peptic ulcer disease (Chapter 141), and the most common cause of bleeding peptic ulcers is the use of NSAIDs. Aspirin and other NSAIDs should be discontinued in patients with bleeding peptic ulcers, unless there is a contraindication to doing so (e.g., secondary prophylaxis for stroke). Patients with documented *Helicobacter pylori* infection should be treated with combination antibiotics (see Table 141-4 in Chapter 141) and proton pump inhibitors (see Table 140-1 in Chapter 140). *H. pylori* eradication does not help ulcers heal but reduces the risk of future peptic ulcer disease.

Proton pump inhibitors are the mainstay of medical therapy for hemostasis and healing of peptic lesions. Acid suppression can promote platelet aggregation and clot formation and reduce the risk of rebleeding. High-dose intravenous proton pump inhibitors (e.g., pantoprazole, 80 mg bolus followed by 8 mg/hour for 72 hours) after successful endoscopic hemostasis can reduce rebleeding rates and mortality in patients with high-risk stigmata of recent hemorrhage.■ Patients with high-risk stigmata should receive proton pump inhibitor infusion for 72 hours before converting to oral proton pump inhibitor therapy. Patients with low-risk or no stigmata can be treated with high-dose oral proton pump inhibitor therapy (see Table 140-1 in Chapter 140) twice daily for 4 to 6 weeks and considered for early discharge. For patients who have upper GI bleeding and who require an NSAID, a proton pump inhibitor combined with a cyclooxygenase-2 inhibitor (e.g., celecoxib; Chapter 36) is preferred to reduce rebleeding. Patients with upper GI bleeding who require secondary cardiovascular prophylaxis should start receiving aspirin plus proton pump inhibitor therapy again as soon as cardiovascular risks outweigh GI risks, usually within 7 days.

Of nonulcer causes of upper GI bleeding, varices (see Fig. 137-1) are the most common cause. Variceal bleeding is treated with a combination of

pharmacotherapy (octreotide, somatostatin), endoscopy (band ligation, sclerotherapy), and balloon tamponade (Chapter 156).

A Mallory-Weiss tear (Chapter 140) at the gastroesophageal junction usually stops bleeding spontaneously, but persistent bleeding should be treated similarly to bleeding from peptic ulcers. Bleeding from erosive esophagitis (see Fig. 136-1 in Chapter 136) and gastritis (see Fig. 141-1 in Chapter 141) is generally treated in the same way as ulcer bleeding, although oral liquid sucralfate (1 g twice daily) is another alternative (Chapter 140). Dieulafoy's lesion, which is an aberrant submucosal artery that erodes into the lumen of the stomach, and tumors (Chapter 199) are rare causes of acute upper gastrointestinal bleeding. Vascular lesions commonly present as chronic, low-grade blood loss rather than as acute bleeding. Critically ill patients can bleed from diffuse gastric erosions, which usually do not respond to endoscopy therapy, but may respond to proton pump inhibitors (see Table 140-1 in Chapter 140).

PROGNOSIS

Despite progressive advances in diagnosis, the mortality rate from acute upper intestinal bleeding requiring hospitalization remains about 4% for young patients and has been reported to be as high as 15% for elderly patients.

Lower Gastrointestinal Bleeding

DEFINITION AND EPIDEMIOLOGY

Lower GI hemorrhage generally refers to bleeding from the colon and anorectum. Severe lower GI bleeding occurs with an annual incidence of 20 per 100,000 population, a rate that is much less than upper GI bleeding. Patients are usually older and present with painless hematochezia, typically without orthostasis. If orthostasis is present, a brisk upper GI bleed, which occurs in 15 to 20% of patients with severe hematochezia, should be considered. Among colorectal causes of severe lower GI bleeding, diverticulosis is the most common. Other frequent causes include internal hemorrhoids, neoplasms, and ischemic colitis (Table 137-4).

DIAGNOSIS

Patients with hematochezia should have a careful history, physical examination, and laboratory evaluation as for upper GI bleeding. A history of diverticulosis (see Figs. 144-4 and 144-5 in Chapter 144) should raise the suspicion for a diverticular bleed (Chapter 144). Abdominal cramping followed by bloody diarrhea suggests ischemic colitis (see Fig. 145-2 in Chapter 145). A recent polypectomy makes a postpolypectomy bleed more likely.

After medical resuscitation, most patients need endoscopic evaluation. Flexible sigmoidoscopy or anoscopy, or both, may be performed more rapidly than full colonoscopy in patients who are highly likely to be bleeding from the anorectum or distal colon. Colonoscopy allows for the identification of a luminal source of bleeding as well as for hemostasis of amenable lesions, but urgent colonoscopy may be no better than elective colonoscopy for improving outcomes. To cleanse the colon and see the colonic mucosa adequately, a bowel purge with 6 L or more of a polyethylene glycol solution must be administered.

If colonoscopy does not reveal the source of bleeding, an upper GI endoscopic evaluation should be performed. If both are negative, capsule endoscopy (Chapter 136) can be used to look for a small intestinal source, such as angiectasias. Alternatively, if bleeding persists or is too rapid to perform a colonoscopy, a tagged red blood cell nuclear scan or angiography can localize the bleeding. A red blood cell scan is useful only if bleeding is at a rate of at least 0.1 mL/minute, whereas angiography requires an even faster bleeding rate of at least 0.5 mL/minute. Neither red blood cell scan nor angiogram identifies nonbleeding stigmata, and neither usually yields an etiologic diagnosis.

TREATMENT Rx

Medical resuscitation is similar as for upper GI bleeding. Colonoscopic treatment (Fig. 137-4) of focal bleeding sources with stigmata of recent hemorrhage relies on the same methods (epinephrine with either thermocoagulation or hemoclips) as for upper GI bleeding. Colonic angiodysplasias (see Fig. 145-5 in Chapter 145) may be a challenge to diagnose, and some patients who are bleeding from them may have their bleeding mistakenly blamed on diverticula. In addition, coagulation of angiectasias and bleeding biopsy sites is feasible during urgent colonoscopy.

Angiographic embolization or the infusion of vasoconstrictors is about 80% successful for treating rapidly bleeding vessels that are diagnosed at angiography, but with a 10% or so risk of causing local ischemia. Surgical management is rarely required for hemostasis of lower GI bleeding because most bleeding is either self-limited or easily managed with medical or endoscopic therapy. The main indications for surgery are malignant lesions (Chapter 199); diffusely bleeding lesions, such as ischemic colitis (Chapter 145) that fail medical therapy; and recurrent diverticular hemorrhage (Chapter 144). If the bleeding source can be localized preoperatively, a segmental colonic resection rather than a subtotal colectomy can be performed.

TABLE 137-4 MOST COMMON COLONIC SOURCES OF SEVERE HEMATOCHEZIA (486 CASES) (EXPRESSED AS PERCENTAGE OF COLONIC SOURCES)*

Diverticulosis	32%
Internal hemorrhoids	13%
Ischemic colitis	12%
Rectal ulcers	8%
Colonic angiodysplasia, angiectasia, angiomas, or radiation telangiectasias	7%
Ulcerative colitis, Crohn's colitis, other colitis	6%
Postpolypectomy ulcer	5%
Ulcerated polyps	4%
Colorectal cancer	3%

*Less common causes include surgical anastomotic ulcers or sutures, nonsteroidal anti-inflammatory agent colopathy, metastases, portal hypertensive colopathy, lymphoma, and endometriosis.

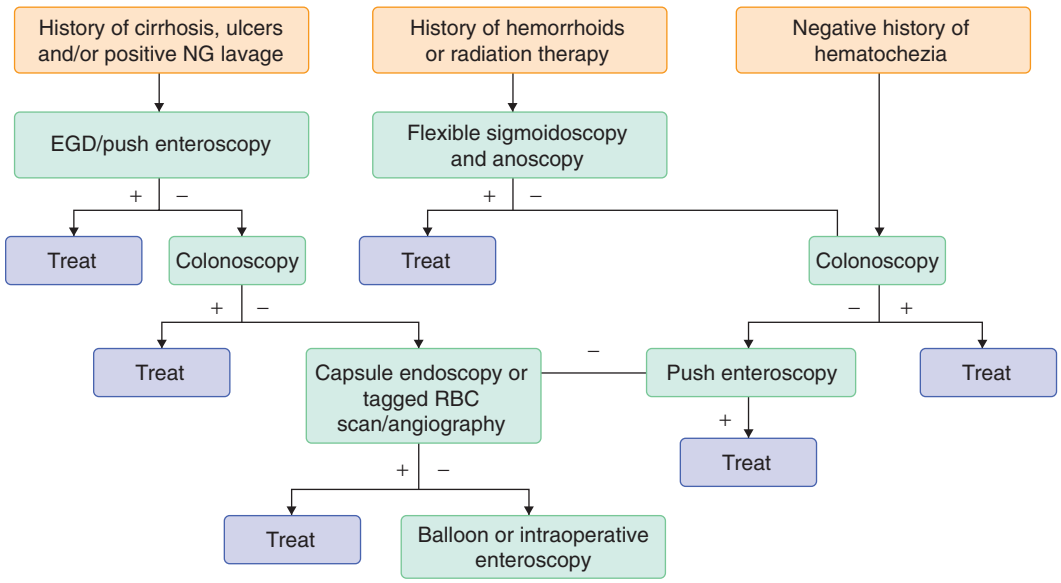

FIGURE 137-4. Management algorithm for severe hematochezia. EGD = esophagogastroduodenoscopy; NG = nasogastric; RBC = red blood cell.

PROGNOSIS

In most patients, the lower GI bleeding stops spontaneously and does not recur. The overall mortality rate from lower GI bleeding is 2 to 4%.

OBSCURE AND OCCULT GASTROINTESTINAL BLEEDING

DEFINITIONS AND EPIDEMIOLOGY

Obscure GI bleeding is persistent or recurrent bleeding, despite a negative initial GI evaluation, including upper endoscopy, colonoscopy, and radiologic evaluation of the small intestine with a small bowel follow-through. Obscure GI bleeding can be classified as either overt bleeding, with melena, maroon stool, or hematochezia, or occult bleeding, with a positive fecal occult blood test, usually in the setting of iron deficiency anemia.

In most large series of hospitalized patients, 5% of overt GI bleeding cases are considered to be obscure, and 75% of these patients have bleeding from the small intestine that is beyond the reach of an upper endoscope or colonoscope. Angiectasias (see Fig. 136-4 in Chapter 136) are the most common source of small intestinal bleeding, followed by ulcers and tumors (Table 137-5). Other causes of obscure GI bleeding include lesions that are within reach of standard endoscopes but that were not recognized as the bleeding site (e.g., a large hiatal hernia with lesions known as Cameron's ulcers on endoscopy, or internal hemorrhoids on colonoscopy) and intermittently bleeding lesions such as a Dieulafoy's lesion (Fig. 137-5), which is an aberrant submucosal vessel without an ulcer.

Iron deficiency (Chapter 162), which has a prevalence of 2 to 5% among adult men and postmenopausal women, can result from overt or occult blood loss (e.g., GI tract lesions, menorrhagia), iron malabsorption (celiac disease, atrophic gastritis), and chronic red blood cell destruction (hemolysis). It should be suspected in patients with low mean corpuscular volume, low ferritin level, or low transferrin saturation.

DIAGNOSIS

The approaches to overt and occult obscure GI bleeding are similar (Fig. 137-6). In cases with recurrent overt bleeding, upper endoscopy and colonoscopy should be repeated, with the type of bleeding dictating which endoscopic procedure to do first; about 30% of cases will be diagnosed by these repeat tests. Colonoscopy with anoscopy should be done first in patients with hematochezia. If there is melena, a push enteroscopy—a long upper-type endoscope that can be passed well beyond the duodenum and into the jejunum—should be

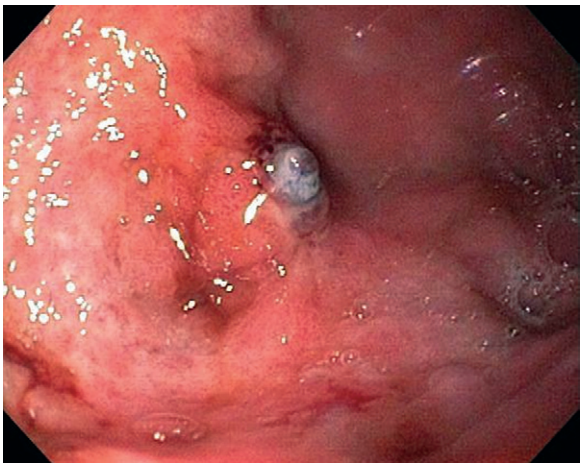

FIGURE 137-5. Dieulafoy's lesion.

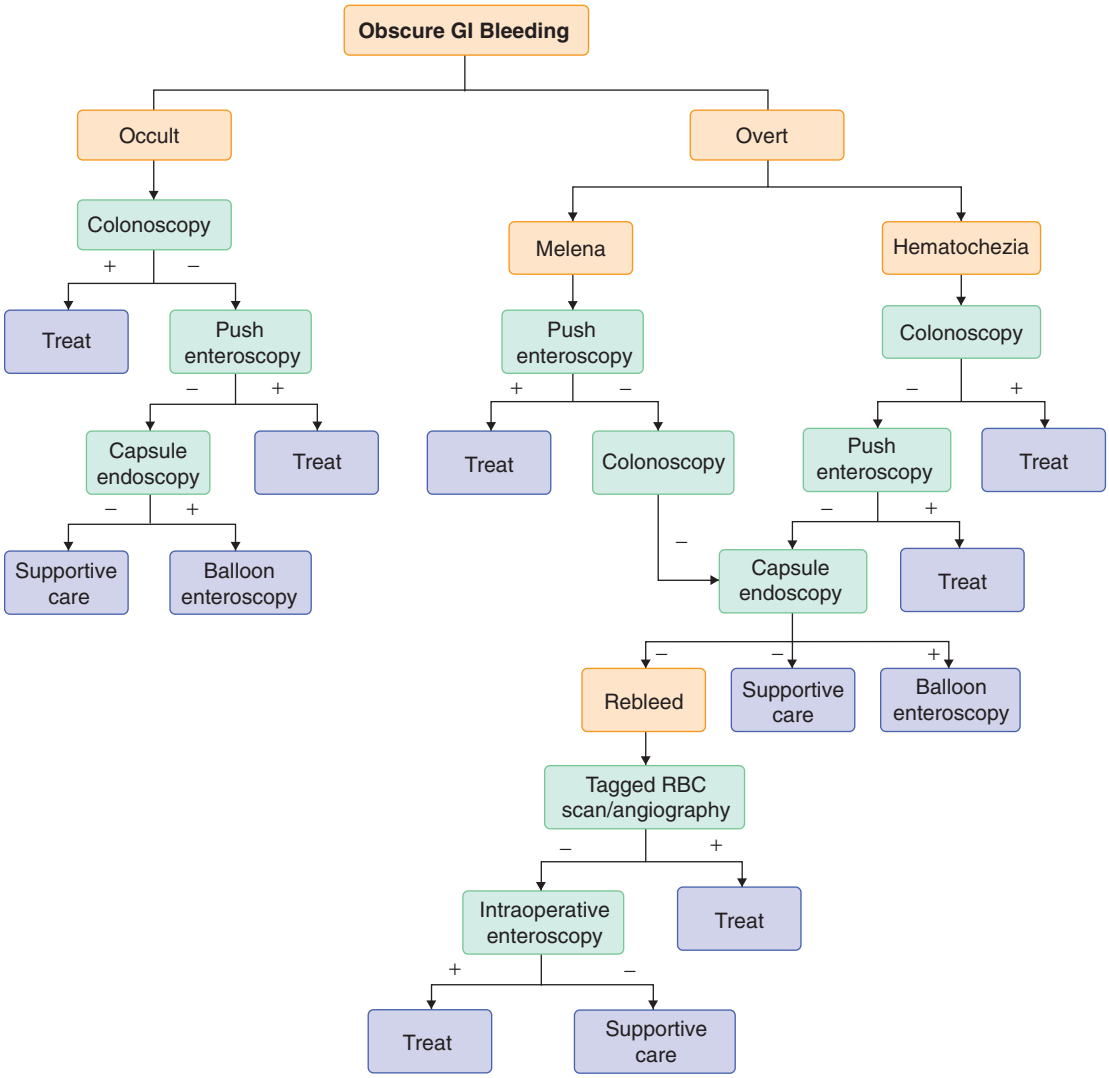

FIGURE 137-6. Management algorithm for obscure gastrointestinal bleeding. GI = gastrointestinal; RBC = red blood cell.

TABLE 137-5 SMALL INTESTINAL LESIONS FOUND DURING DOUBLE-BALLOON ENTEROSCOPY FOR OBSCURE GASTROINTESTINAL BLEEDING IN 488 PATIENTS

LESION	FREQUENCY (RANGE)
None	40% (0-57)
Angiectasias	31% (6-55)
Ulcerations	13% (2-35)
Malignancy	8% (3-26)
Other	6% (2-22)

Rajir GS, Gerson L, Das A, Lewis B. American Gastroenterological Association (AGA) Institute technical review on obscure gastrointestinal bleeding. *Gastroenterology.* 2007;133:1697-1717.

performed. If the first procedure is unremarkable, evaluation should be undertaken from the opposite end. If the second test is negative, capsule endoscopy should be performed. If bleeding from the small intestine is observed on capsule endoscopy, further attempts to diagnose and treat the bleeding should be performed with either balloon enteroscopy, which uses a balloon overtube to slide much farther into the small intestine, or intraoperative enteroscopy. All these long enteroscopes facilitate diagnosis and hemostasis. If the capsule endoscopy is negative, a tagged red blood cell scan or angiography may be used if rebleeding is rapid enough for these tests to be useful.

For occult GI bleeding, colonoscopy should be performed first because fecal occult blood testing was designed to screen for colorectal cancer (Chapter 199). Among patients over age 60 years with positive occult fecal blood tests, about 25 to 35% will have a significant colonic polyp and about 3 to 5% will have a colorectal cancer. Upper endoscopy should follow if the colonoscopy is unremarkable. Afterward, the approach is the same as for overt bleeding; if the capsule endoscopy is negative, however, efforts should be focused toward providing supportive care rather than further invasive evaluation.

Iron Deficiency Anemia

GI evaluation of iron deficiency anemia (Chapter 162) is indicated in all adult men, regardless of age, and all postmenopausal women. Women who have not reached menopause may warrant a GI evaluation after obvious or potential causes of iron deficiency, such as chronic menorrhagia, have been excluded. Colonoscopy should be performed first, followed by upper endoscopy if the colonoscopy was negative. Duodenal biopsies should be taken to look for evidence of celiac disease (Chapter 142). If both endoscopic procedures are unrevealing, capsule endoscopy should be performed. If the capsule study is negative, investigation into non-GI causes for iron deficiency (Chapter 162) may be pursued.

DISORDERS OF GASTROINTESTINAL MOTILITY

MICHAEL CAMILLERI

DEFINITION

Motility disorders result from impaired control of the neuromuscular apparatus of the gastrointestinal tract. Associated symptoms include recurrent or chronic nausea, vomiting, bloating, abdominal discomfort, and constipation or diarrhea in the absence of intestinal obstruction.

PATHOBIOLOGY

Normal Physiology

Neuroenteric Control

Motor function of the gastrointestinal tract depends on the contraction of smooth muscle cells and their integration and modulation by enteric and extrinsic nerves and by the interstitial cells of Cajal. Extrinsic neural control of gastrointestinal motor function consists of the cranial and sacral parasympathetic outflow (excitatory to nonsphincteric muscle) and the thoracolumbar sympathetic supply (excitatory to sphincters, inhibitory to nonsphincteric muscle). The cranial outflow is predominantly through the vagus nerve, which innervates the gastrointestinal tract from the stomach to the right colon. Parasympathetic innervation of the colon is provided by the vagal fibers coursing along the ileocolonic branches of the superior mesenteric artery and the S2 to S4 parasympathetic supply to the distal colon. Sympathetic fibers to the stomach and small bowel arise from T5 to T10 levels of the intermediolateral column of the spinal cord. Sympathetic innervation of the colon arises from T11 to L3 levels of the spinal cord. The prevertebral ganglia play an important role in the integration of afferent impulses between the gut and the central nervous system and in the reflex control of abdominal viscera.

The enteric nervous system is an independent nervous system comprising approximately 100 million neurons organized into ganglionated plexuses. The larger myenteric or Auerbach's plexus is situated between the longitudinal and circular muscle layers of the muscularis externa; this plexus contains neurons responsible for gastrointestinal motility. The submucosal or Meissner's plexus controls absorption, secretion, and mucosal blood flow. The enteric nervous system also plays an important role in visceral afferent function.

The interstitial cells of Cajal are spontaneously active pacemaker cells that coordinate muscular contraction and sense distortion. They form a nonneural pacemaker system at the interface of the circular and longitudinal muscle layers of the intestine and function as intermediaries between the neurogenic enteric nervous system and the myogenic control system, which regulates the electrical activity generated by gastrointestinal smooth muscle cells. Electrical control activity spreads through the contiguous segments of the gut through neurochemical activation by excitatory (e.g., acetylcholine, substance P) and inhibitory (e.g., nitric oxide, somatostatin) transmitters.

Gastric and Small Bowel Motility

The motor functions of the stomach and small intestine are characterized by distinct manometric patterns of activity in the fasting and postprandial periods (Fig. 138-1). The fasting or interdigestive period is characterized by a cyclic motor phenomenon, the interdigestive migrating motor complex. In healthy individuals, one cycle of this complex is completed every 60 to 90 minutes. The complex has three phases: a period of quiescence (phase I), a period of intermittent pressure activity (phase II), and an activity front (phase III) during which the stomach and small intestine contract at highest frequencies (3 per minute in the stomach, 12 per minute in the duodenum, 8 per minute in the ileum). Another characteristic motor pattern in the distal small intestine is the giant migrating complex, or power contraction, which empties residue from the ileum into the colon in bolus transfers.

With eating, the proximal stomach accommodates food by a vagally mediated reduction in its tone, thereby facilitating the ingestion of food without

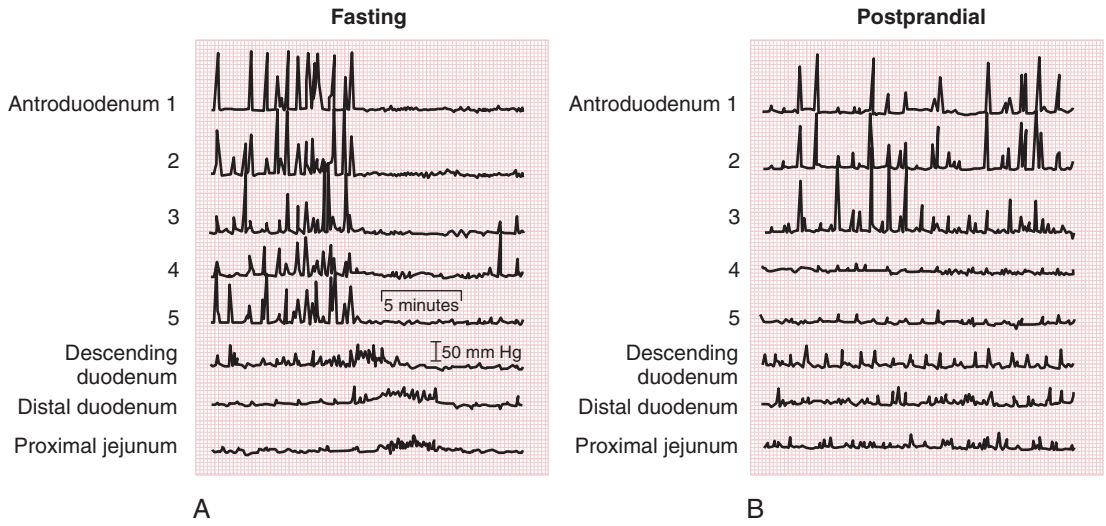

FIGURE 138-1. Fasting and postprandial gastroduodenal manometric recordings in a healthy volunteer. A 535-kcal meal is ingested during the study. Note the cyclic interdigestive migrating motor complex (**A**) and the sustained, high-amplitude but irregular pressure activity after a meal (**B**). (From Coulie B, Camilleri M. Intestinal pseudo-obstruction. *Annu Rev Med.* 1999;50:37-55.)

an increase in pressure. Liquids empty from the stomach in an exponential manner. The half-emptying time for non-nutrient liquids in healthy individuals is usually less than 20 minutes. Solids are retained selectively in the stomach, where they undergo acid and peptic digestion as well as "churning" or trituration by high liquid shearing forces in the antrum. Digestible food particles are emptied after their size is reduced by trituration to less than 2 mm. Gastric emptying of solids is characterized by an initial lag period followed by a linear postlag emptying phase. Secretion of hormones that mediate the motor and digestive process (e.g., gastrin for acid secretion; cholecystokinin for gallbladder contraction and bile and pancreatic secretion; and insulin, glucagon, and incretins such as glucagon-like peptide [GLP] 1 for glucose regulation) is integrated with the arrival of food or chyme at different levels of the gut to ensure optimal digestion.

The small intestine transports solids and liquids at approximately the same rate. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. Chyme moves from ileum to colon intermittently in boluses.

In the postprandial period, the interdigestive migrating motor complex is replaced by an irregular pattern of variable amplitude and frequency. This pattern, which enables mixing, digestion, and absorption, is observed in the gastrointestinal regions in contact with food. The maximum frequency of contractions is lower than during phase III of the interdigestive motor complex, and the duration of this postprandial contractile activity is proportional to the number of calories consumed (about 1 hour for each 200 kcal ingested). Segments of the small intestine that are not in contact with food continue with interdigestive motor patterns.

Vomiting is characterized by a stereotypic sequence of motor events, including contractions of the stomach, abdominal muscles, and diaphragm. This sequence is followed immediately in the proximal small bowel by a propagated, rhythmic contractile response similar to the migrating motor complex.

Colonic Motility

The normal colon displays short-duration (phasic) contractions and a background contractility or tone. Nonpropagated phasic contractions have a role in segmenting the colon into haustra, which compartmentalize the colon and facilitate mixing, retention of residue, and formation of solid stool. High-amplitude propagated contractions, which are characterized by an amplitude greater than 75 mm Hg, propagation over a distance of at least 15 cm, and a propagation velocity of 0.15 to 2.2 cm/second contribute to the mass movements in the colon. In health, these contractions occur on average five or six times per day, most often postprandially and between 6 AM and 2 PM.

Colonic transit is a discontinuous process, slow most of the time and rapid at other times. Residue may be retained for prolonged periods in the right colon, and a mass movement may deliver the contents to the sigmoid colon in seconds. Movement of colonic content is stimulated by feeding (gastrocolonic response). In health, the average mouth-to-cecum transit time is about 6 hours, and transit times through the right colon, left colon, and sigmoid colon are about 12 hours each. As dietary fiber is increased, mean colonic transit time decreases, stool frequency increases, and stool consistency becomes softer. Decreased caloric intake slows colonic transit, whereas a meal (typically >500 kcal) stimulates colonic motor function and propulsion of colonic content. Outlet obstruction in patients with pelvic floor dysfunction or voluntary suppression of defecation often is associated with slow colonic transit and decreased motor response to feeding.

Fluid reabsorption influences gastrointestinal transit. Approximately 9 L of fluid enters the gut from oral intake and endogenous secretions. The small intestine delivers about 1.5 L of fluid to the colon, where most is reabsorbed, leaving a maximum of 200 mL of water excreted in normal stool. Up to 3 L of fluid can be reabsorbed by the colon in a 24-hour period, unless the rate of ileocolonic flow or colonic motility overwhelms the colon's capacity or reabsorptive ability.

Defecation and Continence

Normal defecation requires a series of coordinated actions of the colon, rectum, pelvic floor, and anal sphincter muscles (Fig. 138-2). Filling of the rectum by a volume of 10 mL may be sensed, although the rectum can accommodate 300 mL before a sense of fullness and urge to defecate develop. Distention of the rectum results in the relaxation of the internal anal sphincter (rectoanal inhibitory reflex) and simultaneous contraction of the external anal sphincter to maintain continence. The anal transition zone can sense the difference between solid or liquid stool and gas.

DISEASES OF SLOW TRANSIT THROUGH THE STOMACH AND SMALL BOWEL

PATHOBIOLOGY

Gastrointestinal motility disturbances (Table 138-1) result from disorders of the extrinsic nervous system, enteric nervous system, interstitial cells of Cajal (or intestinal pacemakers), or smooth muscle. Neuropathic patterns are characterized by normal amplitude but incoordinated contractions, whereas myopathies are characterized by low-amplitude contractions (average of less than 40 mm Hg in the antrum and less than 10 mm Hg in the small bowel). Combined disorders occur in systemic sclerosis (Chapter 275), amyloidosis (Chapter 194), and mitochondrial cytopathy (Chapter 429), which initially can manifest with neuropathic patterns and later display myopathic characteristics with disease progression.

Genetic defects that result in congenital dysmotilities include abnormalities of *RET,* the gene that encodes the tyrosine kinase receptor, and abnormalities in the endothelin B system. Neural crest cells migrate from the vagal and sacral crest to the developing gut and, over time, colonize the entire alimentary canal and its appendages. Endothelin B serves to retard maturation of migrating neural crest cells, thus facilitating colonization of the entire gut with nerve cells. Other abnormalities resulting in congenital dysmotility involve other transcription factors, such as Sox10, which enhances maturation of neural precursors, and *KIT,* a marker for the interstitial cells of Cajal. Defects of *RET,* endothelin B, and Sox10 are associated with the phenotypic picture recognized as Hirschsprung's disease, whereas *KIT* defects have been associated with idiopathic hypertrophic pyloric stenosis and congenital megacolon.

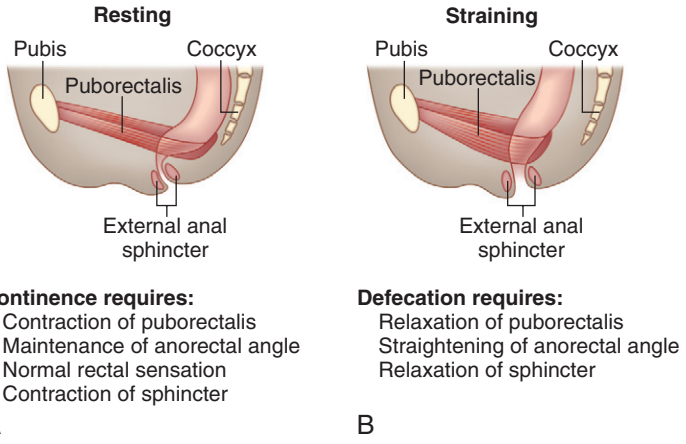

FIGURE 138-2. Pelvic floor and anorectal functions during continence and defecation. Sagittal view through the pelvis in the resting (**A**) and straining (**B**) postures. Coordinated functions of pelvic floor (puborectalis) and anal sphincter are essential for continence and defecation.

TABLE 138-1 CLASSIFICATION OF GASTROPARESIS AND PSEUDO-OBSTRUCTION

TYPE	NEUROPATHIC	MYOPATHIC
Infiltrative	Progressive systemic sclerosis Amyloidosis	Progressive systemic sclerosis Amyloidosis Systemic lupus erythematosus Ehlers-Danlos syndrome Dermatomyositis
Familial	Familial visceral neuropathies	Familial visceral myopathies Metabolic myopathies
Idiopathic	Sporadic hollow visceral myopathy	Idiopathic intestinal pseudo-obstruction
Neurologic	Porphyria Heavy metal poisoning Brain stem tumor Parkinson's disease Multiple sclerosis Spinal cord transection	Myotonia Other dystrophies
Infectious	Chagas' disease Cytomegalovirus Norwalk virus Epstein-Barr virus	
Drug induced	Tricyclic antidepressants Narcotic agents Anticholinergic agents Antihypertensives Dopaminergic agents Vincristine Laxatives	
Paraneoplastic	Small cell lung cancer Carcinoid syndrome	
Postsurgical	Postvagotomy with or without pyloroplasty or gastric resection	
Endocrine	Diabetes mellitus Hypothyroidism or hyperthyroidism Hypoparathyroidism	

Extrinsic Neuropathic Disorders

Extrinsic neuropathic processes include vagotomy, trauma, Parkinson's disease (Chapter 416), diabetes (Chapter 236), amyloidosis (Chapter 194), and a paraneoplastic syndrome usually associated with small cell carcinoma of the lung (Chapter 197). Another common "neuropathic" problem in clinical practice results from the effect of medications, such as α_2-adrenergic agonists, GLP-1 analogues, opiates, and anticholinergics, on neural control.

Damage to the autonomic nerves by trauma, infection, neuropathy, and neurodegeneration may lead to motor, secretory, and sensory disturbances, most frequently resulting in constipation. Patients with spinal cord injury (Chapter 406) above the level of the sacral segments have delayed proximal and distal colonic transit attributable to parasympathetic denervation. In these patients, fasting colonic motility and tone are normal, but the response to feeding generally is reduced or absent. Spinal cord lesions involving the sacral segments and damage to the efferent nerves from these segments disrupt the neural integration of rectosigmoid expulsion and anal sphincter control. In patients with these injuries, there is loss of contractile activity in the left colon and decreased rectal tone and sensitivity, which may lead to dilation and fecal impaction. Parkinson's disease (Chapter 416) and multiple sclerosis (Chapter 419) frequently are associated with constipation.

Enteric and Intrinsic Neuropathic Disorders

Disorders of the enteric nervous system are usually the result of a degenerative, immune, or inflammatory process. Virus-induced gastroparesis (e.g., rotavirus, Norwalk virus [Chapter 388], cytomegalovirus [Chapter 384], or Epstein-Barr virus [Chapter 385]) is associated with infiltration of the myenteric plexus with inflammatory cells. In idiopathic chronic intestinal pseudo-obstruction, in which there is no disturbance of the extrinsic neural control, degeneration of the interstitial cells of Cajal, inflammation, or herpesvirus infection may contribute.

Smooth Muscle Disorders

Disturbances of smooth muscle may result in significant disorders of gastric emptying and of transit through the small bowel and colon. These disturbances include, in descending order of prevalence, systemic sclerosis (Chapter 275), amyloidosis (Chapter 194), dermatomyositis (Chapter 277), myotonic dystrophy (Chapter 429), and metabolic muscle disorders (Chapter 429). Motility disturbances may be the result of metabolic disorders, such as hypothyroidism (Chapter 233) and hyperparathyroidism (Chapter 233), but these patients more commonly present with constipation. Scleroderma may result in focal or general dilation, wide-mouthed diverticula in the small bowel and colon, and delayed transit. The amplitude of contractions is reduced, and bacterial overgrowth may result in steatorrhea or pneumatosis intestinalis. Mitochondrial neurogastrointestinal encephalomyopathy, or familial visceral myopathy type II, is an autosomal recessive condition that may present with hepatic failure in neonates, seizures or diarrhea in infants, and hepatic failure or chronic intestinal pseudo-obstruction in adults.

Gastroparesis and Pseudo-obstruction

CLINICAL MANIFESTATIONS

The clinical features of gastroparesis and chronic intestinal pseudo-obstruction are similar and include nausea, vomiting, early satiety, abdominal discomfort, distention, bloating, and anorexia. In severe cases, there may be considerable dilation, as well as weight loss, with depletion of mineral and vitamin stores. Diarrhea and constipation indicate that the motility disorder extends beyond the stomach. Vomiting may be complicated by aspiration pneumonia or Mallory-Weiss esophageal tears, and patients with a generalized motility disorder may have abnormal swallowing or delayed colonic transit.

A careful family and medication history is essential. Review of systems may reveal an underlying collagen vascular disease (e.g., scleroderma) or disturbances of extrinsic autonomic neural control, including orthostatic dizziness, difficulties with erection or ejaculation, recurrent urinary tract infections, dry mouth, dry eyes, dry vagina, difficulties with visual accommodation in bright lights, and absence of sweating.

On physical examination, a succussion splash indicates stasis, typically in the stomach. The hands and mouth may reveal signs of Raynaud's phenomenon (Chapter 275) or scleroderma. Testing of pupillary responses (to light and accommodation), external ocular movements, blood pressure in the lying and standing positions, and general features of a peripheral neuropathy can identify patients with an associated neurologic disturbance (e.g., diabetic neuropathy) or with the oculogastrointestinal dystrophy that typically is found with mitochondrial cytopathies (see under Smooth Muscle Disorders).

The differential diagnosis includes mechanical obstruction, functional gastrointestinal disorders, anorexia nervosa, and the rumination syndrome. The rumination syndrome is a relatively common, underdiagnosed condition that presents with early (0 to 30 minutes) postprandial, effortless regurgitation of undigested food after virtually every meal.

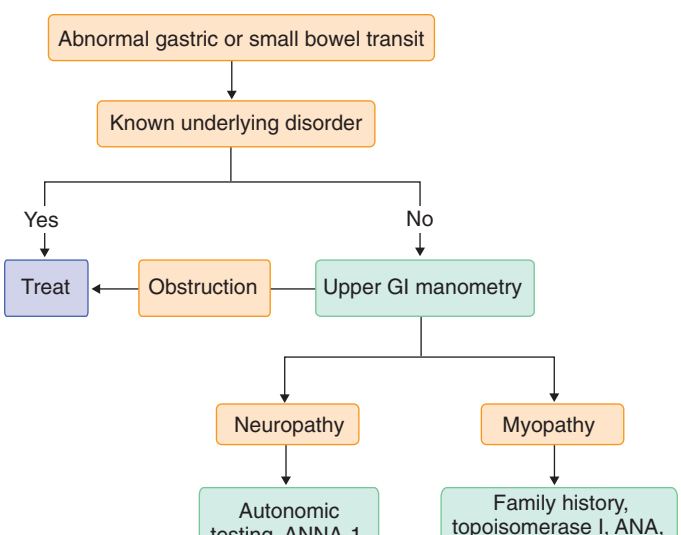

FIGURE 138-3. Flow diagram outlines steps in diagnosis of idiopathic gastroparesis and intestinal pseudo-obstruction. ANA = antinuclear antibody; ANNA-1 = type 1 antineuronal nuclear antibody; CK = creatine kinase; GI = gastrointestinal.

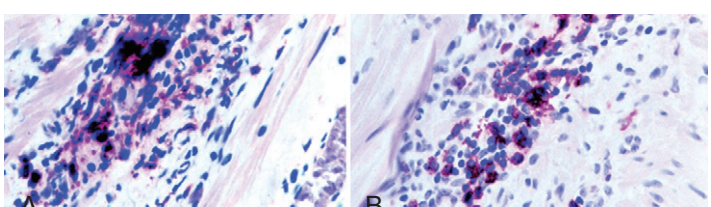

FIGURE 138-4. Micrographs showing both types of T lymphocytes, CD4 (**A**) and CD8 (**B**), detectable within the myenteric plexus of the small intestine (proximal ileum) of a 20-year-old man with chronic intestinal pseudo-obstruction. Note the intense CD4 and CD8 immunoreactivities that represent the predominant component of the immune infiltrate observed in cases of lymphocytic ganglionitis. Alkaline phosphatase anti-alkaline phosphatase immunohistochemical technique (×120) in **A** and **B**. (From De Giorgio R, Camilleri M. Human enteric neuropathies: morphology and molecular pathology. *Neurogastroenterol Motil*. 2004;16:515-531.)

DIAGNOSIS

A motility disorder of the stomach or small bowel should be suspected whenever large volumes are aspirated from the stomach, particularly after an overnight fast, or when undigested solid food or large volumes of liquids are observed during esophagogastroduodenoscopy. The clinician should assess the acuity of the symptoms and the patient's state of hydration and nutrition. The goals of the evaluation are to determine what regions of the digestive tract are malfunctioning and whether the symptoms are due to a neuropathy or a myopathy (Fig. 138-3). Key steps include the following:

1. *Suspect and exclude mechanical obstruction.* In symptomatic patients with pseudo-obstruction, plain radiographs of the abdomen typically show dilated loops of small bowel with associated air-fluid levels. Mechanical obstruction should be excluded by upper gastrointestinal endoscopy and small bowel imaging studies, including a small bowel follow-through or computed tomographic enterography. Barium studies may suggest the presence of a motor disorder, particularly if there is gross dilation, dilution of barium, or retained solid food within the stomach. These studies rarely identify the cause, however, except for systemic sclerosis or mitochondrial cytopathy, which are characterized by megaduodenum, multiple small bowel diverticula, and pneumatosis intestinalis.
2. *Assess gastric and small bowel motility.* After mechanical obstruction and alternative diagnoses such as Crohn's disease (Chapter 143) have been excluded, a transit profile of the stomach or small bowel should be performed. In a gastric emptying study, ingestion of a radiolabeled meal is followed by scanning at 0, 1, 2, 3, 4, and 6 hours. If the cause of the motility disturbance is obvious, such as gastroparesis in a patient with long-standing diabetes mellitus, it is usually unnecessary to pursue further diagnostic testing. If the cause is unclear, gastroduodenal manometry by use of a multilumen tube with sensors in the distal stomach and proximal small intestine can differentiate a neuropathic process (normal-amplitude contractions but abnormal patterns of contractility) from a myopathic process (low-amplitude contractions in the affected segments).
3. *Identify the pathogenesis* (see Table 138-1). In patients with neuropathic causes of uncertain origin, tests should assess autonomic dysfunction (Chapter 427), measure type 1 antineuronal nuclear autoantibodies and other autoantibodies associated with paraneoplastic syndromes, and consider the possibility of a brain stem lesion. In patients with a myopathic disorder of unclear cause, the evaluation should consider amyloidosis (immunoglobulin electrophoresis, fat aspirate, or rectal biopsy; Chapter 194), systemic sclerosis (topoisomerase I; Chapter 275), and thyroid disease (Chapter 233). In appropriate settings, porphyria (Chapter 217) and Chagas' disease (Chapter 355) may need to be excluded. In refractory cases, referral to a specialized center may result in genetic testing or full-thickness biopsy of the small intestine (Fig. 138-4) to identify metabolic muscle disorders and mitochondrial cytopathies.

Diabetes mellitus (Chapter 236) is associated with gastroparesis, pylorospasm, intestinal pseudo-obstruction, diarrhea, constipation, and fecal incontinence. All of these manifestations may be caused by autonomic dysfunction, although more recent evidence points to acute changes in glycemia and, more important, to changes in the structure and function of the interstitial cells of Cajal and enteric nervous system. The prevalence of constipation is 22% among diabetic patients with neuropathy but only 9.2% in diabetic patients without neuropathy, a rate that is not significantly different from that of healthy controls.

4. *Identify complications of the motility disorder, including bacterial overgrowth, dehydration, and malnutrition.* In patients presenting with diarrhea, it is important to assess nutritional status and to exclude bacterial overgrowth by culture of small bowel aspirates (Chapter 142). Bacterial overgrowth is relatively uncommon in neuropathic disorders but is found more often in myopathic conditions, such as scleroderma, that are associated more often with dilation or low-amplitude contractions. An empirical trial of antibiotics (see later) often is used instead of formal testing.

TREATMENT

Rehydration, electrolyte repletion, and nutritional supplementation are particularly important during acute exacerbations of gastroparesis and chronic intestinal pseudo-obstruction. Initial nutritional measures include low-fiber supplements with the addition of iron, folate, calcium, and vitamins D, K, and B_{12} at the usually recommended daily levels. In patients with more severe symptoms, enteral or parenteral supplementation may be required. If it is anticipated that enteral supplementation may be needed for more than 3 months, a jejunostomy tube is recommended. Gastrostomy tubes should be avoided in patients with gastroparesis except for venting purposes. The rumination syndrome is treated using behavioral approaches such as diaphragmatic breathing in the early postprandial period.

Medical Therapy

Medications increasingly are being used to treat neuromuscular motility disorders, but there is little evidence of effectiveness in myopathic disturbances except for the rare case of dystrophia myotonica affecting the stomach and for small bowel systemic sclerosis. Small randomized trials demonstrate symptomatic benefit of metoclopramide and domperidone over placebo. Metoclopramide is a dopamine antagonist with prokinetic and antiemetic properties. Antiemetic effects are due in part to its anti-5-hydroxytryptamine type 3 (HT_3) antagonist actions. Long-term use of metoclopramide is limited by the side effects of tremor and parkinsonian-like symptoms. It is available in tablet or elixir form or as a parenteral preparation and, typically, is taken orally 30 minutes before meals and at bedtime. Usual doses are 5 to 10 mg four times daily, but patients may experience side effects (changes in affect, anxiety) at relatively low doses (even 30 to 40 mg/day). The U.S. Food and Drug Administration (FDA) recommends its use only in patients who do not respond to other treatments and for periods of less than 3 months.

Domperidone (10-20 mg, three times per day before meals) is another dopamine antagonist that is approved in some countries but not in the United States, where it is available through an application to the FDA and local Institutional Review Board. Its efficacy appears similar to metoclopramide, with a lower incidence of somnolence and much lower incidence of involuntary movements.

Erythromycin, a macrolide antibiotic that stimulates motilin receptors at higher doses (250 to 500 mg) and cholinergic mechanisms at lower

doses (40 to 80 mg), results in the dumping of solids from the stomach. It accelerates gastric emptying in gastroparesis, increases the amplitude of antral contractions, and improves antroduodenal coordination. Erythromycin is most effective when it is used intravenously (3 mg/kg every 8 hours by slow infusion) during acute exacerbations of gastroparesis. For oral erythromycin, tolerance and gastrointestinal side effects often prevent use for longer than 1 month, but sometimes liquid erythromycin can be tolerated at 40 to 80 mg three times daily before meals.

Octreotide (50 µg subcutaneously at bedtime), a cyclized analogue of somatostatin, induces small intestinal activity that mimics phase III of the interdigestive migrating motor complex. It retards gastric emptying, decreases postprandial gastric motility, and inhibits small bowel transit. Octreotide appears to be useful in the treatment of dumping syndromes associated with accelerated transit. Octreotide may be used at night to induce migrating motor complex activity and to avoid bacterial overgrowth. If it is required during the daytime, octreotide often is combined with oral prokinetic to "normalize" the gastric emptying rate.

Antiemetics, including diphenhydramine (25 mg orally up to two times per day for up to 3 months), prochlorperazine (orally or by suppository 25 mg up to two times per day), and metoclopramide (5 to 10 mg orally up to three times per day for up to 3 months), can treat nausea and vomiting in patients with gastroparesis and intestinal pseudo-obstruction. The more expensive serotonin 5-HT_3 antagonists (e.g., ondansetron) have not proved to be of greater benefit than these less expensive alternatives in these patients.

Antibiotic therapy is indicated in patients with documented, symptomatic bacterial overgrowth. Although formal clinical trials have not been conducted, it is common practice to use different antibiotics for 7 to 10 days each month, in an attempt to avoid bacterial resistance. Common antibiotics include doxycycline, 100 mg twice daily; metronidazole, 500 mg three times daily; ciprofloxacin, 500 mg twice daily; double-strength trimethoprim-sulfamethoxazole, two tablets twice daily; or rifaximin, 275 mg twice daily. Use of antibiotics in patients with diarrhea and fat malabsorption secondary to bacterial overgrowth results in significant symptomatic relief.

Surgical Therapy

Surgical decompression is rarely necessary in patients with chronic pseudo-obstruction. Venting enterostomy (jejunostomy) is effective, however, in relieving abdominal distention and bloating and in reducing the frequency with which nasogastric intubations and hospitalizations are required for acute exacerbations relative to the period before vent placement. Access to the small intestine by enterostomy also provides nutrients and should be considered in patients with intermittent symptoms. Surgical treatment should be considered whenever the motility disorder is localized to a resectable portion of the gut: completion gastrectomy for patients with post–gastric surgical stasis syndrome, and colectomy with ileorectostomy for intractable constipation associated with chronic colonic pseudo-obstruction.

Gastric electrical stimulation, an approved treatment for humanitarian use, may improve gastric emptying and symptoms in patients with severe gastroparesis, but data on efficacy are inconclusive. Small bowel transplantation currently is limited to patients with intestinal failure who have reversible liver disease induced by total parenteral nutrition or who have life-threatening or recurrent catheter-related sepsis. Isolated transplantation of the small intestine is associated with higher graft and patient survival and fewer complications related to rejection and infection.

DISEASES OF RAPID TRANSIT THROUGH STOMACH AND SMALL BOWEL

Dumping Syndrome and Accelerated Gastric Emptying

Dumping syndrome and accelerated gastric emptying typically follow truncal vagotomy and gastric drainage procedures (Chapter 141) or fundoplication for gastric esophageal reflux disease (Chapter 140). With the widespread use of highly selective vagotomy and the advent of effective antacid secretory therapy, these problems are becoming rare. A high calorie (usually carbohydrate) content of the liquid phase of the meal evokes a rapid insulin response with secondary hypoglycemia. These patients also may have impaired antral contractility and gastric stasis of solids, which paradoxically may result in a clinical picture of gastroparesis (for solids) and dumping (for liquids).

The management of dumping syndrome and accelerated gastric emptying emphasizes dietary maneuvers, such as avoidance of high-nutrient liquid drinks and possibly addition of guar gum or pectin to retard gastric emptying of liquids. Rarely, pharmacologic treatment with octreotide, 25 to 100 µg subcutaneously before meals, is needed to retard intestinal transit and to inhibit the hormonal responses that lead to hypoglycemia.

Rapid Transit Dysmotility of the Small Bowel

Rapid transit of material through the small bowel may occur in the setting of the irritable bowel syndrome (Chapter 139), postvagotomy diarrhea (Chapter 142), short bowel syndrome (Chapter 142), diabetic diarrhea (Chapter 142), and carcinoid diarrhea (Chapter 240). With the exception of irritable bowel syndrome, these conditions may cause severe diarrhea and result in significant losses of fluid and electrolytes. Ileal resection or disease and idiopathic bile acid malabsorption may represent an inability of the distal ileum to reabsorb bile acids because of rapid transit and reduced contact time with the ileal mucosa; this condition may induce colonic secretion and secondary diarrhea. Accelerated transit may be confirmed by scintigraphic studies.

Treatment goals are to restore hydration and nutrition and to slow small bowel transit. Dietary interventions include avoiding hyperosmolar drinks and replacing them with iso-osmolar or hypo-osmolar oral rehydration solutions. The fat content in the diet should be reduced to approximately 50 g/day to avoid delivery of unabsorbed fat to the colon. All electrolyte and nutritional deficiencies of calcium, magnesium, potassium, and water-soluble and fat-soluble vitamins should be corrected. In patients with less than 1 m of residual small bowel, it may be impossible to maintain fluid and electrolyte homeostasis without parenteral support. In patients with a longer residual segment, oral nutrition, pharmacotherapy, and supplements are almost always effective.

The opioid agent loperamide (4 mg 30 minutes before meals and at bedtime for a total dose of 16 mg/day) suppresses the motor response to feeding and improves symptoms but may be ineffective or cause side effects (e.g., hypotension). Bile acid binding (e.g., with cholestyramine (4 g three times daily) or colesevelam (1.875 g twice daily) is indicated for patients with suspected or proven bile acid malabsorption. Verapamil (40 mg twice daily) or clonidine (0.1 mg twice daily), or both, may be used in addition to loperamide. Octreotide (50 µg subcutaneously three times daily before meals) may be used in patients for whom the oral agents are ineffective or poorly tolerated. 5-HT_3 antagonists (e.g., alosetron, 0.5-1 mg orally up to two times per day) may be efficacious in the treatment of carcinoid diarrhea and diarrhea-predominant irritable bowel syndrome, but it should be reserved for patients with severe, unresponsive diarrhea.

COLONIC MOTILITY DISORDERS

Constipation

EPIDEMIOLOGY

Constipation is a common clinical problem, reported by about 20% of the population, and 40% of Americans report needing to strain excessively to pass their bowel movements.

PATHOBIOLOGY

In functional constipation, transit is normal, and there is no evacuation disorder. These patients may have pain in association with constipation, and there is overlap with constipation-predominant irritable bowel syndrome (Chapter 139). In patients with acquired slow-transit constipation, unassociated with colonic dilation, the number of interstitial cells of Cajal in the different layers of the colon is reduced compared with controls.

Idiopathic megarectum and megacolon can be either congenital or acquired; an enteric nervous system defect is suspected. In megacolon, the dilated segment shows normal phasic contractility but decreased colonic tone, with smooth muscle hypertrophy and fibrosis of the muscularis mucosa, circular muscle, and longitudinal muscle layers.

Acquired defects in the enteric nervous system may result in constipation in Chagas' disease (Chapter 355), which is caused by infection with *Trypanosoma cruzi* and results in the destruction of myenteric neurons. Acquired aganglionosis also has been reported with circulating antineuronal antibodies, with or without associated neoplasm.

DIAGNOSIS

It is essential to distinguish an evacuation disorder, also called functional outlet obstruction (Table 138-2), from constipation resulting from slow transit or other causes. In one study in a tertiary center, 50% of 70 patients with severe, unresponsive constipation had impaired evacuation, and the remainder had constipation associated with either normal transit (also called functional constipation) or delayed colonic transit (also called slow-transit constipation). Characterization of constipated patients (Fig. 138-5) relies on the measurement of transit with radiopaque markers or scintigraphy.

TABLE 138-2 CLINICAL CLUES SUGGESTIVE OF AN EVACUATION DISORDER

HISTORY
Prolonged straining to expel stool
Taking up unusual postures on the toilet to facilitate stool expulsion
Support of perineum or digitation of rectum or vagina to facilitate rectal emptying
Inability to expel enema fluid
Constipation after subtotal colectomy for constipation
RECTAL EXAMINATION (WITH PATIENT IN LEFT LATERAL POSITION)
Inspection
Anus "pulled" forward during attempts to simulate strain during defecation
Anal verge descends <1 cm or >4 cm during attempts to simulate strain during defecation
Perineum balloons down during straining, and rectal mucosa prolapses through anus
Palpation
High anal sphincter tone at rest precludes easy entry of examining finger (in absence of painful perianal condition, e.g., anal fissure)
Anal sphincter pressure during voluntary squeeze is minimally higher than tone at rest
Perineum descends <1 cm or >4 cm during attempts to simulate strain during defecation
Puborectalis muscle palpable through posterior rectal wall is tender
Palpable mucosal prolapse during straining
"Defect" in anterior wall of the rectum, suggestive of rectocele
ANORECTAL MANOMETRY AND BALLOON EXPULSION (WITH PATIENT IN LEFT LATERAL POSITION)
Average anal sphincter resting tone >80 cm H_2O or squeeze pressure >240 cm H_2O
Failure of balloon expulsion despite addition of 200 g weight

TREATMENT

The average daily fiber intake is around 12 g/day. In patients with normal-transit constipation, 12 to 30 g/day is effective in relief of constipation. In patients with slow-transit constipation, drug-induced constipation, or evacuation disorders, however, supplementation of 30 g of fiber per day does not result in any improvement in constipation. A second step is to add an osmotic laxative, such as a magnesium salt or polyethylene glycol solution, to enhance the retention of fluid within the lumen by osmotic forces, to increase the fluidity, and to ease aboral transport of colonic content. Polyethylene glycol solutions (such as GoLYTELY, NuLYTELY, MiraLAX, OCL solution) are used frequently as a first-line therapy. If these measures do not suffice, a prokinetic or stimulant agent, such as bisacodyl (5 to 10 mg every 1 to 2 days) may be added.

Newer medications that accelerate colonic transit include prucalopride (2 mg daily), which is beneficial in chronic constipation, and lubiprostone (24 µg twice daily), a chloride channel activator that induces fluid secretion. Methylnaltrexone (0.15 mg/kg subcutaneously every other day for 2 weeks) is 33% more effective than placebo in patients with opiate-induced constipation as a complication of advanced illness. Linaclotide, a guanylate cyclase-C receptor activator that results in fluid secretion, improves bowel habits, global symptoms, and quality of life in patients with chronic constipation, but it is not currently approved for use in the U.S.

When these approaches do not work, the patient should be reassessed to exclude an evacuation disorder. For evacuation disorders, a biofeedback treatment program with muscle relaxation of the anal sphincters and pelvic floor results in a 70% or greater cure rate for the constipation. The response to this treatment program is influenced by comorbidity, such as the coexistence of eating disorders or a psychological or psychiatric diagnosis.

Surgical Therapy

In patients whose constipation is not associated with an evacuation disorder and does not respond to aggressive medical therapies (including combinations described earlier), subtotal colectomy with ileorectostomy is effective in relieving constipation. Laparoscopic colectomy with ileorectostomy achieves the same success rate with less morbidity compared with open colectomy with ileorectostomy.

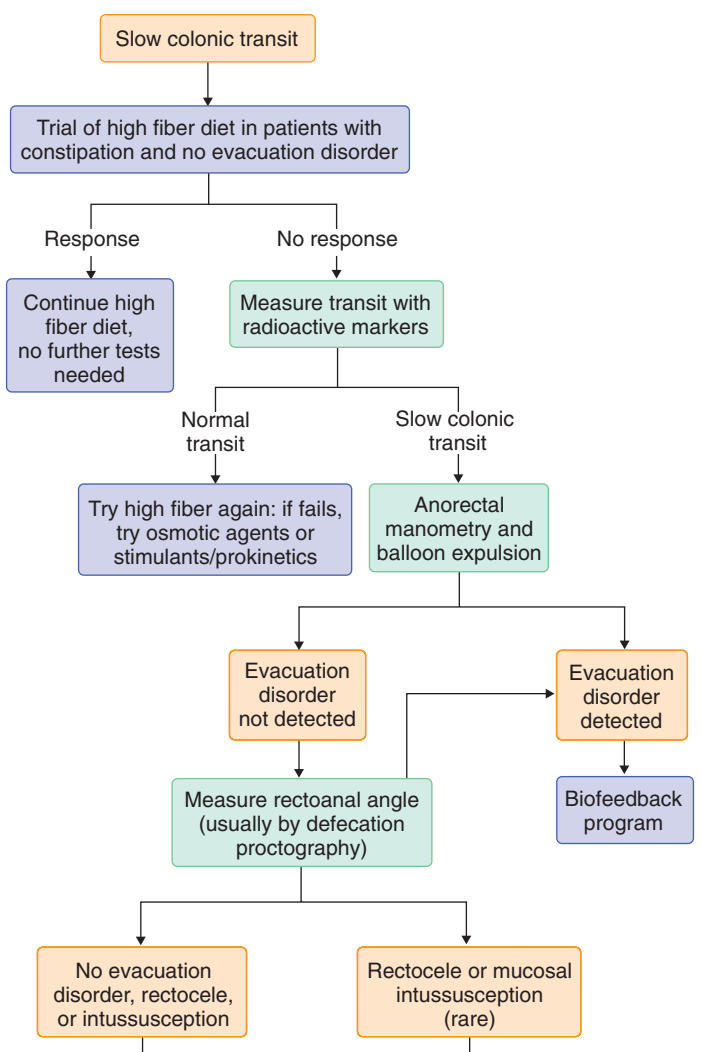

FIGURE 138-5. Flow diagram outlines steps in the management of constipation.

Hirschsprung's Disease

DEFINITION

Hirschsprung's disease occurs in 1 in 5000 live births. It is characterized by a localized segment of narrowing of the distal colon as a result of failure of local development of intrinsic nerves in the myenteric plexus.

PATHOBIOLOGY

A relative deficiency of *KIT*-positive interstitial cells of Cajal has been reported in Hirschsprung's disease and chronic intestinal pseudo-obstruction. Hirschsprung's disease is well characterized histologically by the absence of ganglion cells in the myenteric and submucosal plexus and the presence of hypertrophied nerve trunks in the space normally occupied by the ganglion cells. The lack of nerve growth factor receptors in the muscle layers of the colon involved with Hirschsprung's disease has been shown. The narrowing and failure of relaxation in the aganglionic segment are thought to be due to the lack of neurons containing nitric oxide synthase.

CLINICAL MANIFESTATIONS

Hirschsprung's disease is usually diagnosed at birth because of failure to pass meconium or the presence of megacolon, although it may be identified in childhood as a result of fecal retention, constipation, or abdominal distention. Onset of symptoms or diagnosis after the age of 10 years is rare.

DIAGNOSIS

Diagnosis is based on the typical focal narrowing of the colon, the absence of the rectoanal inhibitory reflex (relaxation of anal sphincter pressure at rest during distention of a balloon in the rectum depends on natural preservation and maturation of intrinsic nerves in the distal bowel), and a deep rectal biopsy specimen showing absence of submucosal neurons with hypertrophied nerve trunks.

TREATMENT

Rx

Treatment involves excision of the affected bowel segment or a pull-through procedure by which normal bowel is anastomosed to the cuff of the rectum, just above the anal sphincters.

FUNCTIONAL GASTROINTESTINAL DISORDERS: IRRITABLE BOWEL SYNDROME, DYSPEPSIA, AND FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN

EMERAN A. MAYER

FUNCTIONAL GASTROINTESTINAL DISORDERS

DEFINITIONS

Irritable bowel syndrome (IBS), functional dyspepsia, and functional chest pain of presumed esophageal origin are characterized by chronic, recurrent symptoms of pain and discomfort referred to the lower abdomen, the epigastrium and upper abdomen, and the retrosternum, respectively. They belong to the family of functional gastrointestinal (GI) disorders that comprise a wide spectrum of chronic GI disorders common in both the adult and pediatric populations. In the absence of disease-specific biomarkers, each syndrome is classified by symptoms and the absence of other conditions that can account for the symptoms. Despite the benign prognoses, functional GI diseases can affect health-related quality of life at least as much as organic diseases.

PATHOBIOLOGY

The pathophysiology of functional GI diseases remains incompletely understood, but these diseases are characterized by alterations in bidirectional interactions between the brain and the gut (brain-gut axis; E-Fig. 139-1), with variable contributions of enhanced perception of visceral signals by the central nervous system (visceral hypersensitivity) and altered signaling from the nervous system to the GI tract, through autonomic nervous system activity. Each diagnostic category of functional GI disease is defined by symptomatic criteria that include different subsets of patients who exhibit different patterns of the brain-gut axis dysregulation and that result in varying abnormalities in GI motility, secretion, immune function, or visceral sensitivity. Despite this heterogeneity, however, functional GI diseases all share certain features, including enhanced sensitivity to stress, the frequent coexistence of psychiatric and chronic pain disorders, an enhanced perception of visceral events, and a greater prevalence in women.

Enhanced Perception of Visceral Pain

About 30 to 70% of patients with functional GI diseases have an altered perception of visceral afferent stimuli ("visceral hypersensitivity"), in which normally innocuous stimuli, such as physiologic contractions, distentions, or chemical stimulation of the intestine, stomach, or esophagus, lead to the sensation of pain or discomfort. The stimulus may be spontaneous peristaltic activity or result from distention by luminal contents, such as ingested food, liquids, gas, or feces. Visceral hypersensitivity may be associated with aberrant referral of visceral sensations to a particular body area, and this referral is often atypical in location and larger compared with most individuals.

Altered Stress Responsiveness

Abnormal autonomic and neuroendocrine responses to psychosocial stressors are a key feature of functional GI disease and may play an important role in both its cause and its exacerbation. For example, stressful events are more likely to lead to abdominal pain and a change in stool pattern in patients with IBS compared with healthy controls, and stress has been correlated with bowel symptoms and physician visit. Data also support an association between stress and functional dyspepsia. Patients with functional GI disease report more lifetime stressful events than healthy controls, and this early life stress may interact with a genetic predisposition to determine the vulnerability of an individual to adult stressors and the subsequent development of functional GI diseases.

IRRITABLE BOWEL SYNDROME

DEFINITION

IBS is defined as chronic, recurring abdominal pain or discomfort that is associated with defecation or a change in bowel habits; the diagnosis also requires the absence of detectable organic disease that may explain the symptoms (Table 139-1). Given the high prevalence of IBS in the general population, comorbid organic GI syndromes may coexist with IBS, including ulcerative colitis (Chapter 143), microscopic and collagenous colitis (Chapter 142), and celiac disease (Chapter 142). As a result, some patients may continue to have GI symptoms after their inflammatory bowel disease or other types of colitis have been treated successfully because at least some of their original symptoms were due to comorbid IBS. For example, a small subset of ulcerative colitis patients exhibit IBS-like symptoms and have demonstrable changes in colonic motility when they are in clinical remission.

IBS is further subdivided into IBS with diarrhea, IBS with constipation, or IBS with mixed bowel habits depending on the predominant bowel habit. Another subset is postinfectious IBS, which includes patients who develop persistent IBS symptoms despite the resolution of an episode or episodes of bacterial gastroenteritis. When patients do not fulfill criteria for these subtypes, they are classified as unspecified IBS.

TABLE 139-1 ROME III DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months (but with symptom onset for at least 6 months) associated with 2 or more of the following:
Improvement with defecation
Onset associated with a change in frequency of stool
Onset associated with a change in form (appearance) of stool
Symptoms that cumulatively support the diagnosis of irritable bowel syndrome
Abnormal stool frequency: ≤3 bowel movements per week or >3 bowel movements per day
Abnormal stool form: lumpy/hard stool or loose/watery stool
Defecation straining
Urgency
Feeling of incomplete bowel movement
Passing mucus
Bloating or feeling of abdominal distention
Absence of alarm symptoms
Weight loss
Bloody stool
Anemia
Family history of inflammatory bowel disease
Colon cancer
Celiac disease

EPIDEMIOLOGY

IBS is a common disorder, with a worldwide prevalence that ranges between 10 and 20%. As is the case with many related functional pain disorders, it is more common in women, with a female-to-male ratio of 2 : 1 to 2.5 : 1. It is generally assumed that IBS most commonly presents between the ages of 30 and 50 years, but IBS is also common in the pediatric population, in which such symptoms have traditionally been referred to as recurrent abdominal pain.

The socioeconomic burden of IBS is substantial, with patients taking three times as many days of sick leave compared with individuals without IBS; about 8% of patients retire early because of their symptoms. IBS is estimated to account for about 12% of primary care visits and 19% of GI specialty visits. In the United States, IBS is estimated to account for $1.6 billion in direct costs and $19.2 billion in indirect costs annually.

PATHOBIOLOGY

Although IBS is the most common and best studied functional GI disease, there is no general agreement on its pathophysiology. However, brain-imaging studies in IBS patients strongly suggest enhanced responses to both expected and delivered visceral pain stimuli, including in brain regions concerned with sensory processing, emotional arousal, and cognitive modulation.

Autonomic Nervous System

Converging results from experimental animal and human studies suggest that stress-induced activation of central autonomic circuits plays an important role in the regulation of gut motility, secretion, and immune modulation. Acute stress-induced activation of contractions and secretions of the hindgut is mediated by sacral parasympathetic pathways, and IBS patients have increased activation of these pathways in response to severe laboratory stressors. Tonic upregulation of sympathetic and sacral parasympathetic activity may result in neuroplastic changes in peripheral target mechanisms within the gut, including the enteric nervous system. For example, increased tonic sympathetic influences on the gut may play a role in the development of constipation.

Altered Gastrointestinal Motility and Secretion

GI motility is quantitatively but not qualitatively different in 25 to 75% of IBS patients compared with healthy controls, but these measured differences are not sufficiently reliable to be used as diagnostic markers. Colonic transit is accelerated in IBS with diarrhea, and high-amplitude propagating contractions occur more frequently in such patients than in controls. These high-amplitude propagating contractions correlate with abdominal pain and may be the mechanism underlying urgency, diarrhea, and associated fecal incontinence in this patient subgroup. By contrast, slowed colonic transit is observed in a subgroup of patients with IBS with constipation. Exaggerated or prolonged colonic motility responses to food intake (gastrocolonic response) may be present in approximately 30% of patients who report an exacerbation of abdominal pain after food intake. Secretory abnormalities and alterations in fluid handling by the intestine may also contribute to alterations in bowel habits.

Hypothalamic-Pituitary-Adrenal Axis

Alterations in neuroendocrine responses in IBS patients may be reflected by altered plasma levels of adrenocorticotropic hormone and cortisol. However, the exaggerated cortisol responses in IBS may be more related to a history of adverse early life events rather than to the IBS itself.

Mucosal Immune Activation

In some patients with postinfectious IBS, symptoms persist after the infective gastroenteritis has resolved. Even after resolution of the initial infection, changes in intestinal permeability, as well as small increases in intraepithelial lymphocytes and enterochromaffin cells, can be detected in postinfectious IBS. However, mucosal changes cannot fully account for the pathogenesis because clinical symptoms do not correlate with the observed mucosal inflammatory changes, most patients with bacterial gastroenteritis do not develop IBS symptoms after infection, and the prevalence of IBS is not greater in countries with endemic GI infections. Psychological stress, female gender, a history of other somatic symptoms (somatization), and the duration of the infection all increase the probability of developing postinfectious IBS.

Patients who meet the current diagnostic criteria for IBS but who do not have a prior history of gastroenteritis may have increased inflammatory cells on mucosal biopsy specimens. Fecal calprotectin, which is a surrogate marker of inflammation and which is increased in most patients with proven organic GI disease, has also been detected in a small subset of IBS patients.

Evidence suggests an increased number of mucosal mast cells in the colon and distal small bowel in IBS patients and a closer proximity of these mast cells with enteric nerves. Mast cell degranulation, in response to increased autonomic nervous system activity, and release of histamine, tryptase, and serotonin may increase nerve activity and contribute to symptoms, but a causative role for mast cells remains unproved.

Altered Intestinal Flora

Some data suggest that the intestinal bacterial flora may be altered in patients with IBS and that these alterations may differ among IBS groups according to predominant bowel habits. Small bowel bacterial overgrowth may contribute to IBS symptoms, especially in patients with predominant bloating-type symptoms, in whom treatment with nonabsorbable antibiotics may reduce symptoms. Qualitative changes in colonic flora, such as a decrease in bifidobacteria, have been described in IBS patients.

Genetics

Familial aggregation has been demonstrated in several studies of IBS patients, and the genetic heritability of functional GI diseases has been estimated to be between 22 and 57%. Candidate gene association studies suggest possible association of IBS with polymorphisms in genes related to the serotonin signaling system.

CLINICAL MANIFESTATIONS

Symptoms

The location of abdominal symptoms in IBS is highly variable, but pain is most typically referred to the lower abdomen. Pain and discomfort are frequently aggravated by emotion or stress, poor sleep, and intake of food, but these aggravating factors cannot be elicited in all patients. By definition, abdominal symptoms are relieved by defecation, but this relief may be temporary.

IBS symptoms occur mainly during wakefulness but may also awaken patients from sleep.

If symptoms are unrelated to defecation or food intake and if patients indicate that symptoms are constant and not relievable by any physiologic intervention, other diagnoses should be considered. Weight loss is uncommon in IBS except in patients with depression (Chapter 404) or eating disorders (Chapter 226), and its presence mandates investigation of an underlying organic cause.

IBS symptoms vary widely, from mild to very severe. Most patients seen by primary care physicians have mild symptoms, whereas most patients seen by gastroenterologists have moderate to severe symptoms.

Psychiatric Comorbidity

Psychiatric disorders (Chapter 404), such as anxiety disorders (e.g., generalized anxiety disorder, panic disorder, and posttraumatic stress syndrome), depression, somatization, hypochondriasis, and phobias, are more common in patients with IBS, even mildly symptomatic patients. The prevalence of coexisting psychiatric disorders can be as high as 40% to more than 90% in patients seen in tertiary referral centers but is lower in patients seen in primary care practices. However, stress plays an important role in exacerbating IBS symptoms in patients seen in all settings.

Comorbid Conditions and Extra-intestinal Manifestations

Patients with IBS have a three-fold or higher prevalence of fibromyalgia (Chapter 282) and migraine headaches (Chapter 405) compared with patients without IBS. IBS also frequently coexists with the chronic fatigue syndrome, and 60% or more of patients with chronic fatigue syndrome have IBS symptoms. Interstitial cystitis, chronic prostatitis (Chapter 131), and chronic pelvic pain are also common in IBS patients.

These associations of IBS with comorbid conditions and other symptoms are more common in female patients, but all patients with IBS on average see primary care physicians for non-GI complaints three times more frequently than do healthy subjects. IBS patients also often complain of extra-intestinal symptoms such as dyspareunia, fatigue, loss of energy, impotence, urinary frequency, backache, and dysmenorrhea.

DIAGNOSIS

Clinical Examination

The Rome III criteria (see Table 139-1) can establish the diagnosis of IBS without additional extensive testing. Alarm features raising concern for an

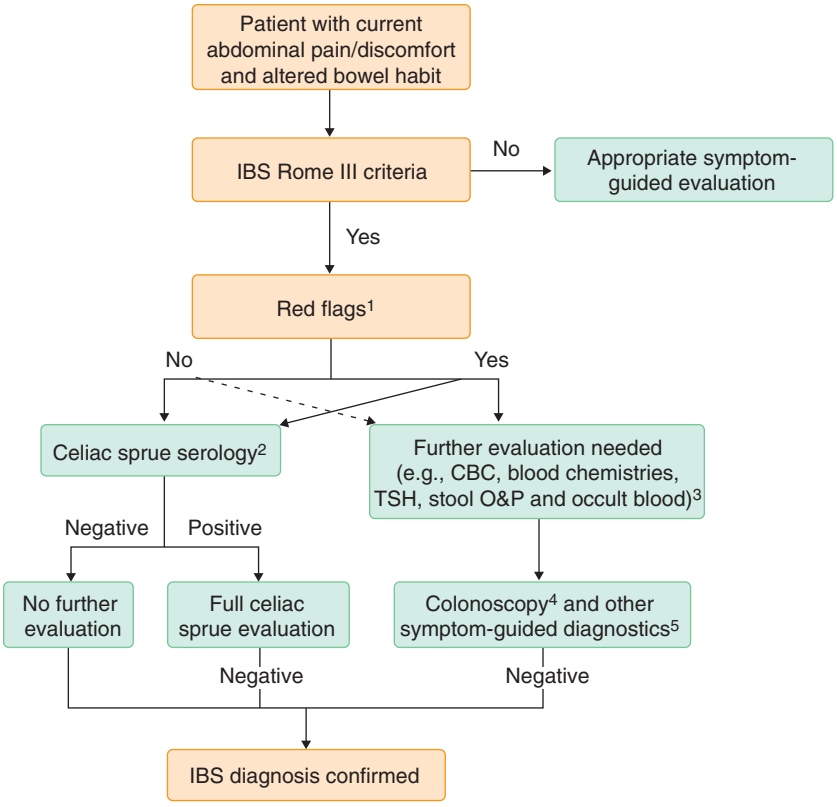

FIGURE 139-1. Diagnostic algorithm for irritable bowel syndrome. (1) Red flags include rectal bleeding, anemia, weight loss, fever, family history of colon cancer, first symptom onset after age 50 years, or major symptom change. (2) Testing for celiac sprue may be useful in patients meeting Rome criteria, in particular in irritable bowel syndrome (IBS) with diarrhea, if there are red flags, and in populations in which the background prevalence of celiac sprue is high. (3) In the absence of red flags, basic complete blood count (CBC), serum biochemistry, stool testing for occult blood and ova and parasites (O&P), and thyroid-stimulating hormone (TSH) levels are only indicated in cases of a supportive clinical history. (4) Colonoscopy is only recommended in the patient with positive red flags. However, according to colon cancer screening guidelines, routine colonoscopy should be performed in irritable bowel syndrome patients at age 50 years or older regardless of irritable bowel syndrome symptoms. (5) If there has been a major qualitative change in the pattern of chronic symptoms, a new comorbid condition producing these symptoms should be suspected and a more comprehensive diagnostic approach is warranted. (From Mayer EA. Clinical perspectives: irritable bowel syndrome. *N Engl J Med.* 2008;358:1692-1699.)

alternative diagnosis include weight loss, bloody stool, anemia, and a family history of inflammatory bowel disease, colon cancer, or celiac disease.

Careful review of medications and dietary supplements may reveal an etiologic agent because many prescribed medications can cause constipation and some diet supplements can lead to the inadvertent ingestion of laxatives. Although specific dietary agents are rarely the cause of IBS symptoms, the presence of lactose malabsorption can be determined by history or by a short trial of a lactose-free diet (Chapter 142). A brief psychosocial assessment is useful in identifying risk factors for chronic pain, such as traumatic early life events or somatization, as well as potential symptom triggers or exacerbating factors, such as anxiety, depression, and life stress.

The physical examination in IBS is usually normal but may reveal abdominal tenderness (most often in the left lower quadrant) or a tender, palpable sigmoid colon. In patients with constipation-predominant IBS and associated defecatory dysfunction, rectal examination may reveal paradoxical contraction of the puborectalis muscle or decreased descent of the pelvic floor when simulating a bowel movement.

Diagnostic Testing

In an otherwise healthy person who is younger than 50 years and who fulfills the ROME III criteria, further diagnostic testing should be minimal and guided by the individual presentation (Fig. 139-1). It remains controversial when to order a complete blood count, sedimentation rate, or thyroid studies, but most agree that it is not cost-effective to obtain these tests in all patients with presumed IBS. Serologic screening for celiac sprue (Chapter 142) should be pursued in patients with diarrhea-predominant or mixed bowel habits and in those with a family history of celiac disease. Colonic biopsies for collagenous or microscopic colitis (Chapter 142) should be considered in the setting of severe persistent diarrhea. The onset of symptoms after age 50 years and the presence of rectal bleeding or unexpected weight loss are indications for colonoscopy to assess for colorectal cancer (Chapter 199). Lower abdominal discomfort occurring with menses or with associated weight loss should trigger gynecologic evaluation. If the duration of diarrhea symptoms is short, it may be useful to assess for giardiasis (Chapter 359) or *Campylobacter* species infection (Chapter 311), but routine stool testing of all patients with diarrhea is not indicated.

Differential Diagnosis

Differential diagnosis for IBS with diarrhea predominance or mixed bowel habit includes inflammatory bowel diseases (e.g., Crohn's disease, ulcerative colitis, collagenous or microscopic colitis) (Chapters 142 and 143), celiac disease (Chapter 142), infection, small bowel bacterial overgrowth (Chapter 142), malabsorptive syndromes (including lactose intolerance) (Chapter 142), bile salt malabsorption (Chapter 142), and pancreatic insufficiency (Chapter 146) or malignancy (including neuroendocrine tumors [Chapter 239] and colorectal adenocarcinoma [Chapter 199]). The differential diagnosis for constipation-predominant IBS includes colonic inertia, pseudoobstruction, paradoxical pelvic floor contraction, or pelvic outlet obstruction from structural causes such as rectal prolapse, rectocele, or short-segment Hirschsprung's disease (Chapter 138).

TREATMENT

General Principles

Symptomatic treatment attempts to normalize bowel habits and decrease abdominal pain in part by reassurance that the symptoms are real and the prognosis is benign. Dietary intervention can be helpful, and specific medications can be targeted to the management of individual symptoms, such as constipation, diarrhea, and abdominal pain (Table 139-2).

Physician-Patient Relationship and Patient Education

The doctor-patient relationship is of utmost importance in the treatment of IBS and other functional GI diseases. Many patients have been told previously that their symptoms are "all in their head" and have had their concerns dismissed. The physician must listen to and determine the patient's understanding of the illness and related concerns because patients frequently seek validation from the physician that their symptoms are real. Patients with functional GI disease typically visit a physician because of a flare of their usual symptoms, and it is important to identify such triggering factors, in particular various psychosocial stressors or, less commonly, a gastroenteric infection.

A thorough explanation of the symptoms and relationship to functional GI disease should be provided to the patient, including the natural history and benign prognosis of the disorder. Patients who are not properly informed tend to have more health care visits, whereas symptoms generally are reduced when diagnostic and prognostic information is explained. The physician must then set realistic short-term and long-term goals, including methods of adapting to symptoms that are not amenable to treatment. Patients often benefit from being involved in their treatment, and the maintenance of a symptom diary is one such example. Apart from providing the patient with a sense of empowerment, the symptom diary can help identify erroneous beliefs as well as lifestyle or dietary factors that may exacerbate symptoms; lifestyle modifications based on this information may provide symptomatic relief.

TABLE 139-2 MEDICATIONS USED IN THE TREATMENT OF IRRITABLE BOWEL SYNDROME*

SYMPTOMS AND MEDICATION	INITIAL DOSE (mg/day)†	TARGET DOSE (mg/day)†	COMMON OR SERIOUS SIDE EFFECTS	Degree of Evidence: OF THE SYMPTOM	Degree of Evidence: OF IBS	FDA Approved: FOR THE SYMPTOM	FDA Approved: FOR IBS
CONSTIPATION							
Laxatives‡ and Secretory Stimulators							
Polyethylene glycol 3350 (MiraLAX)	17,000	70,000	Diarrhea, bloating, cramping	+++	–		
Lactulose (Kristalose)	10,000-20,000	20,000-40,000	Diarrhea, bloating, cramping	+++	–		
Lubiprostone (Amitiza)		24, twice a day	Nausea, diarrhea, headache, abdominal pain and discomfort	+++	–	Yes§	No
Prokinetics							
Tegaserod (Zelnorm)		6, twice a day	Initial diarrhea, abdominal pain, cardiovascular ischemia (rare)	+++	+++	Yes‖	Yes‖
DIARRHEA							
Loperamide (Imodium)	2	2-8	Constipation	+++	–	Yes	No
Alosetron (Lotronex)			Constipation, ischemic colitis (rare)	–	+++	No	Yes¶
BLOATING

Selective Serotonin Reuptake Inhibitors‡‡			Sexual dysfunction, headache, nausea, sedation, insomnia, sweating, withdrawal symptoms				
Paroxetine (Paxil CR)		10-60		–	+	No	No
Citalopram (Lexapro)		5-20		+	+	No	No
Fluoxetine (Prozac)		20-40	Somnolence, dizziness, headaches, insomnia	+	–	No	No

*This list is not exhaustive but includes major medications for which there is evidence from well-designed clinical trials of effectiveness for global irritable bowel syndrome (IBS) symptoms or for individual symptoms (e.g., constipation, diarrhea, or abdominal pain and discomfort). In the column about evidence, + denotes some evidence from at least one controlled trial; ++, moderate evidence from several controlled trials or from meta-analysis of such trials; +++, strong evidence from well-designed, controlled clinical trials; and –, no evidence. FDA denotes U.S. Food and Drug Administration.
†Dosages are in milligrams per day unless otherwise noted.
‡A wide range of osmotic and irritant laxatives, including fiber products, are available over the counter.
§Lubiprostone is FDA approved for the treatment of chronic constipation.
‖Zelnorm was suspended by the FDA in March 2005 because of rare cardiovascular side effects but is now available as part of a restricted-access program for women who have constipation-predominant IBS or chronic idiopathic constipation, without known or preexisting heart problems, that is unresponsive to other medications.
¶Lotronex use is restricted for women with severe diarrhea-predominant IBS, unresponsive to other medications, because of side effects.
**Many probiotics are available over the counter and are not listed. Align is a probiotic for which a beneficial effect for IBS symptoms has been shown in a high-quality, randomized, controlled trial.
††A wide range of tricyclic antidepressants with various side effects and side-effect profiles are available. Two commonly prescribed tricyclic antidepressants are listed.
‡‡Many selective serotonin reuptake inhibitors are available. Only those that have been evaluated in IBS trials are listed. Also not listed are serotonin-norepinephrine reuptake inhibitors.

Dietary Modification

Patients with functional GI disease, especially patients with IBS and functional dyspepsia, often complain that certain types of food exacerbate their symptoms. Perceived food sensitivity may be related to a variety of factors, including conditioned fear responses related to anticipatory anxiety, food intake in general, volume of the meal, or sensitivities to certain food items. For example, some IBS patients report an exacerbation of symptoms with high-fat food, gas-producing food, alcohol, and caffeine. It is important to inform the patient that there is no universal diet that is successful for IBS. A therapeutic trial of a lactose-free diet may be beneficial in some patients. Others may benefit from a low-carbohydrate, high-protein diet. It is essential, however, for patients to realize that if the dietary changes are not effective in reducing symptoms, they can resume consumption of the eliminated foods.

Pharmacologic Therapy

Antispasmodics

Antispasmodic medications, which include anticholinergic agents, calcium-channel blockers, and opioid receptor antagonists, may reverse or attenuate tonic contractions of the sigmoid colon or high-amplitude contractions of the colon, thereby relieving contractility. A meta-analysis of several low-quality studies reported a short-term benefit of the smooth muscle relaxants otilonium and hyoscine over placebo, but these agents are not available in the United States.[1] Antispasmodic medications have been combined with anxiolytic agents (e.g., clidinium bromide, 2.5 mg, and chlordiazepoxide, 5 mg, 1 to 2 tablets every 8 to 12 hours), but evidence supporting their benefit is lacking.

Medications for Bowel Habit Abnormalities and Bloating

In IBS patients with constipation, osmotic laxatives, such as polyethylene glycol or lactulose, or secretory stimulators, such as lubiprostone,[2] can be useful. Dietary fiber supplements (see Table 139-2) (e.g., psyllium fiber supplement starting at 3 to 6 g per day and increasing slowly every 1 to 2 weeks up to a total of 15 to 20 g per day in divided doses two or three times per day) may be effective[3] in some patients but often increase symptoms of gas, bloating, and flatulence.

In the IBS patient with diarrhea, loperamide is generally effective in reducing urgency and uncontrollable bowel movements. Several 5-HT_3 receptor antagonists and 5-HT_4 agonists are effective.[4] For example, alosetron (0.5 to 1 mg orally twice per day) or tegaserod (6 mg orally twice per day)[5] are beneficial, but alosetron should be considered only in patients who have severe

bloating and diarrhea and who have failed all other therapies because of its infrequent but potentially serious side effects.

Manipulation of the intestinal flora with antibiotics (rifaximin 550 mg three times daily for 2 weeks),[5] and probiotics[6] may be effective in some patients, particularly patients with abdominal bloating symptoms. Herbal laxatives such as aloe, rhubarb root products, and peppermint oil may be of use in some patients.

Antidepressants and Psychological Therapies

Low doses of tricyclic antidepressants (e.g., nortriptyline or amitriptyline, 10 to 50 mg at bedtime) are frequently used to treat IBS based on data that about one patient in four may benefit.[7] Doses should be started as low as 5 mg once daily and gradually advanced to a maximum of 75 mg once daily. The therapeutic effect should be expected within days to 2 weeks of initiating therapy; if no beneficial effect is observed at 75 mg once daily or if significant side effects are experienced, the drug should be discontinued. Amitriptyline may be most useful in patients with prominent abdominal pain and diarrhea symptoms and in patients with sleep problems.

To maximize compliance and reduce side effects, the patient should be informed about the rationale of the treatment choice (i.e., the goal is the treatment of pain and not psychiatric symptoms) and informed about the much lower risk for side effects at the low dose range compared with full psychiatric doses.

If the treatment goal is aimed at comorbid depression or anxiety disorders, a selective serotonin reuptake inhibitor (SSRI) generally has fewer side effects than tricyclic antidepressants and appears to be beneficial in patients with IBS.[7] In patients with psychiatric comorbidity, a low-dose tricyclic antidepressant and a full therapeutic dose of an SSRI should also be considered, or a nonselective uptake inhibitor such as duloxetine or venlafaxine may be used.

Cognitive-behavioral therapy, which involves relaxation, change in beliefs, and self-management, can reduce gastrointestinal symptoms in at least 50% of patients,[8] although patients with coexisting depression do not respond as well as other patients. Hypnotherapy also has been reported to improve symptoms.

PROGNOSIS

The natural history of IBS is periods of exacerbation followed by periods of remission, but about 50% of IBS patients become asymptomatic. Patients with coexisting psychiatric disorders are less likely to have their IBS symptoms resolve.

FUNCTIONAL DYSPEPSIA

As with other functional GI diseases, the diagnosis of functional dyspepsia is based on specific symptoms (Tables 139-3 and 139-4). Functional dyspepsia is thought to originate from the upper gastrointestinal tract, but no detectable organic disease can explain the symptoms. Symptoms may include epigastric pain, epigastric burning, postprandial fullness, and early satiation. Abdominal bloating and nausea also may be experienced, but they are less specific and are not considered cardinal symptoms of functional dyspepsia. Symptoms overlap with atypical manifestations of gastroesophageal reflux disease (GERD; Chapter 140), and previous studies on functional dyspepsia may have inadvertently included patients with atypical GERD symptoms.

In the current Rome III criteria, symptoms have been divided into meal-related (postprandial distress syndrome) and meal-unrelated (epigastric pain syndrome) symptoms (see Table 139-4). The clinical utility of these subgroups is controversial because there is considerable overlap between them. Moreover, the concept of distinct pathophysiologies correlating with distinct symptom patterns has not been confirmed.

TABLE 139-3 ROME III DIAGNOSTIC CRITERIA FOR FUNCTIONAL DYSPEPSIA*

1. One or more of the following:
   - Bothersome postprandial fullness
   - Early satiation
   - Epigastric pain
   - Epigastric burning

and

2. No evidence of structural disease (including at upper endoscopy) that is likely to explain the symptoms

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

TABLE 139-4 ROME III DIAGNOSTIC CRITERIA FOR SUBGROUPS OF PATIENTS WITH FUNCTIONAL DYSPEPSIA*

POSTPRANDIAL DISTRESS SYNDROME

One or both of the following:
1. Bothersome postprandial fullness, occurring after ordinary sized meals, at least several times per week
2. Early satiation that prevents finishing a regular meal, at least several times per week

Supportive Criteria

1. Upper abdominal bloating or postprandial nausea or excessive belching can be present.
2. Epigastric pain syndrome may coexist.

EPIGASTRIC PAIN SYNDROME

One or more of the following:
1. Pain or burning localized to the epigastrium of at least moderate severity at least once per week
2. Intermittent pain
3. Pain not generalized or localized to other abdominal or chest regions
4. Pain not relieved by defecation or passage of flatus
5. Pain not fulfilling criteria for gallbladder and sphincter of Oddi disorders

Supportive Criteria

1. The pain may be of a burning quality but without a retrosternal component.
2. The pain is commonly induced or relieved by ingestion of a meal but may occur while fasting.
3. Postprandial distress syndrome may coexist.

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

EPIDEMIOLOGY

Functional dyspepsia is a common disorder, with an estimated prevalence of 15 to 20%. Unlike IBS, there does not appear to be a sex-related difference in prevalence. The socioeconomic burden of functional dyspepsia is substantial; patients with functional dyspepsia take three times as much sick leave as patients with duodenal ulcers. In the United Kingdom, an estimated 2 to 5% of primary care visits and more than 10% of primary care drug expenditures are related to functional dyspepsia. Approximately 1 of 2 individuals with functional dyspepsia seeks health care for symptoms at some time in his or her life. It is therefore not surprising that in the United Kingdom, the annual indirect and direct cost of dyspepsia to society are U.S. $1.46 billion and U.S. $730 million, respectively.

Comorbidity with Irritable Bowel Syndrome

Pain or discomfort in the upper abdomen may at first be assumed to be related to the upper GI tract, but on detailed questioning, the "dyspepsia" may be related to bowel disturbances. One third of patients with functional dyspepsia have concurrent symptoms of IBS, and approximately 40% of IBS patients also report symptoms of functional dyspepsia. Moreover, transitions between the two syndromes in the same patient over time are common. In a 1-year follow-up of patients with IBS or dyspepsia, 22% of IBS patients reported a change in their symptom profile to that of functional dyspepsia, and 16% of patients with functional dyspepsia reported a change to an IBS symptom profile. This transition of patients between different diagnostic categories questions the concept that these symptom-based entities are really distinct pathophysiologic syndromes. Compared with patients with non-life-threatening organic GI disease, patients with functional dyspepsia have higher anxiety but not depression or neuroticism scores.

PATHOBIOLOGY

The pathobiology of functional dyspepsia is not fully understood, and both central and peripheral mechanisms have been proposed. Although enhanced perception of gastric stimuli may be a key central mechanism, the roles of gastric acid, acute and chronic gastric mucosal infections, and gastroduodenal dysmotility remain to be determined. Attempts to classify subtypes of functional dyspepsia based on pathophysiologic abnormalities have been unsuccessful.

As with IBS patients, visceral hypersensitivity is common in functional dyspepsia, and 34 to 65% of patients with functional dyspepsia report pain

and discomfort at lower volumes of gastric distention than healthy control subjects or patients with dyspepsia from organic causes. Chemical sensitivity to capsaicin also has been reported. Central pain amplification also is likely to contribute to the observed gastric hypersensitivity. For example, the presence of lipids in the duodenum increases the sensitivity of patients with functional dyspepsia to gastric balloon distention compared with controls. This abnormal modulation of gastric perception thresholds to distention by lipid in a distant site supports the concept of a centrally mediated mechanism. Furthermore, about 50% of patients with functional dyspepsia experience altered viscerosomatic referral patterns in response to gastric balloon distention.

Several large multicenter studies have demonstrated that only 10 to 15% of patients with functional dyspepsia benefit from acid suppression therapy. This finding suggests that such patients are hypersensitive to either intraduodenal or intra-antral acid or that they suffer from atypical manifestations of GERD. Chronic *Helicobacter pylori* infection may be related to dyspeptic symptoms in patients with functional dyspepsia.

Some data suggest the presence of alterations in gastroduodenal motility in patients with functional dyspepsia, but the low concordance between symptoms and altered motility findings argues against such testing except in highly selected patients. For example, about 40% of patients with functional dyspepsia have evidence of impaired gastric accommodation, which may cause rapid transit of food from the proximal stomach, thereby resulting in early antral distention, which in turn results in dyspeptic symptoms. In addition, postprandial antral hypomotility can be demonstrated by manometric studies in about 50% of patients with functional dyspepsia, and this abnormality correlates with delayed gastric emptying, which has been demonstrated in one third of patients with functional dyspepsia. A correlation between delayed gastric emptying and dyspeptic symptoms of postprandial fullness has been reported. About 20% of patients with functional dyspepsia develop their symptoms after an acute episode of presumed viral or bacterial gastroenteritis or *Giardia* species infection.

DIAGNOSIS

Clinical Examination

Dyspepsia can be suspected to be functional based on a clinical history consistent with the ROME III criteria (see Tables 139-3 and 139-4) and the absence of alarm features (see Table 139-1). The presence of anxiety, in particular symptom-related anxiety and comorbid IBS, increases the likelihood of functional dyspepsia.

The physical examination is generally normal, although epigastric tenderness may be present. In contrast to gastroparesis, a succussion splash is typically absent. Although confirmation of the functional dyspepsia diagnosis, as noted in the Rome III criteria, requires a normal upper endoscopic examination, invasive testing in the absence of alarm features should be considered only in a minority of symptomatic patients, such as patients older than 50 years with new-onset or changing symptoms or a poor response to initial therapy (see Fig. 134-6 in Chapter 134). Evaluation for *H. pylori* (Chapter 141) should be performed by stool antigen, urea breath test, or gastric biopsy. If present, the infection should be eradicated, and then symptoms should be reassessed. Young patients who respond well to a trial of proton pump inhibitor therapy or *H. pylori* eradication do not require further investigation unless alarm features are identified. Nonsteroidal anti-inflammatory medications, dietary supplements, and other prescription or over-the-counter medications can trigger dyspeptic symptoms. The patient's medication list should be reviewed, and nonessential treatments should be discontinued. As in the evaluation of IBS, a psychosocial history may reveal underlying stressors that contribute to symptoms.

Differential Diagnosis

Common organic causes of dyspepsia include peptic ulcer disease (Chapter 141) and gastroesophageal reflux disease (Chapter 140). Delayed gastric emptying is present in a small number of patients with functional dyspepsia but is characteristic and more pronounced in patients with diabetic or idiopathic gastroparesis (Chapter 138). Vomiting of undigested food is characteristic of these forms of gastroparesis, but not of dyspepsia. Gastric and esophageal cancers (Chapter 198) may also present with symptoms of dyspepsia but are much less common. Pancreaticobiliary disorders (Chapters 146 and 158) (including sphincter of Oddi dysfunction, chronic pancreatitis, or pancreatic cancer) also occasionally mimic dyspepsia.

TREATMENT Rx

Acid suppression therapy is safe and may have a beneficial effect over placebo in approximately 10% of patients, who presumably have either atypical GERD (Chapter 140) or duodenal hypersensitivity to gastric acid. The choice of acid suppressive agents is open to debate (see Table 140-1 in Chapter 140), and both histamine (H_2)-receptor antagonists (e.g., famotidine, 20 mg twice per day) and proton pump inhibitors (e.g., omeprazole, 20 mg per day) have been reported to be more effective than placebo. A proton pump inhibitor (e.g., omeprazole, 20 mg/day, or lansoprazole, 30 mg/day) is superior to placebo or an H_2 antagonist in functional dyspepsia, especially in patients with epigastric pain. In a randomized study of step-up and step-down treatment with antacids, H_2-receptor antagonists, and proton pump inhibitors in patients with new-onset dyspepsia, the two treatments were equally successful (about 70%), but the step-up approach was more cost-effective.

A subset of patients with functional dyspepsia improve after eradication of *H. pylori* (Chapter 141), and the likelihood of a positive response is comparable to that with acid suppression. This short-duration treatment also can reduce the risk of subsequent peptic ulcer disease, atrophic gastritis, and gastric cancer, and it currently is recommended by consensus guidelines.

The use of prokinetic drugs such as metoclopramide or domperidone, 10 mg three times per day, before meals is of uncertain benefit. Low-dose tricyclic antidepressant therapy has not been as extensively evaluated in functional dyspepsia compared with IBS, but small studies reported a beneficial effect. The benefits of psychological therapy for functional dyspepsia are not well established, but it may be a reasonable option in patients who do not respond to pharmacotherapy.

PROGNOSIS

As with all functional disorders, functional dyspepsia has a benign prognosis, although symptoms can be persistent.

FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN

DEFINITION

Functional chest pain of presumed esophageal origin (Table 139-5) is a chronic, unexplained midline chest pain that is thought to be of esophageal origin. To make the diagnosis, cardiac causes, gastroesophageal reflux, and well-defined motility disorders (achalasia, scleroderma) must be excluded.

EPIDEMIOLOGY

Most patients who present to a physician with acute chest pain (see Table 50-2 in Chapter 50) have a noncardiac cause, and many are cases of functional chest pain. Most of these are cases of functional chest pain. Despite its frequency, however, the prevalence of functional chest pain and its natural course are not well understood, likely because most patients undergo a cardiac evaluation but then may have no further evaluation of their symptoms.

Functional chest pain is quite common, with prevalence rates as high as 25%, evenly divided between men and women. Its prevalence appears to decline with advancing age. Risk factors for developing functional chest pain are not well defined but include younger age, adversity in childhood, and a history of other functional gastrointestinal conditions. Once symptoms occur, more than 50% of patients have persisting symptoms for longer than 6 months. Even after the initial diagnosis, however, many patients with chronic pain undergo repeated and unnecessary diagnostic cardiac evaluations. Patients with functional chest pain may have comorbid anxiety or panic attacks, but formal referral for psychological treatment is infrequent. When

TABLE 139-5 ROME III DIAGNOSTIC CRITERIA FOR FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN*

Must include all of the following:

- Midline chest pain or discomfort that is not of burning quality
- Absence of evidence that gastroesophageal reflux is the cause of symptoms
- Absence of histopathology-based esophageal motility disorders

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

compared with patients who have known cardiac chest pain, patients with functional chest pain report greater impairment of health-related quality of life in the domains of mental health and vitality. These findings suggest a link between psychological disturbance and functional chest pain, at least in a subgroup of patients.

PATHOBIOLOGY

Visceral hypersensitivity, altered esophageal motility, and psychological factors have all been implicated in the pathophysiology of functional chest pain. A substantial proportion of patients show enhanced sensitivity to esophageal distention by a balloon. These same patients will often also have increased perceptual responses to intraesophageal acid infusion. The origin of such findings is not clear, although alterations in central processing of pain signals (central pain amplification) has been implicated. In addition, altered esophageal motility can be observed in a subset of patients with functional chest pain, with or without visceral hypersensitivity. Increased contraction of the esophageal muscle has long been considered a source of chest pain, although reproducible studies to prove this hypothesis are lacking.

CLINICAL MANIFESTATIONS

Patients may complain of pain that is typical for myocardial ischemia or of pain with a variety of characteristics that would be considered atypical for ischemia (Chapters 50 and 71). The location of pain is typically substernal, but radiation to the arm and neck can be described. The pain typically is not precipitated by exertion and may persist for hours. Nitroglycerin may sometimes be helpful acutely in patients with coexisting esophageal spasm. Patients may describe the discomfort using a variety of adjectives, and those descriptions may be indistinguishable from angina.

DIAGNOSIS

Patients who present with chest pain suspicious for angina should undergo prompt cardiac evaluation (Chapters 50 and 71). In patients with an initial negative cardiac evaluation, causes of functional chest pain can be categorized based on historical features (Table 139-6), and repeated cardiac evaluation for recurrent pain is of low yield. Patients with prominent chest wall pain and tenderness on palpation or with changes in pain with movement usually have musculoskeletal rather than an esophageal pain.

The remaining patients may have an esophageal source of pain (Chapter 140) and should be divided into patients with and without alarm symptoms, such as weight loss, progressive dysphagia, or anemia. Upper endoscopy is useful in patients with alarm features but is of lower yield in patients without them.

Many patients with functional chest pain will have underlying GERD. Because clinical features, such as association with certain foods or pain location, do differentiate well between acid-induced versus non-acid-related causes, evaluation for atypical GERD is best performed by a proton pump inhibitor trial (e.g., omeprazole, 20 mg daily).[11] Patients who respond to a 1- to 2-week trial of daily proton pump inhibitor likely have acid-related symptoms and should be treated for GERD (Chapter 140). In patients whose response is equivocal, a longer proton pump inhibitor trial of 4 to 8 weeks, endoscopy, or 24-hour pH testing (Chapter 140) can be considered.

For patients who do not respond to a proton pump inhibitor, a disorder of esophageal motility or visceral hypersensitivity may be present. Esophageal motility disorders such as high-amplitude contractions ("nutcracker esophagus") or diffuse esophageal spasm can be identified by esophageal manometry (Chapter 140), but the low concordance between symptoms and manometric findings suggests that such testing should be performed only in highly selected patients based on the advice of a gastroenterologist.

Pulmonary disease
Panic attack

TREATMENT

Rx

All patients benefit from reassurance regarding the benign course of functional chest pain. Fears of cardiac disease should be addressed explicitly, and the significance of a negative cardiac evaluation must be reinforced. If the functional chest pain is responsive to a proton pump inhibitor trial, patients should be continued on such therapy or treated with alternative acid-suppressing medications. The optimal duration of treatment is unclear, but it is reasonable to attempt withdrawal of medication and observe patients who have remained asymptomatic for several months. Although evidence from well-designed clinical trials is lacking, low-dose tricyclic antidepressants (e.g., desipramine, 10 to 75 mg per day) may be useful, particularly in patients suspected to have visceral hypersensitivity.

Comorbid psychological symptoms should be addressed with either pharmacologic or cognitive behavioral therapy. Even in the absence of a specific psychiatric diagnosis, relaxation therapy or cognitive behavioral therapy may be of benefit for functional chest pain.

PROGNOSIS

Functional chest pain has a benign prognosis, although symptoms may persist and continue to diminish quality of life.

140 DISEASES OF THE ESOPHAGUS

GARY W. FALK AND DAVID A. KATZKA

NORMAL ANATOMY AND PHYSIOLOGY

The esophagus, which averages about 27 cm in length, is a hollow muscular tube consisting of mucosa, submucosa, and muscularis layers and the absence of a serosal layer. The mucosa is a stratified squamous nonkeratinized epithelium that transitions to a columnar epithelium at the gastroesophageal junction. The muscular layer of the esophagus is composed of striated muscle in

the upper one third and smooth muscle in the lower two thirds. These muscular components are arranged as an inner circular and an outer longitudinal layer. Located between the circular and longitudinal muscle layers is Auerbach's (myenteric) plexus, whereas Meissner's plexus is located within the submucosa and innervates the muscularis mucosae. The esophagus is bounded by an upper esophageal sphincter proximally and the lower esophageal sphincter distally. The upper esophageal sphincter contains functional contributions from the inferior pharyngeal constrictor proximally and the cricopharyngeus distally. By contrast, the lower esophageal sphincter is anatomically and histologically indistinguishable from the lower esophagus. Blood supply for the cervical portion is derived from branches of the inferior thyroid artery. The intrathoracic segment of the esophagus receives its blood supply from bronchial arteries and direct branches from the aorta, and the short abdominal portion of the esophagus is supplied by the left gastric and the inferior phrenic arteries. Venous drainage follows the arterial supply in the cervical and abdominal portions, whereas the thoracic esophagus drains into the azygous and hemiazygos system. Likewise, the lymphatic drainage of the esophagus is segmental, with the cervical portion draining into deep cervical lymph nodes, the thoracic portion into the superior and posterior mediastinal lymph nodes, and the abdominal portion into the gastric and celiac lymph nodes.

The motor functions of the esophagus are to transport a food bolus from the oropharynx into the stomach and then to keep food from returning to the esophagus after it has entered the stomach. The upper esophageal sphincter and the proximal third of the esophagus compose the first portion of the esophagus. The upper esophageal sphincter, which is approximately 2 to 4 cm in length, is controlled by the recurrent laryngeal nerve inferiorly and a pharyngeal plexus superiorly. The muscle layers close the esophageal lumen and shorten the esophagus to facilitate forward transport through the proximal esophagus. After food traverses the proximal esophagus, it moves into the distal two thirds of the esophagus, where peristalsis is achieved by sequential muscular contraction mediated by an interplay of inhibitory and excitatory neurotransmitters. Peristalsis may be primary, that is, initiated by a swallow, or secondary, that is, stimulated by refluxed gastric contents. Although local mechanisms control most esophageal motor function, vagal input is important in the distal esophagus, where smooth muscle myopathies and autonomic neuropathies can cause dysfunction. The distal esophagus is separated from the stomach by the lower esophageal sphincter, which is 4 to 5 cm in length and is functionally distinct because it maintains a tonic high-pressure zone. This sphincter relaxes nearly completely upon swallowing to allow the passage of food and then regains its tone to provide a barrier against reflux. It also relaxes transiently during normal functions, such as belching and vomiting. The vagus nerve, acetylcholine, and nitric oxide influence tone, but the lower esophageal sphincter tone also is influenced by the crural diaphragm as the esophagus traverses the diaphragmatic hiatus.

Esophageal Functional Testing

Options for esophageal functional testing include barium esophagography, esophageal manometry, and esophageal impedance testing. Barium esophagography (Chapter 135) reveals both anatomic and physiologic information about endoluminal lesions, such as malignancies, ulceration, diverticula, hiatal hernia, and strictures; intramural lesions, such as leiomyomas; and extrinsic lesions, such as occur from vascular (aorta, right atrium, subclavian artery) impingement or solid lesions (pulmonary malignancy, adenopathy) that compress the esophagus. Radiography is also an excellent tool for studying motility patterns, such as peristalsis with either liquid or solid contrast material, while precisely visualizing how the esophagus handles a bolus rather than by implying function from pressure or impedance changes.

Esophageal manometry measures pressure changes generated by esophageal wall contraction using multiple ports that simultaneously measure pressure from the pharynx to the lower esophageal sphincter. Esophageal impedance testing measures conductance between catheter-based electrodes based on the substance that is in contact with each electrode. Air, which is a poor conductor of electric current, will yield high impedance, whereas swallowed or refluxed liquids, which are excellent conductors of electricity, will generate a low impedance signal. From these measurements, the direction and velocity of the transport of air and bolus can help assess peristaltic function and measure reflux of acid and nonacid gastric contents.

Symptoms of Esophageal Disease

The most common symptom of esophageal disease is heartburn, which is defined as a sensation of substernal burning. Chest pain without typical heartburn may occur in a variety of esophageal disorders, including gastroesophageal reflux and motor disorders such as in achalasia. However, esophageal pain and even heartburn can be indistinguishable from cardiac angina (Chapter 50), so care must be taken when a patient at risk for coronary artery disease complains of heartburn for the first time.

Dysphagia, or difficulty swallowing, is another cardinal symptom of esophageal disease. Dysphagia with only solid food tends to occur with structural lesions, which cause esophageal constriction, whereas dysphagia with both liquids and solids occurs more often with motility disorders. Patients with oropharyngeal dysphagia will commonly complain of a feeling of food "sticking" in the throat or the inability to propel the bolus from the mouth to the pharynx; they may also complain of the need for multiple swallowing motions to clear the bolus. Because the cranial nerves that generally control the initial phases of swallowing are responsible for other functions as well, symptoms that may be associated with oropharyngeal dysphagia include drooling, dysarthria (due to tongue dysfunction), nasal regurgitation (due to failure to seal off the nasal passage), or coughing and aspiration (due to failure to elevate and cover the laryngeal vestibule). Dysphagia that results from abnormalities in the body of the esophagus may be referred to the chest or the neck, so the location of pain does not predict the location of the disease. Dysphagia may also lead to a variety of behavioral accommodations, including maneuvers such as slow eating, food aversion, avoidance of hard solid food, and drinking of large amounts of liquids with solid meals.

Regurgitation, which is another typical esophageal symptom, may be described as the feeling of food coming up into the chest or, more dramatically, into the mouth. When regurgitation occurs early in the meal, it suggests a proximal lesion. Regurgitation later in the meal suggests a motility abnormality such as achalasia.

Food impaction is an extreme esophageal symptom. When impaction occurs in the oropharynx, patients may develop a "steakhouse" syndrome, in which an impacted food bolus leads to tracheal impaction or compression. With more distal esophageal lesions, impaction may occur any time during the meal, almost always from a mechanical cause. Patients experience the sudden onset of chest pain and the sensation of food sticking, typically after solids such as meats, raw vegetables, and sometimes sticky rice. With complete impaction, patients who cannot handle secretions because of the obstructing bolus are at risk of aspiration.

GASTROESOPHAGEAL REFLUX DISEASE

DEFINITION

Gastroesophageal reflux disease (GERD) develops when the reflux of stomach contents into the esophagus causes troublesome symptoms or complications.

EPIDEMIOLOGY

It is estimated that GERD, defined as at least weekly heartburn or acid regurgitation, has a prevalence ranging from 10 to 20% in the Western world and less than 5% in Asia. The prevalence also tends to be higher in North America than Europe and higher in northern Europe than in southern Europe. Risk factors for developing GERD include obesity and possibly increasing age. A genetic component may also play a role because GERD is more common in patients with a positive family history and in a monozygotic than in a dizygotic twin.

PATHOBIOLOGY

The esophagus is protected from the harmful effects of refluxed gastric contents by the antireflux barrier at the gastroesophageal junction, by esophageal clearance mechanisms, and by epithelial defensive factors. The antireflux barrier consists of the lower esophageal sphincter, crural diaphragm, phrenoesophageal ligament, and the angle of His, which causes an oblique entrance of the esophagus into the stomach. The attachment of the lower esophageal sphincter to the crural diaphragm results in increased pressure during inspiration and when intra-abdominal pressure increases. Disruption of normal defense mechanisms leads to pathologic amounts of reflux.

Reflux of gastric contents from the stomach into the esophagus occurs in healthy individuals, but refluxed gastric contents are normally cleared in a two-step process: volume clearance by peristaltic function and neutralization of small amounts of residual acid by weakly alkaline swallowed saliva. In normal healthy individuals, physiologic reflux occurs primarily when the lower esophageal sphincter transiently relaxes in the absence of a swallow because of a vagally mediated reflex that is stimulated by gastric distention.

In GERD patients, transient relaxation of the lower esophageal sphincter or a low resting lower esophageal sphincter pressure can result in regurgitation, especially when intra-abdominal pressure is increased.

A hiatal hernia, which results in spatial separation between the augmenting effects of the crural diaphragm and the lower esophageal sphincter, predisposes to reflux events by widening the opening of the gastroesophageal junction and decreasing the pressure of the lower esophageal sphincter. The result is an increased exposure of the esophagus to acid, with increased reflux events during transient physiologic relaxation of the lower esophageal sphincter. Hernias also act as a reservoir for gastric contents when normal esophageal clearance mechanisms result in trapping of fluids in the hernia sac; these contents can reflux into the esophagus when the lower esophageal sphincter relaxes during subsequent swallowing.

Obesity results in an increase in intragastric pressure, which increases the gastroesophageal pressure gradient and the frequency of transient lower esophageal sphincter relaxation, thereby predisposing gastric contents to migrate into the esophagus. In addition, obesity enhances the spatial separation of the crural diaphragm and the lower esophageal sphincter, thereby predisposing obese individuals to a hiatal hernia.

The normal defense mechanisms based on peristalsis and saliva can also be impaired. Peristaltic dysfunction is associated with an increasing severity of esophagitis, and ineffective peristaltic clearance may occur when the amplitude of esophageal contractions is less than 30 mm Hg. Saliva production may be impaired by a variety of mechanisms, such as smoking and Sjögren's syndrome (Chapter 276).

The esophageal mucosa contains several lines of defense. A pre-epithelial barrier is composed of a small unstirred water layer combined with bicarbonate from swallowed saliva and from the secretions of submucosal glands. A second epithelial defense is composed of cell membranes and tight intercellular junctions, cellular and intercellular buffers, and cell membrane ion transporters. The postepithelial line of defense is composed of the blood supply to the esophagus. Acid and acidified pepsin in the refluxate are the key factors that damage the intercellular junctions, increase intracellular permeability, and dilate intercellular spaces. If sufficient quantities of refluxate diffuse into the intercellular spaces, cellular damage may occur. Signs and symptoms of GERD occur when defective epithelium comes into contact with refluxed acid, pepsin, or other noxious gastric contents. In addition to the direct noxious effects of refluxed acid, pepsin, and bile, refluxed gastric juice stimulates esophageal epithelial cells to secrete chemokines that attract inflammatory cells into the esophagus, thereby damaging the esophageal mucosa.

CLINICAL MANIFESTATIONS

The classic symptoms of GERD are heartburn and acid regurgitation; atypical symptoms include chest pain, dysphagia, and odynophagia. Extraesophageal manifestations of reflux disease can include cough (Chapter 83), laryngitis (Chapter 437), asthma (Chapter 87), and dental erosions, but these symptoms can be reliably attributed to reflux only if they are accompanied by classic signs and symptoms of reflux disease. Other proposed associations that are not clearly established include pharyngitis, sinusitis, otitis media, and idiopathic pulmonary fibrosis (Fig. 140-1).

When excessive gastric contents overwhelm the mucosal protective factors in the esophagus, esophagitis may be manifest as erosions or ulceration of the esophagus and may also lead to fibrosis with stricturing, columnar metaplasia (Barrett's esophagus) or esophageal adenocarcinoma (Chapter 198). However, approximately two thirds of individuals with reflux symptoms have no evidence of esophageal damage by endoscopy.

DIAGNOSIS

When GERD presents with typical signs and symptoms, such as heartburn or acid regurgitation, that are responsive to antisecretory therapy, no diagnostic evaluation is warranted. Diagnostic endoscopy is warranted in individuals who fail to respond to therapy or have alarm symptoms or signs such as dysphagia (see Fig. 134-6 in Chapter 134), weight loss, anemia, gastrointestinal bleeding, or persistent heartburn (Fig. 140-2). Endoscopy permits the detection of erosive esophagitis and complications such as a peptic stricture (Fig. 140-3) and Barrett's esophagus (Fig. 140-4); mucosal biopsy, which is crucial in these settings, also excludes conditions that can mimic GERD, such as eosinophilic esophagitis. However, most patients have no mucosal damage seen on endoscopy, regardless of whether they are on or off antisecretory therapy.

Esophageal manometry is useful to exclude achalasia in patients with suggestive symptoms. Esophageal reflux testing by 24-hour transnasal pH monitoring, by 48-hour devices attached to the esophageal lumen, or by 24-hour combined impedance and pH monitoring, may be performed while patients are not on therapy to detect pathologic acid and nonacid reflux as well to correlate reflux events with atypical symptoms, especially in patients with normal endoscopies. Barium radiography has no role in the diagnostic evaluation of patients with reflux disease.

TREATMENT Rx

Although avoidance of foods or beverages that may provoke symptoms, such as alcohol, coffee, spicy foods, and late meals, makes physiologic sense, data from clinical trials to support these maneuvers are lacking. Similarly, elevation of the head of the bed for patients with nocturnal regurgitation or heartburn also is logical. Given the association of obesity and GERD symptoms, weight loss should be part of any treatment program for obese patients.

Inhibition of gastric acid secretion (Table 140-1) is the cornerstone of the acute treatment of GERD, and proton pump inhibitors (PPIs) are superior to histamine (H_2)-receptor antagonists for both the healing of esophagitis and the control of symptoms.[1] However, the healing of esophagitis is more predictable than improvement in heartburn symptoms, even with PPIs.[2] There are no major differences in treatment efficacy among the various PPIs, and once-daily dosing is adequate.

Given the chronicity of reflux symptoms, long-term maintenance therapy with PPIs is typically required, with dosing titrated to the lowest dose necessary to control symptoms. Data to support the use of PPIs in the management of extraesophageal GERD syndromes are weak, although selected patients may benefit. The safety profile of PPIs is excellent, but short-term adverse events such as headaches and diarrhea may occur. Recent epidemiologic studies suggest that long-term PPI use may be associated with an increased risk of *Clostridium difficile* infection, community-acquired pneumonia, hip fracture, and vitamin B_{12} deficiency.

Although PPIs are superior to H_2-receptor antagonists for long-term maintenance therapy as well as for short-term relief, H_2-receptor antagonists are

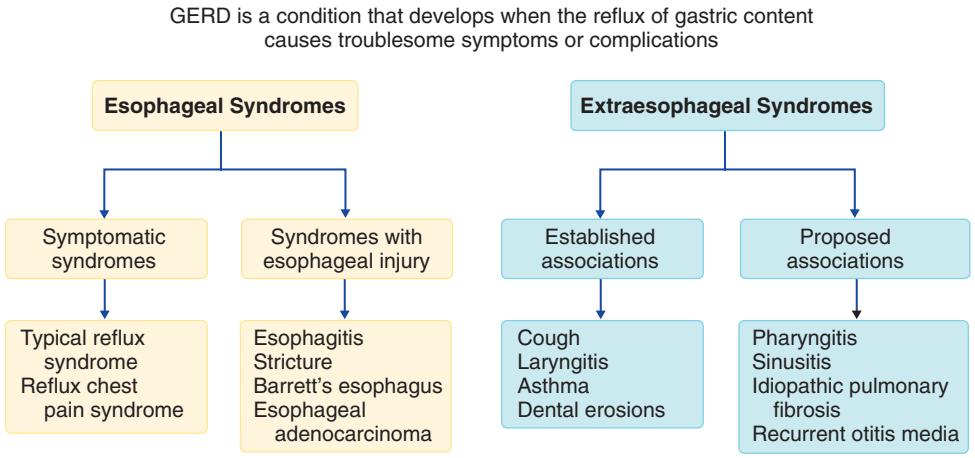

FIGURE 140-1. Montreal classification of gastroesophageal reflux disease (GERD). (From Vakil N, van Zanten S, Kahrilas P, et al. The Montreal definition and classification of gastroesophageal reflux disease: a global evidence-based consensus. *Am J Gastroenterol.* 2006;101:1900-1920.)

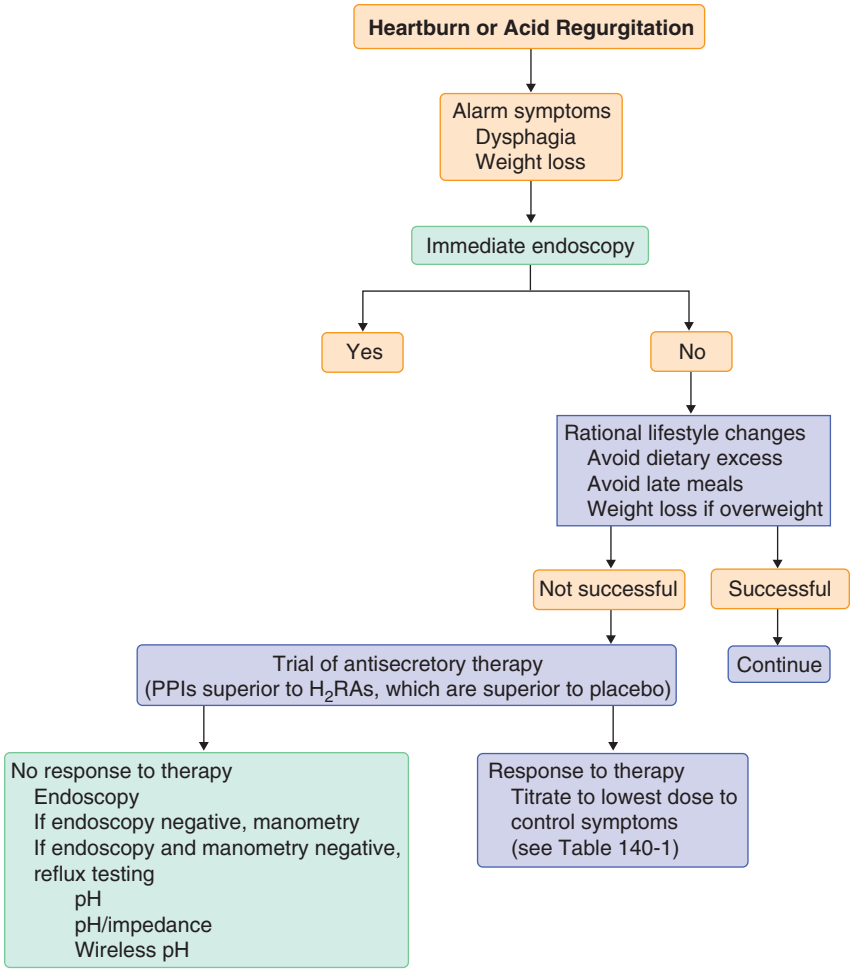

FIGURE 140-2. Algorithm for the management of heartburn or regurgitation symptoms. Surgery is indicated only for patients who are intolerant of antisecretory therapy or who have ongoing symptoms, especially regurgitataion if reflux is well documented. H_2RA = histamine-2 receptor antagonist; PPI = proton pump inhibitor. (Based on Kahrilas PJ, Shaheen NJ, Vaezi MF. American Gastroenterological Association Institute technical review on the management of gastroesophageal reflux disease. *Gastroenterology.* 2008;135:1392-1413.)

TABLE 140-1 DRUG THERAPY FOR ESOPHAGEAL DISORDERS

AGENT	DOSE
ANTACIDS: LIQUID (TO BUFFER ACID AND INCREASE LESP)	
For example, Mylanta II/Maalox TC (acid-neutralizing capacity, 25 mEq/5 mL)*	15 mL qid 1 hour after meals and at bedtime or as needed
GAVISCON (TO DECREASE REFLUX VIA A VISCOUS MECHANICAL BARRIER AND BUFFER ACID)	
$Al(OH)_3$, $NaHCO_3$, Mg trisilicate, alginic acid	2-4 tablets qid at bedtime or as needed
H_2-RECEPTOR ANTAGONISTS (TO DECREASE ACID SECRETION)	
Cimetidine	800 mg bid, 400 mg qid, ≈13 mL bid
Ranitidine	150 mg qid or 10 mL qid; maintenance dose, 150 mg bid, 10 mL bid
Famotidine	20-40 mg bid or 2.5-5 mL bid
Nizatidine	150 mg bid
PROTON PUMP INHIBITORS (TO DECREASE ACID SECRETION AND GASTRIC VOLUME)†	
Omeprazole	20 mg/day; maintenance dose, 20 mg/day
Lansoprazole	30 mg/day; maintenance dose, 15 mg/day
Pantoprazole	40 mg/day; maintenance dose, 40 mg/day
Rabeprazole	20 mg/day; maintenance dose, 20 mg/day
Esomeprazole	20-40 mg/day; maintenance dose, 20 mg/day
Dexlansoprazole	30-60 mg/day; maintenance dose, 30 mg/day

*Patients with reflux are not generally hypersecretors of gastric acid, so the therapeutic doses of antacids are based on their capacity to buffer (normal) basal acid secretion rates of approximately 1 to 7 mEq/hr (mean, 2 mEq/hr) and peak meal-stimulated acid secretion rates of about 10 to 60 mEq/hr (mean, 30 mEq/hr).
†High-dose therapy is a twice-daily administration of the usually daily dose.
LESP = lower esophageal sphincter pressure.

superior to placebo, are useful in patients who are intolerant of PPIs, and can be used at bedtime■ to supplement PPIs in patients who have persistent symptoms. No high-quality data exist to support the common practice of using metoclopramide as either monotherapy or an adjunct to acid suppression therapy■; furthermore, its significant adverse effects argue against the use of this drug in any GERD patients.

Antireflux surgery is an option for patients who have documented esophagitis and who are intolerant of PPIs or unresponsive to them. For the healing of esophagitis, laparoscopic fundoplication yields results comparable to continued PPI therapy.■ However, surgery has a number of serious complications that may affect quality of life, including dysphagia, vagal nerve injury, gas bloat syndrome, and diarrhea. There are inadequate data to support any of the many proposed endoscopic approaches to GERD at present.

PROGNOSIS

Patients with GERD generally do well with conservative antireflux measures and PPI therapy. When surgery is required, the outcome is usually excellent.

Peptic Strictures

Esophageal strictures are a well-recognized complication of GERD, especially in older patients with long-standing reflux symptoms, but population-based studies suggest that the incidence of new and recurrent strictures is declining. Peptic strictures are thought to be a consequence of severe inflammation, which leads to fibrosis, scarring, esophageal shortening, and loss of compliance of the lumen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are typically dysphagia to solids with or without antecedent symptoms of heartburn or acid regurgitation. Strictures may be diagnosed by barium radiography or with upper endoscopy, but barium esophagrams (see Fig. 140-3) have a higher sensitivity for detecting subtle lesions, especially if performed with a solid challenge such a barium-impregnated pill. However, peptic strictures must be distinguished from a wide variety of other causes of luminal narrowing, including pills, prior nasogastric tube intubation, neoplasia, infection, radiation, surgical anastomosis, systemic diseases, caustic substances, and extrinsic compression. As a result, endoscopic biopsy and cytology are critical for differentiating benign from malignant causes of strictures.

TREATMENT Rx

Endoscopic dilation, which remains the cornerstone of therapy, should be done gradually to achieve a luminal diameter that is sufficiently large to relieve symptoms—typically a diameter of 13 mm or greater. After dilation is accomplished, patients should receive chronic PPI therapy (see Table 140-1). For recalcitrant peptic strictures, injection of triamcinolone into the stricture is superior to sham injection in patients who receive balloon dilation and post-procedure PPIs.■

PROGNOSIS

Endoscopic dilation will usually alleviate symptoms, but repetitive dilation is required in a significant minority of patients.

Barrett's Esophagus

Barrett's esophagus, which is an acquired condition that results from severe esophageal mucosal injury, is a metaplastic change in the lining of the distal tubular esophagus, where the normal squamous epithelium is replaced by columnar epithelium. Barrett's esophagus would be of little importance if not for its well-recognized association with adenocarcinoma of the esophagus (Chapter 198). However, the risk of cancer in an individual patient with Barrett's esophagus is low.

EPIDEMIOLOGY

It is estimated that Barrett's esophagus is found in approximately 5 to 15% of patients who undergo endoscopy for symptoms of GERD. Population-based studies suggest that the prevalence of Barrett's esophagus is approximately 1.3 to 1.6%, but about 45% of affected patients do not have reflux symptoms. Barrett's esophagus is predominantly a disease of middle-aged white men, but about 25% of patients are women or are less than 50 years of age. The prevalence of Barrett's esophagus increases until a plateau is reached between the seventh and ninth decades. Risk factors include frequent and long-standing reflux episodes, smoking, male gender, older age, and central male pattern obesity.

PATHOBIOLOGY

Barrett's esophagus results from severe esophageal mucosal injury. Patients who develop Barrett's esophagus typically have more esophageal acid exposure, based on 24-hour pH monitoring, and almost always have a hiatal hernia, which is typically longer and associated with larger defects than in patients without Barrett's. However, why some patients with GERD develop Barrett's esophagus whereas others do not remains unclear, as does the cell of origin of columnar metaplasia. Candidates include dedifferentiation of squamous epithelium into columnar epithelium or stimulation of stem cells from either the basal layer of the esophageal epithelium, the esophageal submucosal glands, or the bone marrow. The transcription factor CDX2, which can be induced by both acid and bile salts, appears to play a role in promoting the development of the columnar epithelium. A small subset of patients may have an inherited predisposition, perhaps with an autosomal dominant pattern.

CLINICAL MANIFESTATIONS

The development of reflux symptoms at an earlier age, an increased duration of reflux symptoms, an increased severity of nocturnal reflux symptoms, and prior complications of GERD such as esophagitis, ulceration, stricture, and bleeding may raise the likelihood of Barrett's esophagus. Nevertheless, patients with Barrett's esophagus are difficult to distinguish clinically from patients whose GERD is uncomplicated by a columnar-lined esophagus. Patients with Barrett's esophagus may paradoxically have impaired sensitivity to esophageal acid perfusion compared with patients with uncomplicated GERD.

DIAGNOSIS

Endoscopically, Barrett's esophagus is characterized by displacement of the squamocolumnar junction so that it is now proximal to the gastroesophageal junction, which is defined by the proximal margin of gastric folds (Fig. 140-4). The diagnosis of Barrett's esophagus is established if a biopsy determines that the squamocolumnar junction is displaced proximal to the gastroesophageal junction and if intestinal metaplasia, which is characterized in part by acid mucin-containing goblet cells, is detected.

The precise junction of the stomach and the esophagus may be difficult to determine endoscopically owing to the presence of a hiatal hernia, inflammation, and the dynamic nature of the gastroesophageal junction. If the squamocolumnar junction is above the level of the esophagogastric junction, as defined by the proximal margin of the gastric folds, biopsy specimens should be obtained for confirmation of columnar metaplasia.

Intestinal metaplasia may be seen in the cardia of normal individuals as well as in persons with chronic reflux disease, and the prevalence of intestinal metaplasia at a normal-appearing gastroesophageal junction varies from 5 to 36%. Dysplasia and an increased risk of carcinoma have been reported in patients who have intestinal metaplasia of the gastroesophageal junction or cardia, but the magnitude of that risk appears to be less than that of short-segment Barrett's esophagus.

TREATMENT Rx

Patients who are diagnosed with Barrett's esophagus require surveillance endoscopy at regular intervals (Fig. 140-5). They characteristically worry about cancer risk, which they typically overestimate, face higher life insurance premiums, and may receive conflicting information on how best to treat their condition.

PPIs (see Table 140-1), which are the cornerstone of medical therapy for Barrett's esophagus, consistently relieve symptoms and heal esophagitis. However, PPIs, even at high doses, provide no more than modest regression of Barrett's histology, perhaps because alleviation of reflux symptoms is not necessarily equivalent to normalization of esophageal acid exposure. In fact, abnormal acid exposure persists in approximately 25% of Barrett's esophagus patients despite twice-daily PPIs. The importance of complete control of esophageal acid exposure in patients with Barrett's esophagus remains unknown. Antireflux surgery also effectively alleviates GERD symptoms in these patients, and the indications for surgery are the same as those for patients with GERD without Barrett's esophagus. Surgery should not, however, be viewed as a cancer prevention tool.

Current practice guidelines, based on observational data, recommend endoscopic surveillance of patients with documented Barrett's esophagus in an attempt to detect dysplasia and cancer at an early and potentially curable stage. Before entering into a surveillance program, patients should be advised about risks and benefits, including the limitations of surveillance endoscopy as well as the importance of adhering to appropriate surveillance intervals. Other considerations include age, likelihood of survival over the next 5 years, and ability to tolerate either endoscopic or surgical interventions for early esophageal adenocarcinoma.

Systematic four-quadrant biopsies should be obtained at 2-cm intervals along the entire length of the Barrett's segment after inflammation related to GERD is controlled with antisecretory therapy. Mucosal abnormalities, especially in the setting of high-grade dysplasia, should be resected endoscopically. Surveillance intervals, determined by the presence and grade of dysplasia, are based on a limited understanding of the biology of esophageal adenocarcinoma. Surveillance initially should be annual in patients with metaplasia, but surveillance every 3 years is adequate after two negative examinations. If low-grade dysplasia is found, the diagnosis should be confirmed by an expert gastrointestinal pathologist because of the marked interobserver variability in the interpretation of these biopsies. If confirmed, aggressive PPI therapy (see Table 140-1) is recommended to decrease inflammation and regeneration, which may make pathologic interpretation difficult. A repeat endoscopy

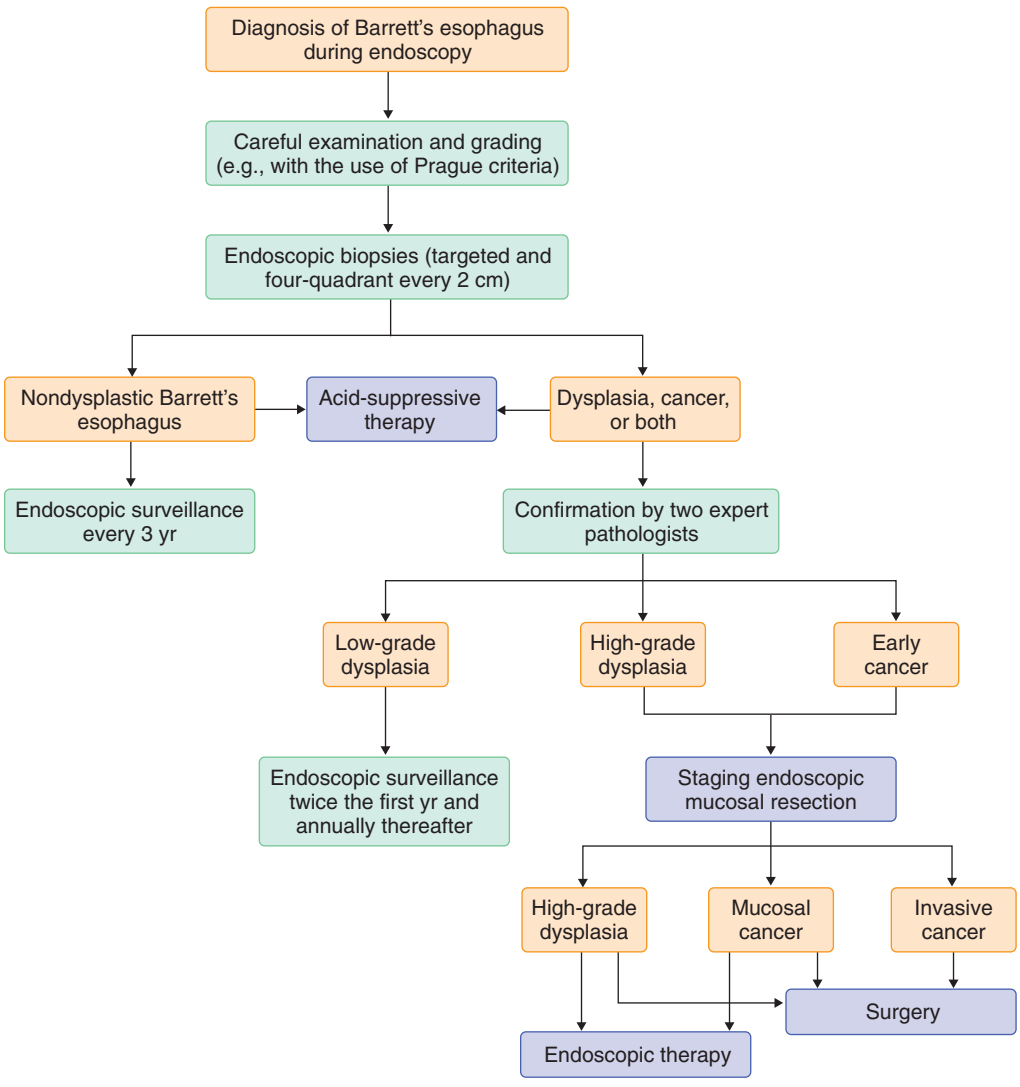

FIGURE 140-5. Proposed treatment algorithm for patients with Barrett's esophagus. (From Sharma P. Barrett's esophagus. *N Engl J Med.* 2009;361:2548-2556, Fig. 3).

should then be performed within 6 months of the initial diagnosis. If low-grade dysplasia is confirmed, annual surveillance is recommended until two consecutive examinations are negative for dysplasia.

If high-grade dysplasia is found, the diagnosis should be confirmed by an experienced gastrointestinal pathologist. Treatment options include continued surveillance, endoscopic therapy by a variety of different methods, or esophagectomy. Factors to consider include the available surgical and endoscopic expertise, age, length of Barrett's epithelium that would require biopsy to eliminate sampling error, compliance with endoscopic surveillance, future need for multiple surveillance endoscopies, and suspicious lesions such as plaque, nodules, and strictures. Currently, endoscopic mucosal resection and radiofrequency ablation■ are the most promising of the endoscopic methods.

PROGNOSIS

The risk that a patient with Barrett's esophagus will develop esophageal adenocarcinoma is approximately 0.5% to 0.7% annually. These data also emphasize that most patients with Barrett's esophagus will never develop esophageal cancer.

ESOPHAGITIS

Eosinophilic Esophagitis

Eosinophilic esophagitis is probably caused by an aberrant immune or antigenic response to food and aeroallergens that trigger chronic inflammation in the esophageal mucosa. The disease is most common in children and adolescents, but adults are commonly affected as well. Patients often have a personal and family history of other allergic disorders. A genetic predisposition is suggested by the finding of an abnormal eotaxin gene in almost 50% of children with this disorder.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Children present with dyspeptic symptoms, whereas adults classically present with solid food dysphagia, food impaction, or chest pain. Diagnosis is made by classic findings on endoscopy, such as linear furrowing and multiple rings (Fig. 140-6), accompanied by biopsies demonstrating eosinophilic infiltration (Table 140-2).

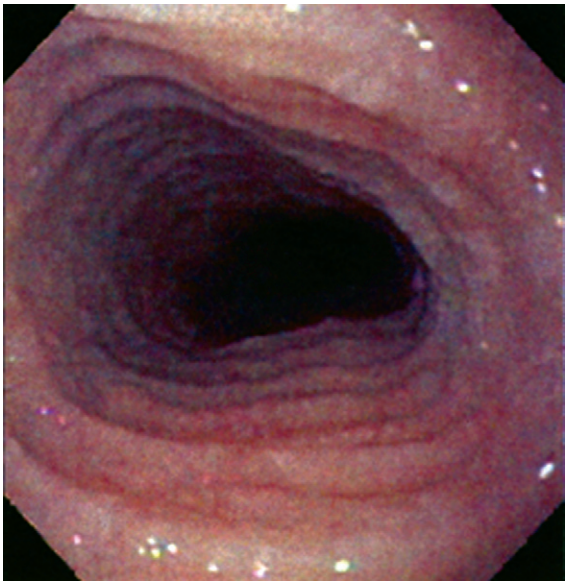

FIGURE 140-6. Endoscopic corrugated (ringed) appearance of esophagus in eosinophilic esophagitis.

TREATMENT AND PROGNOSIS

Rx

Treatment is a 2-month course of topical steroids, such as swallowed fluticasone (440-880 µg twice daily) or budesonide suspension (1 mg twice daily, for 15 days, followed by 0.25 mg twice daily)■ or occasionally a 1-month course of systemic steroids (e.g., prednisone, starting at 40 mg and then tapering). Patients also should undergo a formal allergy evaluation (Chapter 257) to determine whether any food trigger can be identified and avoided. Another option is an empirical six-food elimination diet that eliminates cow's milk protein (casein), soy, wheat, egg, peanut/tree nuts, and seafood. Most patients do well after treatment.

Pill-Induced Esophagitis

Pills (Table 140-3) can induce esophageal injury by producing a caustic acid solution (e.g., ascorbic acid and ferrous sulfate), producing a caustic alkaline solution (e.g., alendronate, button batteries), placing a hyperosmolar solution in contact with the esophageal mucosa (e.g., potassium chloride), or causing direct drug toxicity to the esophageal mucosa (e.g., tetracycline). Because prolonged contact is an essential part of the injury, predisposing factors for pill-induced injury include anatomic barriers, such as a stricture, a prominent aortic arch that compresses the esophagus, or improper ingestion of the pill because of inadequate fluid or improper positioning (i.e., lying down directly after taking the pill). The most common medications are tetracycline and its derivatives, but other commonly implicated medications include nonsteroidal anti-inflammatory drugs (NSAIDs), bisphosphonates, ferrous sulfate, quinidine, and potassium chloride.

Patients usually complain of the acute onset of severe odynophagia. Radiographic or endoscopic findings may range from a discrete ulceration to diffuse esophagitis. Treatment is generally supportive with discontinuation of the medication until the injury resolves. Although acid suppression is commonly recommended, there is no proven evidence for its benefit. Patients should be given careful instructions to avoid lying down immediately after ingesting

TABLE 140-3 MEDICATIONS COMMONLY ASSOCIATED WITH ESOPHAGITIS OR ESOPHAGEAL INJURY

ANTIBIOTICS
Tetracycline
Doxycycline
Clindamycin

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS
Aspirin
Naproxen
Ibuprofen
OTHER MEDICATIONS
Quinidine
Potassium chloride
Ferrous sulfate
Ascorbic acid
Multivitamins
Theophylline

medication and to drink adequate fluids helps prevent injury. Rarely, pill-induced injury may lead to strictures and even fistulas.

Caustic Injury

Potentially devastating caustic esophageal injuries may be caused by highly alkaline solutions, such as sodium hydroxide, or highly acidic solutions, such as sulfuric acid. The most common products that contain these substances are drain cleaners and industrial strength cleaners, but other corrosive substances include hair relaxers, oven and toilet bowl cleaners, and button batteries. Patients require emergent endoscopy to determine the degree of injury, which helps predict long-term prognosis. No clear evidence supports routine steroids or antibiotics. Many patients will have lifelong disease marked by chronic strictures that require frequent dilation and even esophageal reconstruction. In patients with a severe initial injury, the risk of esophageal cancer is significantly increased.

ESOPHAGEAL MOTOR DISORDERS

Oropharyngeal Dysfunction

The cricopharyngeus and inferior pharyngeal constrictor are composed of striated muscle and innervated by upper motor neurons, the brain stem, and the cerebral cortex. Both primary myopathic and neuropathic disorders can result in dysfunction. The most common neurologic cause of oropharyngeal dysphagia is a cerebrovascular accident (Chapter 414). Other neuropathic disorders that may also affect function include myasthenia gravis (Chapter 430), brain stem tumors (Chapter 195), amyotrophic lateral sclerosis (Chapter 418), Parkinson's disease (Chapter 416), Alzheimer's disease (Chapter 409), postpolio syndrome (Chapter 423), Guillain-Barré syndrome (Chapter 428), and botulism (Chapter 304). Myogenic disorders that cause dysfunction include paraneoplastic antibody-mediated syndromes (Chapter 187), thyroid disease (Chapter 233), primary myopathies (Chapter 429) such as dermatomyositis, and drugs that cause myopathy such as statins and amiodarone.

Patients with oropharyngeal abnormalities experience dysphagia, often accompanied by postprandial coughing, hoarseness, and aspiration pneumonia. Treatment focuses on the underlying myopathic or neurologic cause, but prognosis is often poor owing to limited treatment options.

Achalasia

Achalasia, which is the prototypic esophageal motility disorder, is characterized by a hypertensive lower esophageal sphincter with incomplete relaxation upon swallowing, accompanied by aperistalsis of the esophageal body.

EPIDEMIOLOGY AND PATHOBIOLOGY

Achalasia can occur in patients of almost any age, from infants to nonagenarians, but it most commonly presents between 25 and 60 years of age. The prevalence is 10 per 100,000 in the United States, with all races affected and an equal distribution in men and women. The pathophysiology of achalasia most likely reflects an antibody-mediated autoimmune myenteric plexopathy in the lower esophageal sphincter and a generalized neuropathy in the esophageal body. The triggering event is unclear, but a viral cause is suggested. Injury to the lower esophageal sphincter neurons leads to a relative selective deficiency of nitric oxide. With this loss of the main functional inhibitory neurotransmitter, the sphincter becomes hypertensive and loses its ability to relax. The neurochemical process that leads to aperistalsis is unclear.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The cardinal symptoms of achalasia are dysphagia to both liquids and solids, regurgitation, and chest pain. Some patients may have more subtle symptoms, including heartburn, presumably caused by esophageal stasis of acidic food content, weight loss, and aspiration pneumonia; in these settings, diagnosis is often delayed.

The diagnosis of achalasia relies on esophageal manometry and barium radiography. The classic radiographic appearance is esophageal dilation, stasis of contrast material, and a "bird's beak" appearance to the lower esophageal sphincter (Fig. 140-7). Manometry demonstrates high residual pressures of the lower esophageal sphincter and either simultaneous contractions or complete absence of peristaltic contractions. Endoscopy is recommended to exclude secondary causes of achalasia, such as cancer of the gastroesophageal junction. Occasional patients present with a massively dilated esophagus and marked persistent food retention. Radiographically, these patients develop a "sigmoid" esophagus with a radiographic picture similar to a sigmoid colon.

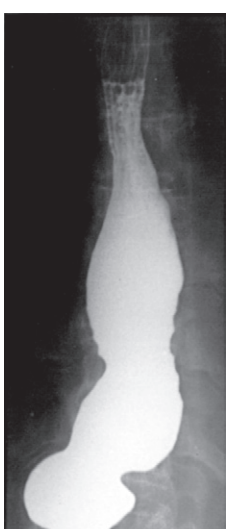

FIGURE 140-7. Esophagogram of a patient with idiopathic achalasia. Note the dilated esophagus with an air-fluid level and distal tapering providing a "bird's beak" deformity in the area of the lower esophageal sphincter. (From Feldman M, Friedman LS, Sleisenger MH, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology, Diagnosis, Management,* 7th ed. Philadelphia: Saunders; 2002.)

Achalasia may represent a paraneoplastic presentation of some malignancies, particularly small cell carcinoma of the lung (Chapter 197); in these patients, the tumor produces an antineuronal antibody (anti-Hu) that mediates the autoimmune lower esophageal sphincter plexopathy and produces a syndrome identical to primary achalasia. Some tumors, such as proximal gastric cancer, may also metastasize to or directly extend into the lower esophageal sphincter and produce an achalasia-like picture, possibly owing to extrinsic compression or tumor infiltration.

TREATMENT

Rx

Treatment options to decrease the functional obstruction at the level of the lower esophageal sphincter include the intrasphincteric injection of botulinum toxin, pneumatic dilation, and cardiomyotomy. Injection of botulinum toxin during endoscopy reduces symptoms and improves esophageal emptying in up to 90% of patients. Because symptoms typically recur within 1 to 2 years, this treatment is best for patients who are not candidates for more definitive therapies or to confirm the diagnosis of achalasia when clinical, radiographic, and manometric criteria are not conclusive.

In pneumatic dilation, a 30- to 40-mm pneumatic balloon is placed fluoroscopically to straddle the lower esophageal sphincter; the balloon is then inflated to tear the muscle fibers of the lower esophageal sphincter. In general, one dilation will achieve 5 years of symptomatic remission in 40% of patients, and three dilations will succeed in 90% of patients. The downside of this procedure is the risk of perforation, which occurs in up to 5% of patients.

The third approach is a Heller myotomy, which is now typically performed laparoscopically. This long myotomy starts at least 2 cm below the lower esophageal sphincter and extends for about 6 cm upward past the sphincter; a loose fundoplication is performed to prevent gastroesophageal reflux. The 5-year success rate approaches 90%.

In patients with massive dilation, esophageal dysfunction may warrant total esophagectomy because of life-threatening symptoms such as continued weight loss, recurrent aspiration pneumonia, or tracheal compression. In patients with underlying malignancy, treatment of the tumor may be helpful, and botulinum toxin has been tried with anecdotal success.

PROGNOSIS

No treatment approach is curative, and all are palliative. Recurrent symptoms may be related to an incomplete myotomy, herniation or unwrapping of the fundoplication, esophageal strictures, Barrett's esophagus, or just the natural history of the disease. Achalasia patients may also be predisposed to squamous cell carcinoma of the esophagus, and some recommend yearly screening for patients who have a chronically large dilated esophagus.

Diffuse Esophageal Spasm

Diffuse esophageal spasm is found in less than 5% of patients who undergo manometry for symptoms of chest pain, dysphagia, or both. The pathophysiology of diffuse esophageal spasm is not well understood, but a deficiency of nitric oxide in the esophageal body may lead to a loss of control of esophageal peristalsis, high pressures, and rapid velocity contractions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Classically, patients have symptoms of intermittent chest pain (Chapter 139), dysphagia, or both. On endoscopic ultrasound, patients may demonstrate thickening of the circular and longitudinal muscle layers. Diffuse esophageal spasm is defined manometrically by simultaneous contractions in at least 20% of all swallows, accompanied by normal peristalsis. Other manometric features include repetitive contractions, high-amplitude contractions with multiple peaks, and variable relaxation of the lower esophageal sphincter. Radiographically, diffuse esophageal spasm is characterized by a "corkscrew" esophagus with multiple simultaneous contractions that obliterate the lumen (Fig. 140-8).

TREATMENT AND PROGNOSIS

Rx

Treatment of these patients is challenging, and clinical trials have not demonstrated efficacy of any therapy. Empirical therapy may be tried with agents that relax smooth muscle or augment the nitric oxide content, such as hyoscyamine (0.125 mg sublingually), calcium-channel antagonists (nifedipine, 10 mg sublingually), nitroglycerin (0.3 mg sublingually), and sildenafil (50 mg orally). Injection of botulinum toxin into the esophageal body has had equivocal results. Antidepressants, particularly low-dose tricyclics (e.g., imipramine, 10 to 50 mg before bedtime), have had some success. For patients with dysphagia, sphincter options include botulinum toxin injection and pneumatic dilation, but surgery is not indicated unless there is evidence of achalasia. In general, these disorders can be difficult to manage but are not life-threatening.

Other Motility Disorders

Nutcracker esophagus, which is a manometric diagnosis characterized by high-amplitude contractions, likely represents a manometric epiphenomenon of little clinical significance. Antisecretory therapy with PPIs (see Table 140-1) is often warranted.

A hypertensive lower esophageal sphincter is of unknown significance, but isolated incomplete relaxation of the lower esophageal sphincter may represent an achalasia variant and should be treated as such. Patients with manometric findings of low-amplitude contractions, failed contractions, or prolonged nonpropagated contractions have hypotensive peristalsis, which is typically seen in patients with severe underlying GERD.

STRUCTURAL ABNORMALITIES

Cricopharyngeal Bars

A cricopharyngeal bar, which is caused by a prominent impression of the cricopharyngeus, reflects an inability to relax the upper esophageal sphincter maximally during the flow of barium, with a sustained increase in pressure. The decrease in cross-sectional area of the upper esophageal sphincter is likely caused by fibrosis. This condition may be asymptomatic or accompanied by symptoms of oropharyngeal dysphagia to solids. Treatment of symptomatic patients is usually surgical, and the response is generally excellent.

Esophageal Diverticula

Esophageal diverticula are encountered in less than 1% of upper gastrointestinal radiographic studies and account for less than 5% of cases of dysphagia. Esophageal diverticula may occur in one of three locations: above the upper esophageal sphincter, in the mid-esophagus, and just above the lower esophageal sphincter.

Zenker's diverticulum is a pouch that protrudes posteriorly above the upper esophageal sphincter (Fig. 140-9). This protrusion occurs through a triangular region known as Killian's triangle, which is bordered above by fibers of the inferior constrictor muscle and below by the cricopharyngeal muscle. It is thought to be caused by increased hypopharyngeal pressure that results from decreased compliance and impaired opening of the upper esophageal sphincter. Small diverticula may be asymptomatic, but increasing size is associated with such symptoms as globus, dysphagia to solids or liquids, regurgitation of undigested food, halitosis, and aspiration. Although no treatment is needed for asymptomatic patients, open or endoscopic surgery is indicated when symptoms occur. Prognosis after surgery is excellent.

Mid-esophageal diverticula, which are focal outpouchings of the middle of the esophagus, are thought to be related to an underlying abnormality of esophageal motility. Symptoms typically include dysphagia with or without regurgitation, and diagnosis is usually made with barium contrast radiography. Surgical diverticulectomy with myotomy is reserved for patients with symptoms.

Epiphrenic diverticula are herniations of mucosa and submucosa through the muscular layers of the distal 10 cm of the esophagus. They may be caused by functional obstruction, owing to underlying motility abnormalities, such as achalasia or diffuse esophageal spasm, or a mechanical obstruction, owing to a leiomyoma, prior surgery, stenosis, stricture tumor, or web. Epiphrenic diverticula may be asymptomatic or cause dysphagia, regurgitation,

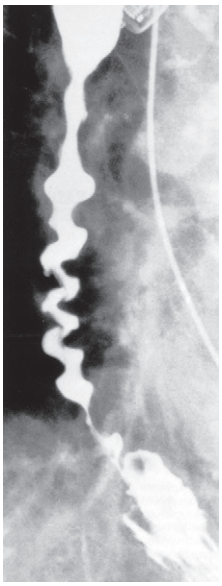

FIGURE 140-8. Barium esophagogram showing a "corkscrew" esophagus in a patient with diffuse esophageal spasm. The patient had dysphagia, chest pain, and normal endoscopic findings. (From Feldman M, ed. *Gastroenterology and Hepatology: The Comprehensive Visual Reference,* New York: Churchill Livingstone; 1997.)

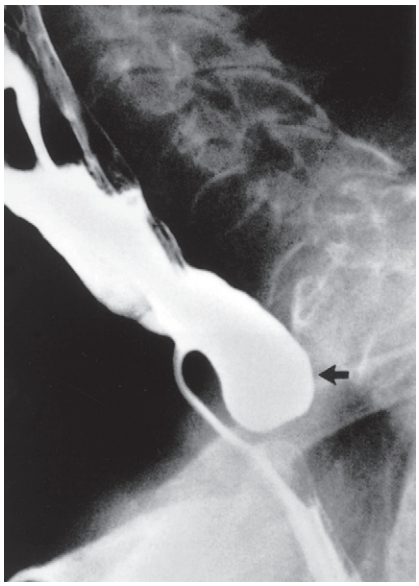

FIGURE 140-9. Barium radiograph of Zenker's diverticulum *(arrow)*. (From Feldman M, ed. *Gastroenterology and Hepatology: The Comprehensive Visual Reference,* New York: Churchill Livingstone; 1997.)

odynophagia, chest pain, heartburn, or aspiration. Diagnosis is typically made by barium radiography (Fig. 140-10), but endoscopy is recommended to exclude a structural cause of obstruction, and esophageal manometry is recommended to evaluate for underlying motility abnormalities. No therapy is warranted in asymptomatic patients, but symptomatic patients generally do well with surgical diverticulectomy, repair of the defect in the esophageal wall, and relief of the underling obstruction, usually with a myotomy and partial fundoplication.

Rings and Webs

Esophageal rings are concentric areas of narrowing, usually in the distal esophagus. *Schatzki's ring* (Fig. 140-11) is a thin, fixed, circumferential membrane-like narrowing at the gastroesophageal junction, typically at the proximal border of a hiatal hernia. The cause may be congenital, secondary to a pleat of redundant mucosa, or related to gastroesophageal reflux. Symptoms typically occur if the ring results in a lumen that is 13 mm or less in diameter. Classic symptoms are intermittent dysphagia to solids or impaction of solid food. Diagnosis is best accomplished with barium radiography, especially for rings larger than 13 mm in diameter, which may be missed at the time of endoscopy. Treatment involves use of large caliber dilators at least 18 mm in diameter, and long-term therapy with PPIs (see Table 140-1) may prevent relapses. Most patients relapse after a single dilation.

Muscular rings, which are located several centimeters above the squamocolumnar junction, are composed of mucosa, submucosa, and muscle. Barium radiography and endoscopy reveal a focal constriction of variable diameter. Optimal therapy is unclear. Dilation leads to only partial or temporary relief. Other treatment modalities include injection of botulinum toxin and anticholinergic agents.

Esophageal webs are thin, eccentric, membranous areas of narrowing that may be found anywhere in the esophagus but most commonly are in the proximal region (Fig. 140-12). The pathogenesis of webs is unknown, but they are associated with a number of systemic diseases, including bullous skin disorders, chronic graft-versus-host disease, and iron deficiency anemia.

Hiatal Hernia

A hiatal hernia involves herniation of elements of the abdominal cavity through the diaphragmatic hiatus. A sliding, or type I hernia, in which the gastroesophageal junction is displaced above the diaphragmatic hiatus, is the most common type. Type I hiatal hernias are typically asymptomatic or present with symptoms of heartburn or acid regurgitation. Treatment is as for GERD (see earlier).

In a type II or true paraesophageal hernia, which is uncommon, the gastroesophageal junction is in its normal location, but the fundus and parts of the greater curvature of the stomach herniate into the mediastinum alongside the esophagus. With type III or mixed paraesophageal hernia, the gastroesophageal junction and a large part of the stomach herniate into the mediastinum. Both types of paraesophageal hernias present with symptoms of postprandial distress, such as epigastric pain, chest pain, substernal fullness, shortness of breath, nausea, or vomiting. Iron deficiency anemia may be seen with large hiatal hernias in which at least one third of the stomach is in the chest; linear gastric erosions at the top of gastric folds at the level of the diaphragm have been implicated as a cause of chronic blood loss. Asymptomatic paraesophageal hernias do not require surgery. Symptomatic paraesophageal hernias warrant surgical therapy because of the risk of strangulation, bleeding, perforation, or obstruction.

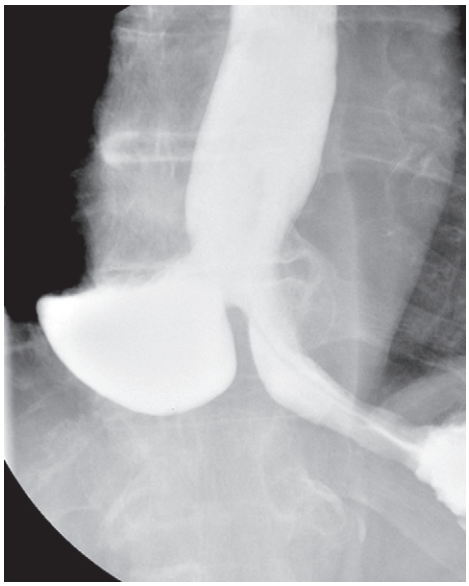

FIGURE 140-10. Barium radiograph of an esophageal epiphrenic diverticulum. (Image courtesy of Marc Levine, MD.)

THE ESOPHAGUS IN SYSTEMIC DISEASES

Scleroderma

Up to 90% of patients with scleroderma (Chapter 275) have esophageal involvement, thereby making it the most common gastrointestinal abnormality in the disease. The classic manometric and radiologic findings are aperistalsis of the distal two thirds of the esophagus, initially because of neuropathy and later because of the myopathy. The main clinical manifestation is severe gastroesophageal reflux that may cause Barrett's esophagus in up to 20% of patients and often causes esophageal strictures. Delayed gastric emptying

FIGURE 140-11. Barium radiograph of Schatzki's ring. (From Feldman M, ed. *Gastroenterology and Hepatology: The Comprehensive Visual Reference.* New York: Churchill Livingstone; 1997.)

FIGURE 140-12. Barium radiograph of an esophageal web. (Image courtesy of Marc Levine, MD.)

may also occur. Marked esophageal stasis may also lead to candidal esophagitis. The diagnosis is confirmed by a patulous (on radiography) or hypotensive (on manometry) lower esophageal sphincter. PPI therapy (see Table 140-1) is the cornerstone of treatment. Lifestyle changes, including small frequent meals and avoiding nighttime meals, may reduce the gastric symptoms. Antireflux surgery can exacerbate dysphagia by creating a functional high-pressure zone in the distal esophagus and is thus contraindicated. Unfortunately, many patients suffer from chronic GERD and are at risk of developing Barrett's esophagus, recurrent strictures, and adenocarcinoma.

Amyloidosis

Amyloidosis (Chapter 194) may lead to smooth muscle and autonomic nervous system dysfunction that involves the esophagus in a pattern similar to scleroderma. Patients will have both dysphagia and severe reflux because of esophageal aperistalsis and a hypotensive lower esophageal sphincter. Dysphagia may result not only from the motility changes but also from diffuse esophageal rigidity and loss of compliance owing to amyloid infiltration of the esophageal wall. Rarely, an achalasia-like pattern may develop. No treatment improves the esophageal manifestations of amyloidosis, other than treatment for the underlying disease and high-dose PPIs given twice daily.

Other Systemic Diseases

Dermatomyositis (Chapter 277) principally involves the striated muscle of the oropharynx and proximal esophagus, but sometimes the distal esophagus may lose normal peristaltic function. Symptoms can be oropharyngeal or esophageal depending on the site of greatest muscular involvement. Dysphagia may be an early presenting symptom of dermatomyositis, and the esophagus may be involved in 10 to 50% of patients. Treatment is directed at the generalized myositis because there are no specific treatments for the esophagus. Swallowing therapy may sometimes be helpful. Return of swallowing commonly lags behind recovery of other striated muscle symptoms.

Esophageal involvement in *systemic lupus erythematosus* (Chapter 274) is not as prominent as in scleroderma, dermatomyositis, or mixed connective tissue disease. Dysphagia occurs in less than 15% of patients and may be caused by decreased salivation from secondary Sjögren's syndrome or reduced esophageal peristalsis. Other causes of esophageal symptoms in patients with systemic lupus erythematosus include GERD, esophageal ulcers, esophageal infection, and medication-induced esophagitis. *Behçet's disease* (Chapter 278) causes esophageal ulcers in less than 15% of affected patients. Ulcers are typically located in the middle third of the esophagus and are often associated with ulcers in the stomach, ileum, or colon. Rare esophageal lesions include strictures, varices, and fistulas connecting with the trachea. These complications can be severely debilitating.

Esophageal involvement in *Crohn's disease* (Chapter 143) is uncommon but has been described in up to 1 to 2% of patients. Occasionally, isolated esophageal disease may occur. Ulceration is the most common manifestation, but strictures, fissures, esophagobronchial fistulas, mediastinal abscesses, and aphthoid lesions have been described. Patients typically complain of dysphagia and odynophagia. Treatment and prognosis are as for the underlying Crohn's disease.

In the *Ehlers-Danlos syndrome* (Chapter 268), hiatal hernias are common, and structural esophageal defects, such as giant epiphrenic diverticula, megaesophagus, and spontaneous esophageal rupture may also be seen.

Skin Disorders that Involve the Esophagus

Lichen planus (Chapter 446) involves the esophagus. Patients generally present in the fourth to seventh decade of life. Histologically, the lesions in up to 25 to 50% of patients show a characteristic lymphohistiocytic inflammatory infiltrate and apoptotic basal keratinocytes. Lesions classically occur on the buccal mucosa and the tongue, but the disease may also involve other areas of the oral cavity and the esophagus, conjunctiva, nose, larynx, stomach, bladder, and anus. Most patients are asymptomatic or have only minor symptoms, but patients with severe esophageal lichen planus often develop strictures and may present with dysphagia, odynophagia, and weight loss. Strictures are typically proximal but may be variable in length, sometimes involving most of the esophageal body. Rare patients may present with esophageal lichen planus in the absence of extraesophageal disease. Endoscopic findings, which can be subtle and nonspecific, include peeling mucosa, hyperemic focal abnormalities, and submucosal plaque or papules. High-dose systemic steroids, starting with at least 40 mg prednisone and then tapering over 1 to 2 months, are often successful, but relapse is common when steroids are tapered. Dilation and intralesional steroids can alleviate the symptoms associated with strictures, but symptoms frequently recur in less than a year and necessitate repeat dilations. The esophageal lesions of lichen planus may have malignant potential.

Pemphigus vulgaris (Chapter 447) patients who experience acute flares may have upper gastrointestinal symptoms (dysphagia, odynophagia, or retrosternal burning) in 80% of cases and biopsy-proven esophageal pemphigus lesions in nearly 50% of cases. Pemphigus vulgaris may rarely be isolated to the esophagus. Paraneoplastic pemphigus (Chapter 447), most commonly reported with lymphoreticular disease, also may involve the esophagus. Like lesions on the skin, esophageal lesions may be flaccid blisters or erosions, but they may also appear as red longitudinal lines along the entire esophagus. Like cutaneous and oral pemphigus, esophageal pemphigus is generally treated with corticosteroids.

In *mucous membrane pemphigoid* (cicatricial pemphigoid, Chapter 447), the esophagus is the most common site of gastrointestinal involvement, but esophageal disease occurs in less than 15% of patients. The esophageal disease can present as many as 10 years after disease onset and may be the only presentation of the disease. Patients complain of dysphagia and odynophagia. Imaging typically shows erosions, strictures, bullae, or webs. Treatment generally is as for the skin disease.

In *dystrophic epidermolysis bullosa* (Chapter 447), approximately 70 to 95% of patients develop esophageal stenosis or strictures. Strictures are especially common in children with recessive dystrophic epidermolysis bullosa, whereas fewer than 10% of patients with dominant dystrophic epidermolysis bullosa develop strictures by age 50 years.

ESOPHAGEAL INFECTIONS

Herpes Simplex Virus

Herpes simplex virus (HSV; Chapter 382) esophagitis, which is usually caused by HSV-1, is a well-recognized disease in immunocompromised patients but may also occur in immunocompetent hosts. HSV typically presents as severe odynophagia. Endoscopy and radiology characteristically demonstrate multiple ulcers and friable mucosa, predominantly involving the distal esophagus. Mucosal biopsies demonstrate typical intranuclear inclusion bodies. Depending on the severity of the esophageal disease and the underlying health of the patient, treatment options may include intravenous acyclovir, 5 mg/kg every 8 hours for 7 days, or oral acyclovir, 800 mg five times daily for 7 days, combined with symptomatic treatment.

Candidiasis

Esophageal candidiasis is common in patients with HIV infection or with impaired cellular immunity owing to hematologic malignancies, immunosuppressive therapy, or diabetes mellitus. Esophageal candidiasis is also occasionally seen in immunocompetent patients with marked esophageal stasis, such as patients with advanced achalasia or scleroderma. Esophageal candidiasis characteristically presents with symptoms of odynophagia, dysphagia, and chest pain. Endoscopy demonstrates scattered or coalescent yellow-white mucosal plaques (Fig. 140-13). Given the high prevalence of esophageal candidiasis in HIV patients, some recommend treating symptomatic HIV patients empirically and reserving endoscopy for refractory symptoms. Mild oropharyngeal candidiasis may be treated with topical clotrimazole (10 mg troche five times daily for 7 to 14 days) or nystatin (600,000 units four times daily for 7 to 10 days), whereas oral fluconazole (100 mg daily for 7 to 14 days) is needed for moderate to severe oropharyngeal and esophageal candidiasis. Intravenous fluconazole or amphotericin B deoxycholate (Chapter 339) are appropriate options for severe esophageal candidiasis or for patients who cannot tolerate oral therapy.

Cytomegalovirus

Cytomegalovirus (CMV) infection of the esophagus is exclusively found in immunocompromised patients. Patients infected with the HIV virus with low CD4 counts are most commonly affected, but CMV also occurs in transplant recipients on immunosuppressive therapy and in immunosuppressed patients with malignancy. Patients typically have severe odynophagia with evidence of radiographic or endoscopic esophageal ulcers. Treatment is usually with intravenous ganciclovir (5 mg/kg once or twice daily for 10 to 14 days) or foscarnet (90 mg/kg every 8 to 12 hours until healing occurs).

Bacterial Esophagitis

Bacterial infection of the esophagus is uncommon but can occur in immunosuppressed patients, typically those with neutropenia and malignancy.

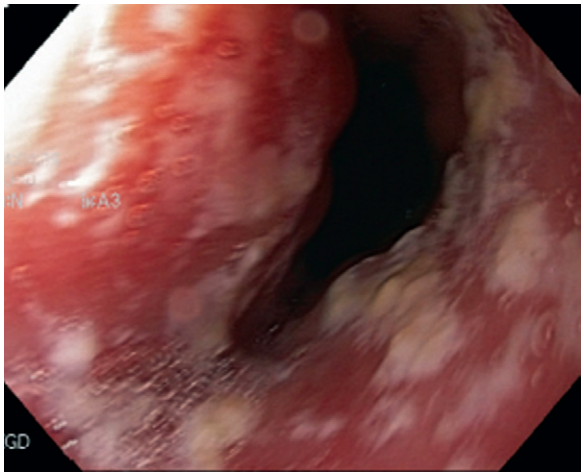

FIGURE 140-13. Candidal esophagitis.

Patients present with chest pain or odynophagia, or both, and endoscopy reveals extensive erosions, usually in the distal esophagus. Biopsy and Gram stain reveal acute and chronic inflammation and bacteria, commonly gram-positive organisms, especially Viridans-group streptococci, *Staphylococcus aureus, Staphylococcus epidermidis,* and *Bacillus* species. Treatment is with the appropriate antibiotics administered parenterally.

Human Papillomavirus

Esophageal infections with HPV are typically asymptomatic. HPV lesions are most frequently found in the mid to distal esophagus as erythematous macules, white plaque, nodules, or exuberant frondlike lesions. The diagnosis is made by histologic demonstration of koilocytosis (an atypical nucleus surrounded by a ring), giant cells, or immunohistochemical stains. Treatment is usually not necessary, although large lesions may require endoscopic removal. Other treatments, such as interferon, bleomycin, and etoposide, have yielded varying results. HPV infection is a risk factor for esophageal squamous cell carcinoma, but the value of endoscopic surveillance is not known.

MISCELLANENOUS ESOPHAGEAL CONDITIONS

Esophageal Emergencies

BOERHAAVE'S SYNDROME

Boerhaave's syndrome, or spontaneous rupture of the esophagus, is a transmural full-thickness tear of the esophageal wall. A sudden rise in intraesophageal pressure during forceful vomiting is the cause in most cases. The tear is most commonly in the lower third of the esophagus, 2 to 3 cm proximal to the gastroesophageal junction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The classic presentation is vomiting, lower thoracic pain, and subcutaneous emphysema. Other findings may include pleural effusions, especially left sided, tachypnea, abdominal rigidity, fever, and hypotension. Because the condition is rare and classic antecedent vomiting is not always reported, rupture is often recognized only after the development of mediastinitis.

The chest radiograph may demonstrate mediastinal widening, a unilateral pleural effusion, hydropneumothorax, and pneumomediastinum. The esophagram, typically with a water-soluble agent, reveals extravasation, although false-negative results may be encountered. Computed tomography (CT) scanning with an oral contrast agent, which is perhaps the best diagnostic option, typically demonstrates air in the mediastinum.

TREATMENT AND PROGNOSIS

Rx

Successful therapy depends on early recognition and the underlying condition of the patient. The classic approach is operative repair in conjunction with broad-spectrum antibiotics and nutritional support, especially if the diagnosis is made within the first 24 hours. Aggressive conservative therapy with percutaneous drains, broad-spectrum parenteral antibiotics, and nutrition has also been successful. In selected individuals, endoscopic insertion of self-expanding covered metallic stents is an option. The mortality rate can be as high as 100% without treatment.

MALLORY-WEISS TEAR

A Mallory-Weiss tear (see Fig. 137-2 in Chapter 137) is a mucosal tear, often at the gastroesophageal junction, usually caused by severe vomiting or retching. The syndrome is more common in alcoholic patients. In about 85% of patients, it is associated with acute upper gastrointestinal bleeding, which requires transfusion in about 70% of patients and urgent intervention in about 10% of cases (Chapter 137). Most tears heal spontaneously within about 48 hours.

IATROGENIC PERFORATION

Esophageal perforation may occur as a result of a variety of iatrogenic causes, including endoscopy, dilation, endosonography, or surgery as well as with foreign body ingestion. Typical symptoms include chest pain with or without abdominal pain, subcutaneous emphysema, and fever. Diagnosis may be made immediately at the time of endoscopy or radiography. Chest radiographs may show pneumomediastinum, subcutaneous emphysema, hydrothorax, or hydropneumothorax. A Gastrografin swallow may show a leak, and chest CT may show mediastinal air. Acute perforations are life-threatening emergencies that warrant immediate closure before contamination of the mediastinum. For acute perforation caused by endoscopy, endoscopic clips or stents are an option. Conservative therapy also is an option for well-contained perforations with minimal mediastinal, pleural, or peritoneal contamination and no obvious signs of sepsis. Prognosis is generally good if the perforation is recognized and treated early, preferably within 12 to 24 hours.

FOREIGN BODIES

Impaction of food or foreign bodies is a common gastrointestinal emergency. Meat impaction is most commonly seen in adults, but other foreign objects that also may be ingested accidentally or by design include batteries, coins, or bones. Many patients have an underlying esophageal abnormality, such as a Schatzki's ring, stricture, eosinophilic esophagitis, tumor, or achalasia. The clinical presentation includes dysphagia, odynophagia, foreign body sensation, chest pain, excessive salivation, and difficulty handling secretions. Immediate endoscopic extraction with concomitant airway protection is recommended because prolonged impaction may result in penetration into the esophageal wall followed by perforation and mediastinitis.

ESOPHAGEAL VARICES

Esophageal varices are described in Chapter 137.

ESOPHAGEAL FISTULAS

Tracheoesophageal fistulas may arise from a variety of different causes, including trauma, infectious esophagitis, necrosis after prolonged endotracheal intubation, esophageal cancer, and radiation therapy. Patients are often critically ill and may not tolerate surgery. Metallic stents are a treatment option.

Atrial-esophageal fistulas are a rare complication after radiofrequency ablation (Chapter 66) for atrial fibrillation. The clinical presentation is nonspecific and includes features such as dysphagia, fever, leukocytosis, bacteremia, massive intestinal bleeding, and septic shock. Diagnosis requires a high index of suspicion and is aided by a chest CT scan. Surgery is required; the prognosis is excellent with early recognition and treatment but can be dire if treatment is delayed.

Congenital Abnormalities

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Children with congenital esophageal anomalies commonly survive into adulthood after successful surgery. As adults, these patients commonly have gastroesophageal reflux that warrants PPI therapy. Strictures at prior surgical anastomoses are common, and patients may require periodic endoscopic dilation.

HETEROTOPIC GASTRIC MUCOSA (INLET PATCH)

Inlet patches, which are areas of gastric columnar epithelium, are present in up to 4.5% of adults, and are usually found incidentally at the time of routine endoscopy. Typically, a red columnar patch varying in size from a few millimeters to a few centimeters is seen just below the cricopharyngeus. Inlet patches can be associated with hoarseness, sore throat, and globus sensation. Strictures, ulcers, and rare malignant transformation have also been described. Treatment options include PPIs (see Table 140-1) and endoscopic ablation.

OTHER CONGENITAL ESOPHAGEAL DISORDERS

Duplication cysts, which may be located anywhere in the esophagus, may be in continuity with or separate from the esophageal lumen. Symptoms, which may present initially in adulthood, include dysphagia owing to luminal compression, chest pain, and regurgitation. Treatment is surgical.

Dysphagia lusoria is caused by an aberrant right subclavian artery that originates from the right aortic arch and causes partial compression of the esophagus as it crosses over to the left side. Patients may complain of dysphagia. This condition is most commonly detected incidentally during barium radiography, where it is visualized as a crossing diagonal impression at the junction of the proximal and middle thirds of the esophagus. Surgery is rarely indicated because of the complexity of the operation and the difficulty in establishing a clear relationship between the radiographic findings and symptoms.

ACID PEPTIC DISEASE

ERNST J. KUIPERS AND MARTIN J. BLASER

Acid peptic diseases can involve the esophagus (Chapter 140), the stomach, and the duodenum. Dyspeptic symptoms also can occur in patients who have no endoscopic abnormalities, in whom it is termed *nonulcer dyspepsia* (Chapter 139).

DEFINITIONS

Gastric and duodenal ulcers usually occur in an area of inflamed mucosa. This inflammation, termed *gastritis, duodenitis, or bulbitis,* can sometimes be recognized during endoscopy by signs of edema, reddening, and swelling of the mucosa, but microscopic evaluation of endoscopic biopsy specimens is required for a definitive diagnosis of mucosal inflammation.

Gastritis is categorized by endoscopic and histologic criteria, with granulocytes predominating in active gastritis and mononuclear cells in chronic gastritis. Gastritis is also classified by the segment of involved stomach: antral-predominant gastritis, corpus-predominant gastritis, or pangastritis. Finally, the absence or presence of premalignant stages of damage to the mucosa as a result of long-standing inflammation defines the categories of nonatrophic and atrophic gastritis, respectively. Endoscopic findings are usually nonspecific, unless the gastric mucosa has either a typical miniature cobblestone appearance, termed *nodular gastritis* (a lesion found particularly in children colonized by *Helicobacter pylori*), or grossly enlarged folds without evidence of cancer, termed *hypertrophic gastritis*.

A *peptic ulcer* is a mucosal defect at least 0.5 cm in diameter that penetrates the muscularis mucosae. Smaller mucosal defects are called *erosions* (Fig. 141-1). Gastric ulcers are subdivided into proximal ulcers, located in the body of the stomach, and distal ulcers, located in the antrum and angulus of the stomach. Gastric ulcers are located mainly along the lesser curvature, in particular at the transitional zone of corpus- to antral-type mucosa. This transitional zone is often in the area of the angulus but may shift proximally. Duodenal ulcers usually are located on the anterior or posterior wall of the duodenal bulb (Fig. 141-2), or occasionally at both sites ("kissing" ulcers). Lesions distal to the duodenal bulb are termed *postbulbar ulcers.* Patients who previously underwent a distal gastric resection (Billroth I or II procedure) can develop ulceration at the gastroduodenal anastomosis (anastomotic ulcer). However, ulcers occurring after Billroth II resection are located predominantly in the jejunal mucosa at the junction between the afferent and efferent loops. Other peptic ulcers can occur at sites of metaplastic or heterotopic gastric mucosa, for example, in Meckel's diverticulum, the rectum, or Barrett's esophagus. Patients with a large hiatal hernia can develop gastric ulceration, known as *Cameron's ulcers,* at the level of the herniation. *Dieulafoy's ulcers*, which are small mucosal defects over an intramural arteriole, can lead to severe bleeding. Although these lesions can occur throughout the gastrointestinal tract, two thirds occur in the stomach.

EPIDEMIOLOGY

The worldwide prevalence of gastritis reflects the prevalence of *H. pylori.* Colonization with this bacterium is virtually always associated with chronic active gastritis, which persists as long as an individual remains colonized and only slowly disappears 6 to 24 months after the eradication of *H. pylori.* In developing countries and among first-generation immigrants from these countries, the prevalence of *H. pylori* gastritis is high (often ≥80%) in all age groups, including children. In Western countries, the prevalence of *H. pylori* gastritis increases with age; it is currently less than 20% in young adults but 40 to 60% in elderly persons.

Although peptic ulcer disease is strongly related to *H. pylori* gastritis and duodenitis, the epidemiology of ulcer disease has shown secular variations even when *H. pylori* was ubiquitous. The incidence of peptic ulcer disease rose steeply in Western countries in the late 19th and early 20th centuries and has decreased over the past 30 years, yet peptic ulceration remains a common disorder. The decline in incidence, associated with a decrease in hospital admissions and surgery for ulcer disease, is believed to reflect mainly the decreasing prevalence of gastric colonization with *H. pylori.* The declining incidence of ulcer disease is also the result of the widespread application of eradication therapy, which strongly reduced recurrent ulcers in *H. pylori*–positive patients. Other factors may include the widespread use of acid suppressive medication. Nevertheless, hospital admissions for complications of ulcers and mortality from ulcer disease have remained relatively stable in both the United States and other countries, as the reduction in *H. pylori*–associated ulcers in younger persons has been counterbalanced by an increase in ulcers related to nonsteroidal anti-inflammatory drugs (NSAIDs) in older persons.

In Western countries, duodenal ulcers occur more frequently than gastric ulcers. The predominant age at which duodenal ulcers occur is between 20 and 50 years, whereas gastric ulcers most commonly occur in patients older than 40 years. The incidence of gastroduodenal ulcer disease is approximately 1 to 2 per 1000 inhabitants per year. Two thirds of patients with ulcers are male, and the disease is more common in smokers. The risk of recurrent disease after initial healing is high; more than 50% of patients have a recurrent ulcer within 12 months of healing in the absence of treatment. Maintenance acid suppressive therapy reduces this recurrence rate, but only therapeutic measures that remove the underlying cause of the ulcer can prevent most ulcer recurrences.

PATHOBIOLOGY

Helicobacter pylori

Most peptic ulcers are associated with colonization with *H. pylori* (Fig. 141-3). Initial clinical studies of the association between *H. pylori* and ulcer disease reported that approximately 85% of patients with gastric ulcer disease and 95% of patients with duodenal ulcer disease were colonized by *H. pylori.* Most persons who are *H. pylori* positive do not have any specific complaints, nor do they develop ulcer disease. The estimated risk for the development of ulcer disease during persistent *H. pylori* colonization is 5 to 15%—that is, three- to eight-fold higher than the risk for patients who are *H. pylori* negative. The risk for the development of an ulcer in the presence of *H. pylori* is determined by a combination of host- and bacteria-related factors. Host factors include immune response, smoking, and stress. Bacterial factors that increase the risk of ulcer include a high production of the *VacA* product, which reflects the presence of the s1m1 genotype; a high level of cytokine induction, owing to the presence of genes in the *cag* pathogenicity island; and enhanced adherence, resulting from *babA*.

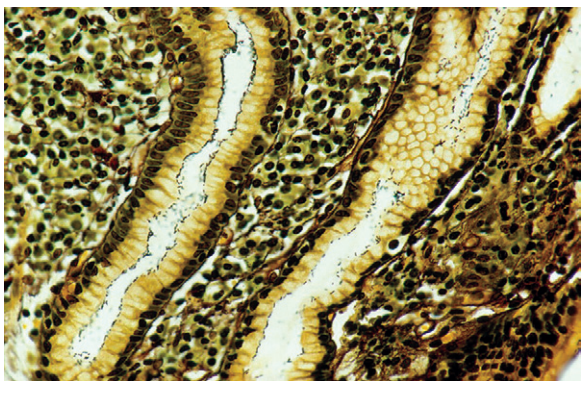

FIGURE 141-3. Gastric mucosa colonized with *Helicobacter pylori* appearing as curved bacilli on the mucosal surface.

Nonsteroidal Anti-inflammatory Drugs and Aspirin

The other common cause of gastroduodenal ulcer disease is the use of NSAIDs. At least 2 to 4% of the population in many countries use acetylsalicylic acid, acetic acid derivatives (diclofenac, indomethacin, sulindac), or propionic acid derivatives (ibuprofen, ketoprofen, naproxen) on a daily basis. Within 14 days after the start of such treatment, about 5% of patients develop mucosal breaks, that is, erosions and ulcers. In patients who continue therapy for 4 weeks or longer, this proportion increases to 10%. The concomitant presence of *H. pylori* infection increases the incidence of NSAID-related ulcers. The risk of developing an ulcer during NSAID use is also higher in patients who are older than 60 years, those with a previous ulcer, patients who use corticosteroids or high-dose NSAIDs, and those with major comorbid diseases. In patients who use anticoagulants, such as warfarin, or who have severe comorbid disease, an NSAID-induced ulcer is more likely to lead to life-threatening gastroduodenal hemorrhage.

On the basis of their activities, NSAIDs are divided into cyclooxygenase 1 (COX1) and COX2 inhibitors (Chapter 36). The COX1 enzyme is involved in the production of prostaglandins, which play a role in normal cell regulation. The COX2 enzyme, which is also involved in the production of prostaglandins, is induced by inflammatory responses. Most NSAIDs have a nonselective COX inhibitory effect; selective COX2 inhibitors are associated with fewer gastroduodenal ulcers, but their use is limited by their adverse coronary effects (Chapter 36). Because of the strong association between NSAIDs and ulcer disease and the risk for recurrence of ulcers with their continued use, patients with ulcers must be thoroughly assessed for the use of NSAIDs.

Helicobacter pylori–Negative, Non-NSAID Ulcer Disease

In most series, *H. pylori* and NSAID use account for 80 to 95% of cases of ulcer disease. The remaining cases are often referred to as *idiopathic* or *H. pylori–negative, non-NSAID* acid peptic disease. The proportion of ulcer disease that is idiopathic is increasing throughout the world as the prevalence of *H. pylori* decreases. Further, it is likely that some ulcers in *H. pylori*–positive patients were not caused by *H. pylori.* Consistent with this notion is the fact that some *H. pylori*–positive patients develop recurrent ulcers after successful bacterial eradication, so presumably their ulcer disease was idiopathic. It is not known whether the increase in idiopathic ulcer disease is simply proportional to the decrease in *H. pylori*–associated ulcers or whether it reflects a true increase in the incidence of idiopathic ulcers.

In patients with idiopathic ulcer disease, specific clues to the underlying cause are often provided by the medical history, including comorbidity and drug use; the endoscopic appearance of the ulcer; and the histologic features of the ulcer's margins and surroundings. In most cases, these initial data can direct further diagnostic studies (Table 141-1).

Malignant Ulcer Disease

Gastroduodenal ulcers can result from underlying malignant disease. In the stomach, these tumors are related to gastric adenocarcinoma and, rarely, to mucosa-associated lymphoid tissue (MALT) lymphomas (Chapter 198). Malignant ulcers in the duodenum may result from primary duodenal carcinomas or from penetrating pancreatic cancers. Duodenal cancers have an association with polyposis syndromes, especially familial adenomatous polyposis and, to a much lesser extent, MUTYH-associated polyposis and Peutz-Jeghers syndrome (Chapter 199). In both the stomach and the duodenum, ulcer disease can also be caused by metastatic tumors, including cancers of the breast, colon, thyroid, or kidney, or by melanoma, disseminated lymphoma, or Kaposi's sarcoma. Malignant ulcers are characteristically irregular in shape with heaped borders, but they may also be flat or depressed lesions. Current high-resolution and magnification endoscopes allow visualization of the altered mucosal structure surrounding an ulcer, including changes in the microvascular pattern. For a definite diagnosis of malignancy, multiple biopsy specimens are needed, usually from the ulcer margins.

Systemic Inflammatory Disorders

A few gastroduodenal ulcers are caused by systemic inflammatory diseases, in particular, Crohn's disease (Chapter 143). Patients with Crohn's disease affecting the proximal gastrointestinal tract often have multiple ulcers

TABLE 141-1 DIFFERENTIAL DIAGNOSIS OF PEPTIC ULCER DISEASE

ORIGIN	CONDITION	FREQUENCY*	DIAGNOSTIC TEST	FINDINGS
Microbes	*Helicobacter pylori*	Very common	*Helicobacter pylori* tests Histology	Bacteria, enzymes, antigens, antibodies Gastritis
	Helicobacter heilmannii	Rare	Histology	Spiral bacteria, gastritis
	Treponema pallidum	Very rare	Serology	Antibodies
	Mycobacterial infection	Very rare	Histology, immune response testing, chest radiograph	Acid-fast bacteria, granuloma, immune response, pulmonary infiltrate
	Cytomegalovirus, herpes simplex virus type 1	Rare	Histology, serology	Virus inclusions, antibodies
Drug use	NSAIDs, aspirin	Very common	History, urine test	NSAID use
	Bisphosphonates	Rare	History	Bisphosphonate use
	Corticosteroids	Rare	History	Corticosteroid use, comorbidity
	Amphetamines, cocaine	Rare	History, drug testing	Drug use
	Anticoagulants, coagulopathy	Rare	Endoscopy	Ulcer after intramural bleed
Malignancy	Gastric cancer	Common	Histology	Malignancy
	Duodenal cancer	Rare	Histology, CT	Malignancy
	Pancreatic cancer	Common	Histology, CT	Malignancy
	Mucosa-associated lymphoid tissue lymphoma	Rare	Histology	Malignancy
	Metastatic cancer	Rare	Histology	Malignancy
Gastritis syndromes	Eosinophilic gastritis	Rare	Histology	Eosinophilic infiltration
	Lymphocytic gastritis	Rare	Histology, celiac disease screening	Lymphocytic infiltration, villous atrophy
Hyperacidic syndromes	Zollinger-Ellison syndrome	Rare	Serum gastrin, secretin test	Extreme hypergastrinemia, positive secretin test
	Antral G-cell hyperfunction	Very rare	Serum gastrin, secretin test	Moderate hypergastrinemia, negative secretin test
	Retained gastric antrum	Very rare	Medical history, gastrin	Billroth II resection, hypergastrinemia
	Systemic mastocytosis	Very rare	Histology of affected sites	Mast cell infiltration
	Chronic myelogenous leukemia	Very rare	Leukemia evaluation	Leukemia
Ischemia	Mesenteric vascular occlusion	Common	Angiography	Vascular disease
	Polycythemia vera	Rare	Blood counts	Polycythemia
Specific ulcer types	Cameron's ulcer	Common	Endoscopy	Ulcer in large hiatal hernia
	Marginal ulcer	Common	Endoscopy	Ulcer at anastomosis
	Dieulafoy's ulcer	Common	Endoscopy	Singular bleeding focus with minimal mucosal disruption
Systemic inflammation	Crohn's disease	Common	Histology, ileocolonoscopy	Inflammation, granulomas
	Vasculitides	Rare	Histology, systemic evaluation	Vasculitis, signs of systemic disease
	Gastric amyloidosis	Very rare	Histology	Amyloid deposition
Other conditions	Stress ulcer	Fairly common in patients in intensive care units	Endoscopy	—
	Radiation therapy, chemotherapy	Rare	Endoscopy, history	—

*Frequency as a cause of gastroduodenal ulcer disease.
CT = computed tomography; NSAID = nonsteroidal anti-inflammatory drug.

characterized by irregular longitudinal shapes. Ulcers in the duodenum occur atop Kerckring's folds. Patients with gastroduodenal ulcers from Crohn's disease do not invariably have evidence of disease elsewhere in the digestive tract, nor do blood tests always suggest an active inflammatory bowel disorder. The demonstration of ulcerative inflammation elsewhere in the digestive tract, in particular in the terminal ileum and colon, strongly supports the diagnosis of Crohn's disease, as do granulomas on a biopsy specimen. However, the absence of granulomas does not exclude Crohn's disease, and these lesions are not specific for Crohn's disease; they are also associated with *H. pylori* gastritis and other conditions, particularly sarcoidosis (Chapter 95). Sarcoidosis can also lead to gastroduodenal ulcer disease.

Other inflammatory disorders that can cause gastritis or gastroduodenal ulcers include various forms of vasculitis affecting the mesenteric system, in particular Behçet's disease (Chapter 278), Henoch-Schönlein purpura (Chapter 278), Takayasu's arteritis (Chapter 278), polyarteritis nodosa (Chapter 278), systemic lupus erythematosus (Chapter 274), Churg-Strauss syndrome (Chapter 278), and Wegener's granulomatosis (Chapter 278). Lymphocytic gastroduodenitis, which is strongly associated with celiac disease (Chapter 142), may lead to duodenal ulceration and subsequent stenotic web formation. Ulcer disease also may occur in patients with polycythemia vera (Chapter 169), possibly in relation to reduced mucosal blood flow. Vasculitis underlying ulcer disease should be considered in patients with chronic or recurrent ulceration in whom other causes have been excluded. Lymphocytic phlebitis, which is a rare vasculitic inflammatory disorder affecting the mesenteric veins, may cause gastric ulcer disease. Systemic amyloidosis (Chapter 194) affecting the stomach wall may lead to gastric ulcer disease. Rare cases of duodenal ulceration have been described in the presence of annular pancreas or congenital bands obstructing the descending duodenum.

Hypergastrinemic Syndromes

Peptic ulcers can result from chronic gastric hyperacidity related to hypergastrinemia. The most important hypergastrinemic disorder is Zollinger-Ellison syndrome (Chapter 201), a condition of marked hyperacidity leading to severe peptic ulcer disease caused by a gastrin-producing endocrine tumor. These patients usually have multiple therapy-resistant bulbar and postbulbar duodenal ulcers. The diagnosis can be confirmed by the presence of a high fasting serum gastrin level (often but not always ≥10-fold increased and >1000 pg/mL). Similar gastrin levels are sometimes seen in patients treated for chronic ulcer disease with high-dose proton pump inhibitors. For clarification, secretin testing can be performed: in patients with Zollinger-Ellison syndrome, the injection of secretin (1 U/kg) increases serum gastrin levels by more than 50%, or 120 pg/mL or greater in those with fasting gastrin levels less than 10-fold above normal. Imaging techniques, such as computed tomography (CT), magnetic resonance imaging, isotope scanning, endoscopic ultrasonography, videocapsule endoscopy, and balloon-assisted enteroscopy, may be used to detect the primary tumor, which is often located in either the pancreas or the proximal small bowel. In some patients, Zollinger-Ellison syndrome occurs as part of multiple endocrine neoplasia (Chapter 239), particularly in association with hyperparathyroidism. Other

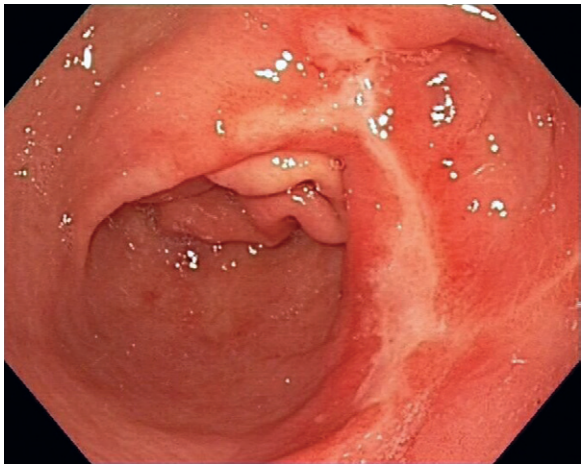

FIGURE 141-4. Endoscopic view of an irregular gastric ulcer at the posterior wall and smaller curvature in a patient with chronic mesenteric ischemia due to subtotal stenosis of the celiac trunk.

hypergastrinemic hyperacidity syndromes are the retained gastric antrum syndrome (see later) and antral G-cell hyperfunction. In the latter, fasting serum gastrin levels are only modestly increased and do not rise after the injection of secretin, but they respond in an exaggerated way to meals, thereby leading to hyperacidity. When the condition occurs in an *H. pylori*–positive patient, bacterial eradication therapy may be curative. However, some patients with G-cell hyperfunction are *H. pylori* negative.

Ischemia

Stenosis or occlusion of the celiac trunk or the superior mesenteric artery (Chapter 145) also can lead to ulceration in the mucosa of the proximal digestive tract (Fig. 141-4). These ulcers typically occur in elderly patients with risk factors for atherosclerosis, but they can also occur in younger subjects with mesenteric obstruction due to other causes. Ischemic ulcers tend to heal slowly and recur. Pallor of the mucosa, consistent with decreased mucosal blood flow, may be noted at endoscopy. Upper mesenteric ischemia is often associated with upper abdominal pain, which can be elicited by a meal or by physical activity. These symptoms may cause patients to decrease their food intake, leading to weight loss before their clinical presentation. The prevalence of upper mesenteric ischemia with secondary ulcer disease is unknown, in part owing to its variable presentation, often with a history of gradual symptoms; the lack of standardized and reliable diagnostic tests; and clinicians' unfamiliarity with the condition. Diagnostic evaluation includes a duplex ultrasound scan for vascular flow and conventional or CT angiography of the affected arteries. Validated functional tests for gastroduodenal mucosal perfusion are not widely available, but a technique for directly measuring mucosal oxygen saturation during endoscopy is investigational.

Stress Ulcers

Patients with severe medical conditions, such as major trauma, sepsis, extensive burns, head injury, or multiorgan failure, can develop stress ulcers in the stomach or duodenum. Major risk factors for stress ulceration in severely ill patients include mechanical ventilation, coagulopathy, and hypotension, but factors such as hepatic and renal failure and the use of ulcerogenic medications may contribute. Stress ulcers occur independently of *H. pylori* colonization. Ulcers associated with head injury are known as Cushing's ulcers, and ulcers associated with extensive burns are known as Curling's ulcers. Stress ulcers were once common in patients in intensive care units, but improvements in overall management, including respiratory and hemodynamic care, acid inhibition, and emphasis on adequate feeding, have reduced the incidence of these ulcers, which currently affect 1 to 2% of these patients. Stress ulcers may be asymptomatic, but they can also cause complications, especially bleeding.

Other Factors

Cameron's Ulcer

Patients with large hiatal hernias (Chapter 140) may present with proximal gastric ulcers, termed *Cameron's ulcers,* at the level of the hiatus, where the stomach is compressed. These ulcers are usually asymptomatic but may cause occult or overt bleeding. During upper gastrointestinal endoscopy, patients with large hiatal hernias and iron deficiency anemia should be carefully examined in normal and retroverted positions for the presence of Cameron's ulcers.

Anastomotic or Marginal Ulceration

Patients who have undergone partial gastrectomy sometimes develop recurrent ulcers, often located at the anastomosis or within the jejunum immediately opposite the anastomosis. Ischemia and chronic inflammation resulting from *H. pylori* and biliary reflux may cause such ulcers, as may underlying cancer. If biopsy excludes cancer, treatment includes acid suppression and *H. pylori* eradication, if needed. Ulcer disease can be caused by the retained gastric antrum syndrome after partial gastrectomy when the antrum is not completely excised from the detached duodenum. Because it then lacks exposure to acid and is thus not physiologically downregulated, it continues to secrete gastrin despite normal or even high acid levels. Marginal ulcers can also occur after bariatric Roux-en-Y gastric bypass surgery.

Other Microbes

Colonization with *Helicobacter heilmannii* (formerly known as *Gastrospirillum hominis*), which is probably a zoonotic organism, is associated with mild gastritis and sometimes with transient ulcer disease. Ulcer disease also may be infectious, resulting from secondary syphilis (Chapter 327), mycobacterial infection (Chapter 332), infection with herpes simplex virus type 1 (Chapter 382), or cytomegalovirus infection (Chapter 384).

Alcohol

Short-term heavy alcohol use or long-term moderate to heavy alcohol use can lead to signs of acute and chronic gastritis. No evidence indicates that this gastritis is associated with a significant risk for peptic ulceration, although alcohol use increases the risk of bleeding in patients with peptic ulcer disease.

Hyperhistaminic Syndromes

Similar to the hypergastrinemic syndromes, persistent elevation of histamine can lead to hyperacidity as a result of the chronic stimulation of parietal cells. Elevated histamine levels are observed in two rare syndromes. *Systemic mastocytosis* (Chapter 263) is characterized by a proliferation of mast cells in the bone marrow, skin, liver, spleen, and gastrointestinal tract, often associated with both spontaneous and trigger-induced (e.g., alcohol) release of histamine and other vasoactive substances. Patients with systemic mastocytosis often have gastrointestinal symptoms, including pain, diarrhea, and blood loss. Ulceration results from chronic gastric acid hypersecretion. Clues to the diagnosis include symptoms of pruritus, urticaria, or rash. The bone marrow and affected organ mast cell infiltrates carry a specific *C-kit* mutation and express CD2 and CD25. Histamine hypersecretion leading to peptic ulcer disease can also occur in *chronic myelogenous leukemia* (Chapter 190) with basophilia.

Other Drugs

Treatment with oral bisphosphonates, widely used for osteoporosis (Chapter 251), is complicated by gastric erosions and ulceration in an estimated 3 to 10% of treated patients. The risk for ulcer disease may be synergistically increased by NSAID use but is probably independent of *H. pylori* colonization. Although corticosteroid treatment can be complicated by peptic ulcer disease, the relative risk is only slightly increased, except in patients with serious comorbid diseases, using long-term or high-dose therapy, or with prior ulcers. Other patients who use corticosteroids are not at serious risk for ulcer disease and therefore do not require measures to prevent ulcers.

Persons who use amphetamines and crack cocaine (Chapter 33) frequently develop ulcer disease, often with perforation, possibly as a result of vascular insufficiency. Chemotherapy, particularly when given selectively as a high-dose intra-arterial infusion in the celiac system, can be complicated by ulcer disease. Patients on anticoagulant therapy and those with other coagulopathies may rarely develop intramural hematoma of the gastrointestinal tract. Depending on the location, these hematomas may cause obstruction, but they can also leave large ulcers when they rupture into the lumen. Radiation therapy of the upper abdomen is sometimes complicated by chronic ischemic ulceration, especially in long-term follow-up.

CLINICAL MANIFESTATIONS

The clinical manifestations of acid peptic disease (Table 141-2) do not always predict the various morphologic presentations found at endoscopy. Indeed,

TABLE 141-2 KEY SYMPTOMS AND SIGNS OF PEPTIC ULCER

UNCOMPLICATED ULCER
No symptoms ("silent ulcer" in up to 40% of cases)
Epigastric pain
Pain may radiate to the back, thorax, other parts of abdomen (cephalad most likely, caudad least likely)
Pain may be nocturnal (most specific), "painful hunger" relieved by food, or continuous (least specific)
Nausea
Vomiting
Heartburn (mimics or associated with gastroesophageal reflex)
COMPLICATED ULCER
Acute perforation
Severe abdominal pain
Shock
Abdominal board-like rigidity (and rebound and other signs of peritoneal irritation)
Free intraperitoneal air
Hemorrhage
Hematemesis and/or melena
Hemodynamic changes, anemia
Previous history of ulcer symptoms (80%)
Gastric outlet obstruction
Satiation, inability to ingest food, eructation
Nausea, vomiting (and related disturbances)
Weight loss

TABLE 141-3 DIAGNOSTIC PATHS AND TOOLS IN ULCER DISEASE

PATH 1: MORPHOLOGIC DIAGNOSIS
Gastroduodenoscopy
Barium contrast (inferior alternative)
Endoscopic ultrasound (selected cases only)
Computed tomography (useful in selected cases)
PATH 2: ETIOLOGIC DIAGNOSIS
***Helicobacter pylori* Testing**
Histologic examination of gastric mucosa
Stool antigen test
Carbon-13 urea breath test
Serum antibodies
Ulcer Associated with Nonsteroidal Anti-inflammatory Drug Use
History of drug ingestion
Decreased platelet adherence
Molecular identification (complex, expensive)
Acid Hypersecretory Syndromes
Serum gastrin elevation
Gastrin provocative tests (intravenous secretin, meal)
Gastric analysis

a silent ulcer may be recognized only when it presents abruptly with a complication, most commonly hemorrhage or perforation, or it may be discovered incidentally when a diagnostic test is performed for other reasons. Nevertheless, the typical presentation of acid peptic disease is recurrent episodes of pain. The pain is almost invariably located in the epigastrium and may radiate to the back or, less commonly, to the thorax or other regions of the abdomen (see Table 141-2). Some patients describe the pain as burning or piercing, whereas others describe it as an uncomfortable feeling of emptiness of the stomach, referred to as *painful hunger.* Indeed, the pain may improve with the ingestion of food, only to return in the postprandial period. The timing of the pain in relation to meals and the soothing effects of food are nonspecific, however, and may also occur in patients with functional dyspepsia without ulcer. Nocturnal epigastric pain that awakens a patient several hours after a late meal is more likely to represent ulcer pain.

Besides the pain during symptomatic episodes, patients may complain of retrosternal burning (heartburn) or acidic regurgitation into the throat, symptoms that reflect associated gastroesophageal reflux (Chapter 140), which is aggravated by hyperacidity or delayed gastric emptying. Nausea and vomiting may also occur but are nonspecific. The presence of significant diarrhea should raise the possibility of Zollinger-Ellison syndrome (Chapter 201), but diarrhea also may result from the heavy use of magnesium-containing antacids. In untreated patients, symptoms tend to be intermittent, with flares of daily pain lasting 2 to 8 weeks, separated by prolonged asymptomatic intervals. During periods of remission, patients may feel well and may be able to eat even heavy or spicy meals without apparent discomfort.

Physical Examination

The physical examination is usually unrevealing. If significant bleeding has occurred (Chapter 137), the patient may present with pallor and may be hypovolemic (Chapter 106). It is always useful to inquire about the characteristics of the stool, because ulcer-related bleeding may manifest not only obviously in the form of hematemesis but also insidiously as melena (black feces). In the case of massive ulcer bleeding with the rapid bowel passage of blood, patients may also present with red rectal blood loss. When a patient has acute perforation, severe epigastric and abdominal pain develops, and the patient appears distressed. Characteristically, intense contracture of the abdominal muscles is apparent on palpation, together with rebound tenderness and other signs of peritoneal irritation. With large amounts of intra-abdominal air, percussion may reveal hypertympany over the liver.

DIAGNOSIS

In a patient who presents with symptoms consistent with ulcer disease, the diagnostic evaluation should proceed along two different but complementary paths: confirmation of the anatomic abnormality and investigation of its cause (Table 141-3). In most patients, it is advisable to follow both diagnostic paths simultaneously, but sometimes it is reasonable to skip the anatomic verification as a cost-saving strategy and proceed to management based on the probable cause.

Anatomic Diagnosis

Endoscopy (Chapter 136) is the primary investigative tool in patients suspected of having acid peptic disease. This technique can detect erosive gastritis (see Fig. 141-1) or an ulcer in the gastric wall or duodenal bulb (see Fig. 141-2). Because of the high prevalence and the often spontaneous improvement of dyspeptic symptoms, endoscopy usually should not be performed immediately; rather its use should be restricted to patients with persistent or recurrent symptoms. However, immediate endoscopy is indicated in patients with alarm symptoms such as weight loss, dysphagia, anorexia, considerable vomiting, anemia, or signs of overt bleeding.

Endoscopy is both highly sensitive and highly specific for the detection of ulcer disease. The most common locations for a peptic ulcer are the stomach and duodenal bulb, but peptic ulcers sometimes occur in the esophagus, the small bowel, and a Meckel's diverticulum lined with heterotopic gastric mucosa. Endoscopic ultrasound may detect an unsuspected submucosal component or enlarged lymph nodes, such as may occur in gastric neoplasia, especially lymphoma and linitis plastica (Chapter 198). Ulcers in the dorsal wall of the duodenal bulb, especially at the transition from the bulb to the postbulbar descending portion of the duodenum, are most difficult to visualize, and they sometimes require a side-viewing endoscope, particularly when endoscopic treatment is needed. Other regions where gastroduodenal ulcers can be easily missed are the cardia and the gastric angulus. Dieulafoy's lesions may be difficult to diagnose because of their small mucosal defects and intermittent bleeding. Some patients require more than one endoscopy, preferably during acute bleeding, to localize the lesion. Endoscopy is also useful for ascertaining the presence of concomitant disorders, including esophagitis and duodenitis, or complications, such as bleeding or a visible vessel (see Fig. 141-2); obtaining biopsy specimens, such as for histologic examination and to assess for *H. pylori* (see Fig. 141-3); and performing therapeutic interventions.

In rare cases, such as stenosis that blocks the advancing endoscope, conventional barium contrast radiographs (Chapter 135) are indicated. Additional investigations by endosonography or CT are needed when an underlying malignant disease is suspected. The endoscopist should obtain biopsy samples from all gastric ulcers, especially those with a suspicious appearance, to exclude potential malignant disease. Because duodenal ulcers are less likely to be malignant, biopsies are usually not required unless malignancy is specifically suspected.

Etiologic Diagnosis

Diagnosis also must focus on establishing the cause of the ulcer. The first step is to determine whether *H. pylori* or NSAID use is present, because these are the major risk factors for peptic ulcers and can be contributing factors in ulcers with other precipitating causes.

Testing for Helicobacter pylori

In populations with a high prevalence of *H. pylori,* nearly all patients with peptic ulcer disease are positive for *H. pylori,* so diagnostic testing has little value except when antimicrobial susceptibility testing is needed. The prevalence of *H. pylori* remains high in immigrants from developing countries, where most people become *H. pylori* positive in youth. In Western countries, approximately 50% of individuals who are older than 65 years are colonized with *H. pylori,* but the prevalence is less than 20% in those younger than 30 years. In these younger persons, the proportion of patients with ulcers who are *H. pylori* negative is higher than in older patients, making diagnostic testing for *H. pylori,* followed by targeted therapy in those who are positive for the bacterium, more attractive than empirical therapy.

The presence of *H. pylori* can be ascertained by four possible approaches. *Histologic examination* of gastric mucosal biopsies, which is the standard procedure when diagnostic endoscopy is initially performed, is quite sensitive and specific for *H. pylori.* However, the accuracy of this technique may be affected by sampling error, improper orientation of the specimen, and recent therapy with proton pump inhibitors or antibiotics.

A second option is *serology,* which is a relatively simple, inexpensive test that has reduced predictive value in areas where the prevalence of *H. pylori* is low. Serology is not helpful to verify whether *H. pylori* has been eradicated with antibiotics because it may take many months or even years for *H. pylori* antibodies to fall to undetectable levels. None of the diagnostic tests that do not involve endoscopy can determine whether an ulcer is present.

A third option is a *stool antigen test,* which is more accurate than serology. Finally, the *carbon-13 or carbon -14 urea breath test,* which relies on the detection of *H. pylori* urease activity, is a noninvasive and relatively simple test, but it is more expensive than stool or blood testing. Although the test becomes negative as soon as *H. pylori* is eradicated, a minimum interval of 4 to 6 weeks after antibiotic treatment is recommended to reduce false-negative results.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are usually established as the putative cause of an ulcer based on information obtained from the patient. Assessment of NSAID use in an individual patient presenting with ulcer disease can be difficult, both because NSAID use is common and often intermittent and because many different NSAIDs are widely available over the counter in most countries. NSAID use is usually evaluated by detailed medical history, focusing not only on current and recent drug use but also on symptoms of pain, including musculoskeletal complaints. Further information from family members, family practitioners, and pharmacists is sometimes helpful. If surreptitious use of NSAIDs is suspected, direct serum and urine testing for aspirin and NSAID derivatives is feasible, or aspirin use can be assessed indirectly by a platelet adherence assay; however, these tests are not commonly used in clinical practice.

Hypersecretory Syndromes

Hypersecretory syndromes not related to *H. pylori* or NSAIDs are rare causes of ulcer disease and are diagnosed by special tests (see Table 141-3). Zollinger-Ellison syndrome should be strongly considered in patients with multiple ulcers, particularly in atypical locations such as distal to the duodenal bulb, and when diarrhea is present, because these finding are uncommon in *H. pylori*–related peptic ulcer disease. Hypergastrinemic syndromes (e.g., Zollinger-Ellison syndrome, antral G-cell hyperplasia) are best diagnosed by a determination of serum gastrin levels, both basal and after stimulation with intravenous secretin (gastrinoma detection) or a test meal (antral G-cell hyperplasia detection). When detected early, gastrinomas may be resectable (Chapter 201).

Gastric analysis, which is performed by placing a nasogastric tube to aspirate gastric juice and to quantify gastric acid output (both basal and after stimulation with subcutaneous pentagastrin), is indicated in only two rare circumstances: patients with elevated serum gastrin levels suggestive of Zollinger-Ellison syndrome or antral G-cell hyperplasia, but with equivocal responses to standard gastric provocative tests, and patients with indirect signs of gastric hypersecretion (e.g., enlarged folds and abundant clear fluid at endoscopy), normal gastrin levels, and negative provocative gastrin tests but who may still be hypersecretors, such as patients with recurrent ulcer disease despite a prior vagotomy with or without antrectomy. A basal acid output greater than 15 mEq/hour or greater than 5 mEq/hour in a postoperative patient is considered a positive test result.

The diagnosis of Zollinger-Ellison syndrome is best confirmed by gastric analysis showing a basal acid output greater than 15 mEq/hour in conjunction with a fasting serum gastrin level exceeding 1000 pg/mL in the presence of gastric pH less than 2. To skip the cumbersome gastric analysis, a gastric pH determination showing a fasting pH of 2 or less is adequate. For serum gastrin levels in the range 100 to 1000 pg/mL and intragastric pH greater than 2, an increase in the serum gastrin to more than 200 pg/mL after a secretin stimulation test is suggestive of the diagnosis. An elevated serum gastrin level alone is not sufficient to diagnose Zollinger-Ellison syndrome, because serum gastrin levels tend to increase over time with atrophic gastritis and are also increased in patients receiving proton pump inhibitor therapy.

Other Causes

In patients in whom a gastroduodenal ulcer cannot be ascribed to colonization with *H. pylori,* use of NSAIDs, or a hypersecretory syndrome, the establishment of a definite etiologic diagnosis may require a more thorough evaluation, starting with a medical history that focuses on the use of other ulcerogenic agents and the presence of symptoms that could suggest an underlying systemic disease. The next step is to evaluate biopsy samples from ulcer borders and from the antrum, corpus, and duodenum. The ulcer specimens may reveal overt or suspicious signs of malignancy, in particular adenocarcinoma (Chapter 198) or lymphoma. In these cases, further diagnostic evaluation should include staging of the malignancy. Alternatively, the biopsies may provide evidence of other infectious conditions, specific types of gastritis, celiac disease, ischemia, amyloidosis, or a systemic inflammatory condition. These data can be combined with clues provided by the endoscopic evaluation, including the character and location of the ulcer, signs of ischemia, and signs of inflammation at other locations. Further evaluation should focus on the presence of systemic disorders and may include a chest radiograph, angiography, ileocolonoscopy, and abdominal CT.

Differential Diagnosis

The differential diagnosis of ulcer-like symptoms includes many disorders of the upper abdominal organs, including malignant diseases of the stomach (Chapter 198), duodenum (Chapter 199), pancreas (Chapter 200), or bile ducts (Chapter 202). The differential diagnosis of upper abdominal symptoms also includes liver and gallstone disease (Chapter 158), pancreatitis (Chapter 146), and motility disorders (Chapter 138). In many patients with upper abdominal dyspeptic complaints, no underlying cause can be identified. In this "nonulcer" or functional dyspepsia group, complaints characteristic of gastroesophageal reflux, ulcer symptoms, or dysmotility symptoms may be prominent. A few of these patients (generally 5%) benefit from eradication of *H. pylori,* with a slow decrease of dyspeptic complaints over 12 to 24 months, but functional dyspepsia is not a proven or widely accepted indication for treatment of *H. pylori.* If such treatment is considered, both the patient and the physician should be prepared for persistent symptoms despite eradication of *H. pylori.*

Diagnostic Scenarios: Acute or Initial Clinical Presentation

Younger (≤45 years old) patients without alarm symptoms or signs such as anemia, rapid weight loss, or other evidence of serious disease do not necessarily require endoscopy, and evidence indicates that malignant gastric disease is unlikely. When a generalist physician is treating a patient who lives in an area of the world with a relatively high prevalence of *H. pylori* infection (>10% of the population is positive), a test-and-treat approach can begin with an *H. pylori* stool antigen determination, urea breath test, or *H. pylori* serologic examination. If the test is positive, the patient can be treated with the appropriate *H. pylori* eradication drugs (see later) and observed for 4 to 6 weeks. If the patient is also taking an NSAID, either orally or parenterally, the same approach is appropriate, but the NSAID should be discontinued. If the *H. pylori* test is negative in a person taking NSAIDs, these drugs should be discontinued, and the patient should be treated with a proton pump inhibitor for 4 to 6 weeks. In patients who are not taking NSAIDs or who do not improve after these drugs are discontinued, endoscopy is indicated to determine whether an ulcer is present.

Conversely, gastroenterologists more commonly proceed directly to endoscopy. If no abnormalities are apparent or the endoscopic study shows only "gastritis" without an overt ulcer, a biopsy should be obtained to

ascertain by histologic examination or urease testing whether *H. pylori* is present. If *H. pylori* is found by endoscopic biopsy, eradication treatment may be given; however, the effect of *H. pylori* eradication on relief of functional dyspeptic symptoms is only about 5% greater than with placebo.[1]

If endoscopic examination shows an ulcer, its location determines the subsequent approach. An ulcer in the duodenal bulb has only a remote chance of representing a malignant lesion and need not routinely be examined by biopsy. By contrast, biopsy is mandatory for a gastric ulcerative lesion identified at endoscopy, because malignant gastric disease may present with similar clinical manifestations and may resemble benign ulcer disease morphologically; even if histologic assessment does not identify a malignant process, repeat endoscopy is recommended about 1 month after therapy to verify complete healing and for biopsy of the scar.

TREATMENT

Helicobacter pylori Infection

H. pylori–associated ulcers often heal spontaneously, but acid suppressive therapy accelerates healing and ameliorates symptoms. Four weeks of acid suppressive therapy heals 70 to 80% of ulcers, and this number increases to more than 90% after 8 weeks of therapy. If *H. pylori* infection persists, however, ulcers recur in 50 to 90% of patients within 12 to 24 months; this rate can be reduced to 20 to 30% with maintenance acid suppression and to less than 5% with *H. pylori* eradication.[2] Eradication treatment is therefore mandatory (Table 141-4). Treatment for 10 to 14 days has about a 5 to 10% advantage over 7- to 10-day therapy,[3] and quadruple drug therapy is probably better than triple therapy.[4] Nevertheless, 7-day treatment may be acceptable in regions where local studies have shown that a particular treatment is very effective, and it is probably the most economical option in countries with low health care budgets. For patients in whom such therapy fails, a 4- to 10-day course of quadruple therapy is advised. This second-line regimen eradicates *H. pylori* in an additional 80 to 90% of patients. Resistance of *H. pylori* to metronidazole varies between 10 and 80% throughout the world. Clarithromycin resistance is increasing and is now estimated to be 5 to 10% in the United States because of the widespread use of macrolides to treat upper respiratory infections. Resistance to amoxicillin and tetracycline is rare and is not usually relevant in clinical practice. Sequential therapy may be superior to standard triple therapy and is a good alternative for both first- and second-line treatment.

Continuation of acid suppressive therapy after antibiotic treatment is needed only when symptoms persist[5] or in cases of complicated ulcer disease until eradication of *H. pylori* has been confirmed. Ascertainment of therapeutic efficacy must be delayed at least 1 month after the end of treatment to prevent false-negative results related to the organism's temporary suppression but not eradication. When repeat endoscopy is needed (e.g., a gastric ulcer requires repeated histologic examination to exclude underlying malignancy), repeat screening for *H. pylori* can be performed using the gastric biopsy specimens for histologic examination, culture, or urease testing. If no clinical indication exists for repeat endoscopy, *H. pylori* status can be determined by a carbon-13 urea breath test, stool *H. pylori* antigen, or repeated serology. Serologic determination is based on a more than 40 to 50% decrease in immunoglobulin G antibody levels in the first 6 months after treatment compared with pretreatment levels in that patient.

After successful *H. pylori* eradication, the risk of recurrent infection in most populations is small. In a minority of patients, ulcers recur either owing to re-infection or in the presence of another ulcerogenic factor, particularly NSAID use.

Disease Related to Nonsteroidal Anti-inflammatory Drug Use

In patients who are diagnosed with acid peptic disease while they are taking NSAIDs or aspirin, the first step is to stop such therapy. Acid suppression with a proton pump inhibitor (in doses similar to those used for *H. pylori*) leads to healing of 85% of NSAID-induced gastric ulcers and more than 90% of duodenal ulcers within 8 weeks of therapy, whereas acid suppression with an H_2-blocker, equivalent to ranitidine 300 mg twice daily, heals approximately 70% of ulcers within 8 weeks. The mucosal protective drug misoprostol (200 mg four times daily) has a similar effect. Treatment must be continued for at least 8 weeks, and maintenance therapy is needed in patients who continue to take NSAIDs. Gastric ulcers, larger lesions, and recurrent lesions heal more slowly.

Ulcer occurrence during NSAID therapy suggests a causative relationship, but patients should also be tested for *H. pylori*. In patients who are *H. pylori* positive, eradication therapy should be considered because there are no clear clinical parameters distinguishing between these etiologic factors. In patients who continue to take NSAIDs, maintenance therapy with a proton pump inhibitor is superior to *H. pylori* eradication for the prevention of recurrent ulcer,[6] except in patients who use aspirin, for whom *H. pylori* eradication alone may be curative.

Idiopathic Ulcer Disease

Patients with idiopathic ulcer disease despite a thorough assessment for underlying causes are treated primarily with an acid suppressant, usually a proton pump inhibitor, because they are at considerable risk for recurrent ulcer disease. After the underlying cause is identified and adequately treated, acid suppressive therapy can be withdrawn if there are no additional risk factors for ulcer disease, such as NSAID therapy or *H. pylori* infection.

PREVENTION

Primary Prevention

A test-and-treat strategy for *H. pylori* colonization may be considered for patients with dyspeptic symptoms, but there is no specific way to prevent *H. pylori*–associated ulcer disease. In contrast, primary prevention of NSAID-associated ulcer disease is widely advocated for patients at high risk because of a prior ulcer, severe concomitant disease, use of warfarin or high-dose corticosteroids, or older age (>65 years). H_2-blockers (at a dose equivalent to ranitidine 300 mg twice daily) partially prevents duodenal ulcer disease during NSAID therapy but has no effect on preventing gastric ulcers unless a higher dose (equivalent to famotidine 40 mg twice daily) is given. Proton

TABLE 141-4 OVERVIEW OF ANTIBIOTICS USED FOR *HELICOBACTER PYLORI* ERADICATION

DRUG CLASS	DRUG	TRIPLE THERAPY* DOSE	QUADRUPLE THERAPY† DOSE	SEQUENTIAL THERAPY‡ DOSE
Acid suppression	Proton pump inhibitor	20-40 mg bid§	20-40 mg bid§	20-40 mg bid§
Standard antimicrobials	Bismuth compound‖	2 tablets bid	2 tablets bid	
	Amoxicillin	1 g bid		1 g bid
	Metronidazole¶	500 mg bid	500 mg tid	500 mg bid
	Clarithromycin	500 mg bid		500 mg bid

Salvage antimicrobials	Levofloxacin	300 mg bid	300 mg bid	
	Rifabutin	150 mg bid		
	Furazolidone	100 mg bid		
	Doxycycline		100 mg bid	
	Nitazoxanide		1 g bid	

*Triple therapy consists of a proton pump inhibitor or bismuth compound, together with two of the listed antibiotics, usually given for 7-14 days.
†Quadruple therapy consists of a proton pump inhibitor plus either the combination of a bismuth compound, metronidazole, and tetracycline given for 4-10 days, or the combination of levofloxacin, doxycycline, and nitazoxanide for 10 days.
‡Sequential therapy consists of 10 days of proton pump inhibitor treatment, plus amoxicillin during days 1-5 and a combination of clarithromycin and an imidazole (when available, tinidazole; otherwise, metronidazole) during days 6-10.
§Proton pump inhibitor dose equivalent to omeprazole 20 mg bid.
‖Bismuth subsalicylate or subcitrate.
¶An alternative is tinidazole 500 mg bid.

pump inhibitors (at a dose equivalent to omeprazole 20 mg once daily) and misoprostol (in doses varying between 400 and 800 mg/day) partially protect against both gastric and duodenal ulcers during NSAID use. Misoprostol and proton pump inhibitors are equally effective,[7] but adherence with therapy is lower with misoprostol owing to its side effects. Patients should be advised of the importance of adherence because less than 80% adherence to gastroprotection is associated with a more than two-fold increased risk for ulcer disease compared with those who are fully adherent. During low-dose aspirin therapy, primary prevention of ulcers is advocated for the same risk groups, using a proton pump inhibitor or an H_2-receptor antagonist.[8]

Secondary Prevention

Secondary prevention of *H. pylori*–associated ulcer disease is mandatory and consists of successful bacterial eradication. Testing to ascertain *H. pylori* status after eradication therapy is indicated in patients with prior complicated ulcer disease or with persistent or recurrent symptoms after therapy, as well as in patients who fail to complete the therapeutic course.

Secondary prevention of NSAID-related ulcer disease is preferentially achieved by the withdrawal of NSAIDs. In patients who must continue taking NSAIDs, a change to a selective COX2 inhibitor in combination with a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily is advocated, especially for patients with complicated ulcer disease.[9] This combination is associated with a lower risk of secondary peptic ulcer complications than treatment with a COX2 inhibitor alone.

Secondary prevention of recurrent ulcers in patients who use aspirin may depend on *H. pylori* status. In *H. pylori*–positive patients, *H. pylori* eradication is as effective as a proton pump inhibitor for the prevention of recurrent ulcers.[10] In *H. pylori*–negative patients, additional acid suppressive therapy at a dose equivalent to esomeprazole 20 mg twice daily should be prescribed. Secondary prevention of idiopathic ulcer disease consists primarily of maintenance therapy with a proton pump inhibitor and treatment of the underlying condition.

PROGNOSIS

The majority of peptic ulcers heal spontaneously within weeks to months. However, if the underlying condition is not adequately treated, a large proportion of ulcers recur. Both initial and recurrent ulcers can give rise to complications. The four major complications are intractability, perforation, hemorrhage, and stenosis. Each distinct situation requires specific management approaches. Patients with complicated ulcer disease are at particular risk for recurrent complications and need careful assessment for secondary prevention.

Hemorrhage

Hemorrhage (Chapter 137), which is the most common complication of peptic ulcer disease, occurs in about one in six patients with ulcers over the course of their ulcer activity. Ulcers caused by NSAIDs account for a larger proportion of these hemorrhages. Peptic ulcer is thus the most common cause of nonvariceal upper gastrointestinal bleeding, accounting for 40 to 60% of cases in most populations. Bleeding is associated with a 5 to 15% risk of rebleeding and up to a 10% risk of mortality. Hemorrhage may occur along a continuum from a serious acute event associated with hemodynamic shock and high mortality to slow or intermittent blood loss leading to chronic anemia. Approximately 80% of patients with bleeding ulcers describe a prior history of symptomatic disease, and about 20 to 30% have suffered a previous hemorrhage. Assessment of the magnitude of bleeding is of paramount importance in determining the need for transfusion and subsequent management (Table 141-5). Initial hematocrit levels may be misleading and are likely to fall because of hemodilution. Rapid bleeding is usually apparent on the basis of clinical signs (pallor, systolic blood pressure ≤100 mm Hg, pulse ≥100/minute); immediate fluid resuscitation and transfusions are indicated to prevent circulatory collapse. Mortality is particularly related to complications of the bleed, such as aspiration, and exacerbation of underlying disease, such as pulmonary, cardiovascular, renal, and hepatic disease. On rare occasions, patients may actually bleed to death, especially when a larger artery is affected, such as when an ulcer in the posterior wall of the duodenal bulb perforates the gastroduodenal artery.

Initial treatment aims at hemodynamic stabilization. Endoscopy is the mainstay of therapy and should be performed within 24 hours of presentation in high-risk cases, especially patients who are hemodynamically unstable, require transfusion, or have more severe comorbidities. Endoscopy can be performed to ascertain the origin of the bleeding, and, if necessary, provide therapy to stop the bleed and reduce the risk of rebleeding.

TABLE 141-5 BLATCHFORD SCORING SYSTEM TO DETERMINE THE NEED FOR INTERVENTION IN PEPTIC ULCER BLEEDING

VARIABLE	VALUE AT ADMISSION	SCORE COMPONENT VALUE
Blood urea (mmol/L)	6.5-7.9	2
	8.0-9.9	3

	90-99	2
	<90	3
Other markers	Pulse ≥100/min	1
	Presentation with melena	1
	Presentation with syncope	2
	Hepatic disease	2
	Cardiac failure	2

Data from Stanley AJ, Ashley D, Dalton HR, et al. Outpatient management of patients with low-risk upper gastrointestinal haemorrhage: multicentre validation and prospective evaluation. *Lancet.* 2009;373:42-47. Intervention (endoscopic hemostasis, surgery, transfusion) is rarely needed for patients with an admission score ≤2 but is required in more than 40% of patients with a score ≥6.

TABLE 141-6 ENDOSCOPY RESULTS IN PATIENTS WITH BLEEDING ULCERS

ENDOSCOPY RESULT	ULCER CHARACTERISTICS*	RISK OF RECURRENT BLEEDING (%)
Active bleeding	Arterial bleeding	80-90
	Oozing bleeding	10-30
Stigmata of recent bleeding	Nonbleeding visible vessel	50-60
	Adherent clot	25-35
	Flat pigmented spot	0-8
No signs of bleeding	Clean ulcer base	0-12

*The ulcer characteristics determine the risk of recurrent bleeding during follow-up.

The appearance of the ulcer determines the need for endoscopic treatment and the risk of rebleeding (Table 141-6) and mortality. "Clean base" ulcers and those with flat pigmented spots carry a low risk of rebleeding and do not require endoscopic treatment. In contrast, ulcers with active bleeding or stigmata of recent bleeding, in particular a visible vessel or adherent clot, require treatment to stop the bleed and reduce the otherwise high risk of recurrence.

Endoscopic therapy may lead to a three-fold reduction in episodes of recurrent bleeding and in the need for surgical intervention, as well as a 40% reduction in mortality.[10] Treatment modalities include injection therapy with epinephrine or a sclerosant, thermocoagulation, and mechanical pressure by means of clips. Thermocoagulation can be performed by direct contact, such as with a heater probe, or by a noncontact method, such as argon plasma coagulation. The efficacy of these methods is generally comparable, except that epinephrine injection alone is inferior to the other modalities but can be useful when combined with any of the others.[10,11] If an adherent clot is found, an attempt should be made to remove it by water flushing or snaring to allow an assessment of the underlying ulcer base and the treatment of any underlying visible vessels to reduce the risk of rebleeding.[12]

The pre-endoscopy administration of intravenous proton pump inhibitor therapy (at a dose equivalent to a bolus of 80 mg esomeprazole, followed by a continuous infusion of 8 mg/hour until endoscopy) reduces bleeding and the need for emergent endoscopic treatment, but it has no effect on the need

TABLE 141-7 ROCKALL SCORING SYSTEM FOR THE RISK OF MORTALITY FOLLOWING PEPTIC ULCER BLEEDING

	Score			
VARIABLE	**0**	**1**	**2**	**3**

for transfusion or the occurrence of rebleeding or death. For patients with active bleeding or stigmata of recent bleeding, endoscopic treatment should be followed by an intravenous proton pump inhibitor given as a bolus at a dose equivalent to 80 mg esomeprazole over 30 minutes, followed by a continuous infusion at a dose equivalent to esomeprazole 8 mg/hour for 72 hours, to reduce rebleeding and the need for further intervention.[13] Other therapies, including tranexamic acid, vasopressin, somatostatin, and octreotide, should be considered experimental (Chapter 137). Second-look endoscopy is not routinely indicated but can be considered in very high-risk cases, particularly when there is doubt about the adequacy of initial visualization or treatment.

About 70 to 80% of rebleeds occur within the first 3 days and generally should be managed by repeat endoscopy. If endoscopy fails to stop the bleed or prevent further rebleeding, surgery and interventional radiology are equivalent options. Surgery includes stitching of the ulcer and occlusion of the feeding artery, usually the gastroduodenal artery. Interventional radiology uses angiography to insert a coil in the culprit vessel at the site of the bleed. Single-center observational experience suggests that each of these methods is equally effective in the hands of experienced clinicians, and the choice depends on local availability and expertise.

The risk for a fatal outcome of an upper gastrointestinal hemorrhage can be estimated based on five clinical and endoscopic parameters (Table 141-7). In several studies, mortality in patients with a bleeding peptic ulcer was less than 2% among those with a score of 2 points or less, 10% in those with 3 to 5 points, and up to 46% in those with 6 points or more. Management of patients who recover after a peptic ulcer hemorrhage is similar to the treatment of patients with uncomplicated ulcers. Eradication of *H. pylori* provides excellent protection against both recurrence and rebleeding of *H. pylori*–related ulcers. NSAID-induced ulcers are preferentially managed by the withdrawal of NSAIDs or, if this is not feasible, by the combination of a COX2 inhibitor and a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily. In patients with a history of ulcer bleeding and concomitant cardiovascular disease requiring antiplatelet therapy, the combination of low-dose aspirin and a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily is associated with a lower risk of complicated ulcer than is clopidogrel monotherapy.[14] If a patient who requires antiplatelet therapy presents with a bleeding ulcer, antiplatelet therapy should be continued or restarted as soon as possible if the risk of a cardiovascular event outweighs the risk of recurrent bleeding.[15]

Perforation

Perforation may manifest as an acute event, whereby gastric contents spill into the peritoneal cavity, or more insidiously as the ulcer slowly penetrates into surrounding tissues. Acute free perforation typically causes abrupt and severe abdominal pain associated with abdominal muscular spasm that produces board-like rigidity of the abdomen and other manifestations of peritoneal irritation. Secondary hemodynamic shock is common. The clinical diagnosis can be confirmed in approximately 80% of patients by a plain chest radiograph with the patient standing (Fig. 141-5); a CT scan can be obtained if doubt persists. Leukocytosis and elevated C-reactive protein levels develop rapidly, and mild hyperamylasemia may occur. Treatment begins by correcting hemodynamic, fluid, and electrolyte imbalances. Nasogastric suction is helpful, and prophylactic antibiotics (e.g., amoxicillin-clavulanic acid 1 g every 8 hours intravenously) are usually administered. Unless a specific contraindication exists, emergency surgery is usually indicated, although more conservative approaches are sometimes appropriate. Given the success in achieving the long-term cure of ulcer disease through the eradication of *H. pylori* and the withdrawal of NSAIDs, suturing of the perforated ulcer may be adequate, permitting the patient to avoid a more radical vagotomy with or without gastric resection.

Intractability

Intractability is a term strictly applied to an ulcer that persists even after intensive and prolonged proton pump inhibitor therapy. Symptoms may or may not be present. These rare cases may result from poor compliance with recommended treatment, surreptitious use of ulcerogenic drugs, or other diseases (e.g., Crohn's disease, ischemia, infection with bacteria other than *H. pylori,* viral infection). If these issues are recognized and these diagnoses are pursued, further complications and interventions such as surgical vagotomy and pyloroplasty can almost always be avoided.

Acid peptic disease related to alcohol or bisphosphonates should be addressed by discontinuing the precipitating agent. Treatment of Zollinger-Ellison syndrome requires high-dose proton pump inhibitors and/or surgery (Chapter 201). Those rare ulcers caused by Crohn's disease (Chapter 143), vasculitis (Chapter 278), sarcoidosis (Chapter 95), polycythemia vera (Chapter 169), amyloidosis (Chapter 194), and other rare disorders should be addressed by treating the underlying condition. Stress ulcers and Cameron's ulcers are treated by potent acid suppression therapy (e.g., omeprazole 20 mg twice daily).

Stenosis

Gastric outlet obstruction is now a rare complication of ulcer disease because of the early detection and treatment of most ulcers. Most patients who develop clinically relevant gastric outlet obstruction have had an ulcer in the duodenal bulb and/or pyloric channel. Edema and inflammation play an important role, and occasionally a patient with active disease presents with symptoms of outlet obstruction as manifested by nausea, vomiting, and gastric stasis without a tight, chronic stenosis. Management therefore involves three key steps. This first is nasogastric tube aspiration and gastric lavage to clean the stomach of retained debris, followed by early endoscopy.

This step facilitates an accurate diagnosis. Nasogastric suction may need to be maintained for several days if vomiting resumes when the tube is clamped. The second step consists of intense antisecretory therapy using intravenous proton pump inhibitors in a dose equivalent to a bolus of 80 mg esomeprazole over 30 minutes, followed by a continuous infusion of 8 mg/hour. Finally, the cause of the ulcer needs to be addressed, usually by eradicating *H. pylori* and withdrawing NSAIDs. If the initial treatment resolves the clinical situation and the patient can resume eating, it is often not necessary to undertake further treatment of the outlet stenosis; however, tight, fibrous scarring may require endoscopic balloon dilation or surgery.

APPROACH TO THE PATIENT WITH DIARRHEA AND MALABSORPTION

CAROL E. SEMRAD

DEFINITIONS

Normal stool frequency ranges from three times a week to three times a day. As a symptom, diarrhea can be described as a decrease in stool consistency (increased fluidity), stools that cause urgency or abdominal discomfort, or an increase in the frequency of stool. Consistency is defined as the ratio of fecal water to the water-holding capacity of fecal insoluble solids, which are composed of bacterial mass and dietary fiber. Because it is difficult to measure stool consistency and because stool is predominantly (60 to 85%) water, stool weight becomes a reasonable surrogate of consistency.

As a sign, diarrhea is defined by the weight or volume of stool measured over a 24- to 72-hour period. Daily stool weights of children and adults are less than 200 g, and greater stool weights are an objective definition of diarrhea; however, this definition misses 20% of diarrheal symptoms in patients who have loose stools that are less than this daily weight.

Acute diarrheas persist for less than 2 to 3 weeks or, rarely, 6 to 8 weeks. The most common cause of acute diarrhea is infection. Chronic diarrheal conditions persist for at least 4 weeks and, more typically, 6 to 8 weeks or longer. There are four mechanisms of diarrhea: osmotic, secretory, exudative, and altered motility. Because many diarrheal diseases are due to more than one of these mechanisms, it is clinically useful to categorize diarrhea as malabsorptive (fatty), watery, and inflammatory.

EPIDEMIOLOGY

Diarrhea is the second leading cause of mortality worldwide and is particularly problematic for elderly people and for children younger than 5 years of age in developing nations. Infectious diarrheal conditions cause 1.8 million childhood deaths annually, despite the improved use of oral rehydration solutions, zinc, and vitamin A supplements. About one third of these deaths have been due to rotavirus infection (Chapter 388), but the recently introduced oral monovalent rotavirus vaccination has diminished its incidence and mortality in developing and developed nations.

In the United States, about 48 million people suffer from food-borne illness each year, with 128,000 hospitalizations and 3000 deaths, most in elderly people. The complaint of diarrhea accounts for more than 7 million outpatient visits per year. Total costs for diarrheal diseases are about $1.2 billion in direct (health care) costs and $5.4 billion in indirect costs (days lost from work).

PATHOBIOLOGY

Abnormalities of Fluid and Electrolyte Transport

To understand the osmotic, secretory, and inflammatory mechanisms of diarrhea, it is necessary to understand how the normal intestine handles fluid and solutes in health and disease. Whether a hypotonic meal, such as a steak and water, or a hypertonic meal, such as milk and a doughnut, is consumed, the volume of the meal is augmented by gastric, pancreatic, biliary, and duodenal secretions. The permeable duodenum then renders the meal approximately isotonic with an electrolyte content similar to that of plasma by the time it reaches the proximal jejunum. As the intestinal slurry moves toward the colon, the Na^+ concentration in the luminal fluid remains constant, but Cl^- is reduced to 60 to 70 mmol/L, and bicarbonate (HCO_3^-) is increased to a similar concentration as the result of Cl^- and HCO_3^- transport mechanisms in the enterocyte and HCO_3^- secretion in the ileum (Fig. 142-1B and C). In the colon, K^{++} is secreted, and the Na^+ transport mechanism of the colonocyte, together with the low epithelial permeability, extracts Na^+ and fluid from the stool. As a result, the Na^+ content of stool decreases to 30 to 40 mmol/L; K^{++} increases from 5 to 10 mmol/L in the small bowel to 75 to 90 mmol/L; and poorly absorbed divalent cations, such as Mg^{2++} and Ca^{2++}, are concentrated in stool to values of 5 to 100 mmol/L. The anion concentrations in the colon change drastically because bacterial degradation of carbohydrate (i.e., unabsorbed starches, sugars, and fiber) creates short-chain fatty acids that attain concentrations of 80 to 180 mmol/L; at colonic pH, organic anions, such as acetate, propionate, and butyrate, are present. In the setting of carbohydrate malabsorption, the generation of high concentrations of these short-chain fatty acids may decrease stool pH to 4 or lower. The osmolality of the stool is approximately that of plasma (280 to 300 mOsm/kg H_2O) when it is passed.

At the cellular level Na^{++} transport by the epithelium from lumen to blood (by Na^{++}-coupled sugar and amino acid transport in the small intestine, by Na^{++}/H^{++} exchange proteins in the small intestine and proximal colon, and by aldosterone-regulated $^+$ Na^{++} channels in the distal colon) creates a favorable osmotic gradient for absorption (see Fig. 142-1A and B). Chloride transport by the epithelium from blood to lumen (by cystic fibrosis transmembrane conductance regulator [CFTR] and the calcium-activated chloride channel in the small intestine and colon) creates an osmotic gradient for secretion (see Fig. 142-1C). Normally, the intestine is in a net absorptive state, regulated by extrinsic adrenergic nerves and proabsorptive neuropeptides and hormones (see Fig. 142-1D). Stimulation of secretion by neurotransmitters, hormones, and inflammatory mediators (Table 142-1; see Fig. 142-1D) can offset this balance.

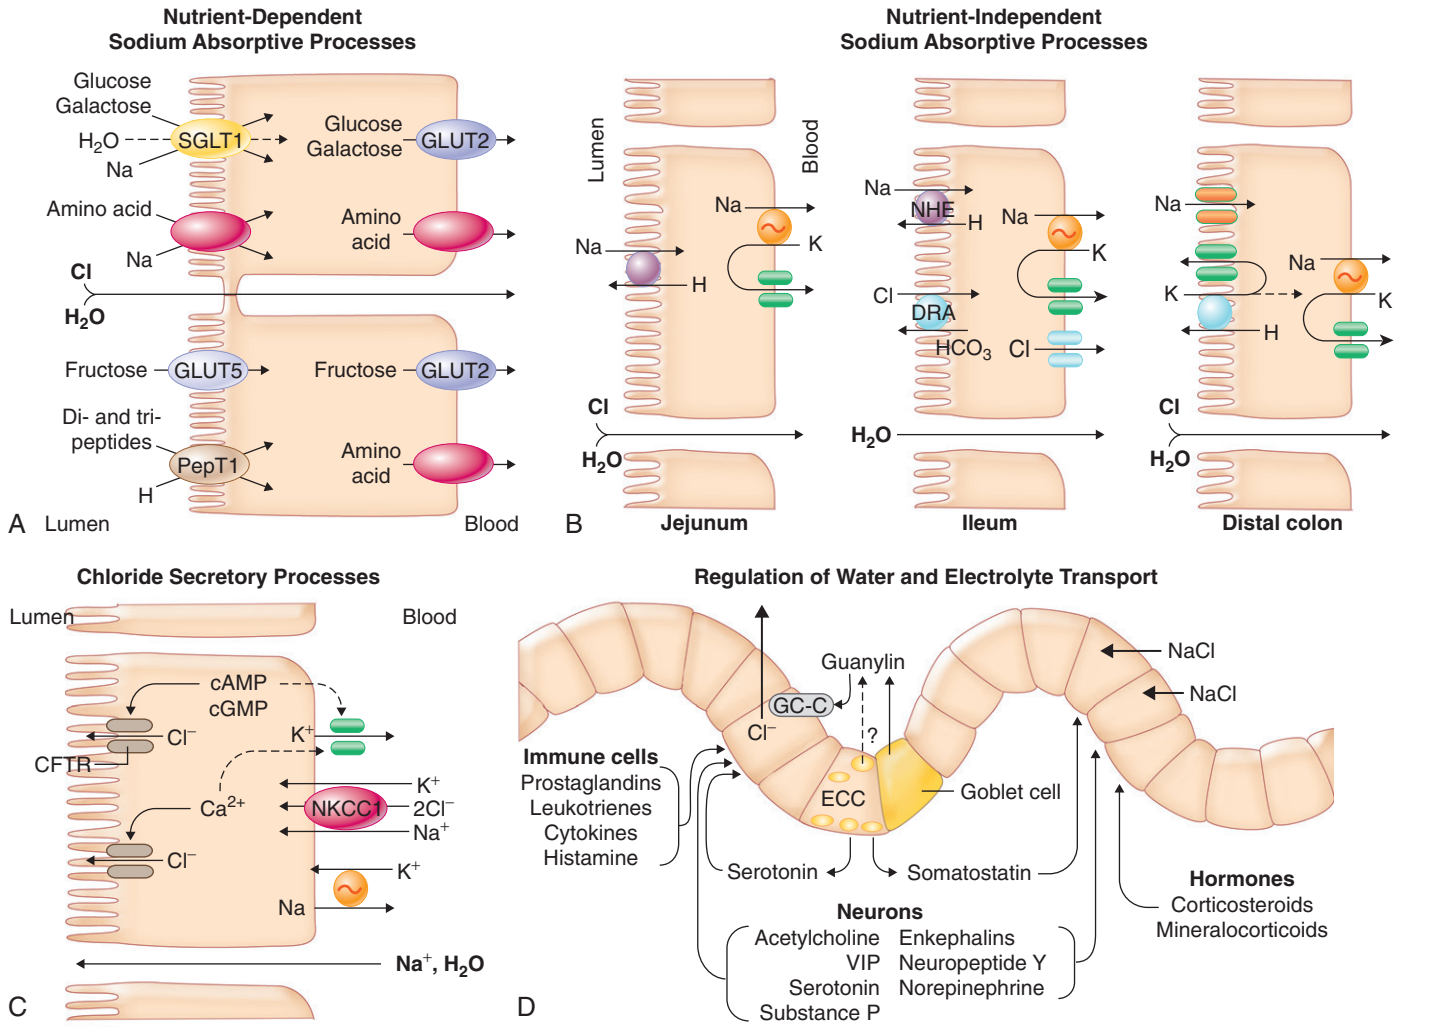

FIGURE 142-1. Mechanisms of intestinal transport of water and electrolytes. A, Intestinal sodium absorption. Sodium is actively absorbed in villus cells of the small intestine and surface cells of the colon. The sodium-potassium adenosine triphosphatase (Na^{++},K^{++}-ATPase) present on the cell basolateral membrane maintains a low intracellular Na^{+++} concentration and an electronegative cell interior favoring Na^{+++} movement across the apical membrane from lumen into cell. In the small intestine, glucose and galactose are taken up with sodium and water at the apical membrane by the sodium-glucose ligand transporter (SGLT1). Several different sodium-dependent amino acid carriers, some with overlapping substrate specificities, transport cationic, anionic, and neutral amino acids into villus cells. Dipeptides and tripeptides are transported by a hydrogen-coupled oligopeptide carrier, PepT1, that is driven by luminal hydrogen ions generated by the epithelial Na^{+}/H^{++} exchanger. Fructose is taken up by the facilitative glucose transporter (GLUT5). **B,** Sodium also is absorbed by nutrient-independent transport processes in the small intestine and colon. The Na^{++}/H^{++} (NHE) and Cl^{-}/HCO_3^{-} (DRA) exchangers are inhibited by agents that elevate intracellular cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), or calcium. **C,** Chloride secretion by intestinal crypt cells. Chloride can be secreted actively throughout the small intestine and colon. Intracellular mediators of secretion (cAMP, cGMP, Ca^{2++}) open apical Cl^{-} channels (cystic fibrosis transmembrane conductance regulator [CFTR], calcium-activated chloride channel [TMEM16]) and basolateral K^{++} channels. Chloride moves from crypt cells into the intestinal lumen, favoring movement of Cl^{-} from the blood into cells by the $Na^{++}/K^{++}/2Cl^{-}$ cotransporter (NKCC1). Bicarbonate (HCO_3^{-}) also may be secreted via the CFTR channel. **D,** Regulation of intestinal water and electrolyte transport. Normally, the intestine is in a net absorptive state under the control of extrinsic adrenergic nerves from the sympathetic nervous system. Guanylin, the natural ligand for the *Escherichia coli* stable-toxin receptor (membrane-bound guanylyl cyclase [GC-C]), may be important in regulating local chloride secretion. The normal tone of the intestine is modified by the enteric nervous system, endocrine and inflammatory cells in the intestinal mucosa, and circulating hormones. The enteric nervous system releases a variety of neurotransmitters, some that stimulate chloride secretion (e.g., vasoactive intestinal peptide [VIP], acetylcholine) and others that promote sodium absorption (e.g., enkephalins, neuropeptide Y). Hormones produced locally from enterochromaffin cells (ECC) in the intestinal epithelium and inflammatory mediators released from immune cells directly affect enterocytes and nearby nerves. Circulating hormones (e.g., aldosterone, glucocorticoids) enhance sodium absorption in the intestine. Glucocorticoids also inhibit release of arachidonic acid and production of prostaglandin by inflammatory cells.

Diarrhea is due primarily to alterations of intestinal fluid and electrolyte transport and less to smooth muscle function. Each 24 hours, 8 to 10 L of fluid enters the duodenum. The diet supplies 2 L of this fluid; the remainder comes from salivary, gastric, hepatic, pancreatic, and intestinal secretions. The small intestine normally absorbs 8 to 9 L (80%) of this fluid and presents 1.5 L to the colon for absorption. Of the remaining fluid, the colon absorbs all but approximately 100 mL. Diarrhea can result from increased secretion by the small intestine or the colon if the maximal daily absorptive capacity of the colon (4 L) is exceeded. Alternatively, if the colon is diseased so that it cannot absorb even the 1.5 L normally presented to it by the small intestine, diarrhea results.

Watery diarrheas may be due to osmotic, secretory, or inflammatory mechanisms. With ingestion of a poorly absorbed (e.g., Mg^{2++}) or unabsorbable (polyethylene glycol, lactulose or, in lactase-deficient individuals, lactose) solute, the osmotic force of the solute pulls water and secondarily sodium and chloride ions into the intestinal lumen. A considerable proportion of the osmolality of stool results from the nonabsorbed solute. This gap between stool osmolality and the sum of the electrolytes in the stool causes osmotic diarrhea.

Active chloride secretion or inhibited sodium absorption, which also create an osmotic gradient favorable for the movement of fluids from blood to lumen, explains the pathophysiology of the secretory diarrheas. Agents that increase enterocyte cyclic adenosine monophosphate (cAMP) (e.g., cholera toxin, prostaglandins), cyclic guanosine monophosphate (cGMP) (e.g., *Escherichia coli* stable toxin), or intracellular ionized calcium (Ca^{2++}) (e.g., acetylcholine) (see Table 142-1) inhibit non-nutrient Na^{++} absorption and stimulate Cl^{-} secretion (see Table 142-1 and Fig. 142-1C and D).

Inflammatory diarrheas, which may be watery or bloody, are characterized by enterocyte damage, villus atrophy, and crypt hyperplasia. The damaged enterocyte membrane of the small intestine has decreased disaccharidase and peptide hydrolase activity, reduced or absent Na^{++}-coupled sugar or amino acid transport mechanisms, and reduced or absent sodium chloride absorptive transporters. Conversely, the hyperplastic crypt cells maintain their ability to secrete $^{-}$ Cl^{-} (and perhaps HCO_3^{-}). If the inflammation is severe,

immune-mediated vascular damage or ulceration allows blood, pus, and protein to leak (exudate) from capillaries and lymphatics and contribute to the diarrhea. Activation of lymphocytes, phagocytes, and fibroblasts releases various inflammatory mediators that induce intestinal chloride secretion (see Fig. 142-1D). Interleukin-1 (IL-1) and tumor necrosis factor, which also are released into the blood, cause fever, anorexia, and malaise.

TABLE 142-1 STIMULI OF INTESTINAL SECRETION

AGENT	INTRACELLULAR MEDIATOR	RELATED DIARRHEAL ILLNESS
Enterotoxins		
Cholera, *E. coli* heat labile toxin, *Salmonella, Yersinia*	cAMP	Travelers, endemic
E. coli heat stable toxin	cGMP	
Rotatoxin (NSP4)	?	Viral gastroenteritis
Serotonin, PAF	Ca	Inflammatory, allergic
PG, leukotrienes	cAMP, Ca	Invasive enteric bacteria*
PG	cAMP	Villous adenoma
Histamine	Ca	Intestinal allergies, mastocytosis, scombroid poisoning
VIP	cAMP	VIPoma, ganglioneuromas
5-HT, substance P, bradykinin	Ca	Malignant carcinoid
Calcitonin	?	Medullary carcinoma thyroid
Acetylcholine	Ca	Insecticides, nerve gas poisoning, cholinergic drugs
Ricinoleic acid	cAMP, Ca	Laxative abuse†
Caffeine	cAMP	Coffee, sodas, tea

**Shigella* species, *Clostridium difficile,* enteroinvasive *E. coli, Vibrio parahaemolyticus, Clostridium perfringens.*
†Also phenolphthalein, anthraquinones, bisacodyl, dioctyl sodium sulfosuccinate, and senna.
5-HT = 5-hydroxytryptamine; Ca = calcium; cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; PAF - platelet-activating factor; PG = prostaglandin; VIP = vasoactive intestinal peptide.

ACUTE DIARRHEA

CLINICAL MANIFESTATIONS

Approximately 80% of acute diarrheas are due to infections with viruses, bacteria, and parasites. The remainder is due to medications that have an osmotic force, stimulate intestinal fluid secretion, or contain poorly or nonabsorbable sugars (e.g., sorbitol), or less commonly to fecal impaction, pelvic inflammation (e.g., acute appendicitis [Chapter 144]), or intestinal ischemia (Chapter 145).

Food-Borne and Water-Borne Infectious Diarrhea

Most infectious diarrheas are acquired through fecal-oral transmission from water, food, or person-to-person contact (Table 142-2). Patients with infectious diarrhea often complain of nausea, vomiting, and abdominal cramps that are associated with watery, malabsorptive, or bloody diarrhea and fever (dysentery) (Chapters 310 through 320, 344, 345, 358 to 360, 364, 365, 387, and 388). As documented using polymerase chain reaction methods of diagnosis, most outbreaks of nonbacterial acute gastroenteritis in the United States and other countries are caused by noroviruses (Norwalk agent; Chapter 388). Rotavirus (Chapter 388) predominantly causes diarrhea in infants, usually in the winter months, but also may cause nonseasonal acute diarrhea in adults, particularly in elderly people. Mechanisms for diarrhea include decreased fluid absorption due to destruction of villus enterocytes and stimulation of fluid secretion by NSP4 rotatoxin and viral activation of the enteric nervous system.

Food-borne bacterial diseases in the United States are primarily due to *Salmonella* (Chapter 316), *Campylobacter jejuni* (Chapter 311), and *E. coli* O157:H7 (Chapter 312), and less commonly *Shigella* (Chapter 317). Outbreaks of *E. coli* O157:H7 have been associated with petting zoos, uncooked ground beef, and green leafy vegetables. These bacteria most often invade the distal small bowel and colon, where they multiply intracellularly and damage the epithelium. Diarrhea is due to the stimulation of intestinal secretion by inflammatory mediators, decreased absorption across the damaged epithelium, and exudation of protein into the lumen. *Shigella* species and enterohemorrhagic *E. coli* produce a similar toxin, the "Shiga toxin," which is cytotoxic to intestinal epithelial cells and causes inflammation, cell damage, and diarrhea with blood and pus.

Outbreaks of *Cryptosporidium* (Chapter 358) have been reported in water parks. This parasite causes diarrhea by adhering and fusing to the epithelial cell membrane in the small bowel, thereby causing cell damage. Organisms that are specific for seafood include *Vibrio parahaemolyticus* (Chapter 310),

TABLE 142-2 EPIDEMIOLOGY OF ACUTE INFECTIOUS DIARRHEA AND INFECTIOUS FOOD-BORNE ILLNESS

VEHICLE	CLASSIC PATHOGENS
Water (including foods washed in such water)	*Vibrio cholerae,* caliciviruses (Norwalk agent), *Giardia, Cryptosporidium*
Food	
Poultry	*Salmonella, Campylobacter, Shigella* species
Beef, unpasteurized fruit juice	Enterohemorrhagic *Escherichia coli*
Pork	Tapeworm
Seafood and shellfish (including raw sushi and gefilte fish)	*V. cholerae, Vibrio parahaemolyticus,* and *Vibrio vulnificus; Salmonella* and *Shigella* species; hepatitis A and B viruses; tapeworm; anisakiasis
Cheese, milk	*Listeria* species
Eggs	*Salmonella* species
Mayonnaise-containing foods and cream pies	Staphylococcal and clostridial food poisonings
Fried rice	*Bacillus cereus*
Fresh berries	*Cyclospora* species
Canned vegetables or fruits	*Clostridium* species
Sprouts	Enterohemorrhagic *E. coli, Salmonella* species
Animal-to-person (pets and livestock) contact	*Salmonella, Campylobacter, Cryptosporidium,* enterohemorrhagic *E. coli,* and *Giardia* species
Person-to-person (including sexual) contact	All enteric bacteria, viruses, and parasites
Daycare center	*Shigella, Campylobacter, Cryptosporidium,* and *Giardia* species; viruses; *Clostridium difficile*
Hospitalization, antibiotics, or chemotherapy	*C. difficile*
Swimming pool	*Giardia* and *Cryptosporidium* species
Foreign travel	*E. coli* of various types; *Salmonella, Shigella, Campylobacter, Giardia,* and *Cryptosporidium* species; *Entamoeba histolytica*

Adapted from Powell DW. Approach to the patient with diarrhea. In: Yamada T, Alpers DH, Owyang C, et al, eds. *Textbook of Gastroenterology,* 3rd ed. Philadelphia: Lippincott-Raven; 1999.

which causes either watery or bloody diarrhea, and *Vibrio vulnificus,* which causes watery diarrhea and, especially in patients with liver disease, a fatal septicemia. Ingestion of meat contaminated by anthrax (Chapter 302) causes fever, diffuse abdominal pain, and bloody stool or vomitus. Anthrax invades the intestinal mucosa; the organism, or anthrax toxin, causes inflammation, ulceration, and necrosis.

In addition to enteric infections, certain systemic infections (e.g., viral hepatitis [Chapter 150], listeriosis [Chapter 301], legionellosis [Chapter 322]) and emerging infections (e.g., Hanta virus [Chapter 389], severe acute respiratory syndrome [SARS, Chapter 374], avian influenza [Chapter 372]) may cause or manifest with substantial diarrhea.

Environmental and Food Poisonings

Food poisoning refers to the accumulation of toxin in food owing to the growth of toxin-producing organisms, most commonly *Staphylococcus aureus* (Chapter 296), *Bacillus cereus, Clostridium perfringens* (Chapter 304), and *Clostridium botulinum* (Chapter 304). Diarrhea is usually of rapid onset, as early as 4 hours after ingestion, and is often associated with vomiting. Natural toxins also are responsible for mushroom *(Amanita)* poisoning (Chapter 110), which can also cause acute liver and kidney failure.

Environmental poisonings may be caused by heavy metals (arsenic from rat poison, gold, lead, mercury) that impair cell energy production. Arsenic (Chapter 21) also induces cardiovascular collapse at high doses. Insecticide (organophosphates and carbamates) poisoning occurs most commonly in field workers or from the ingestion of contaminated herbs or teas (Chapter 110); diarrhea, excessive saliva, and pulmonary secretions are caused by acetylcholine-stimulated chloride secretion in intestine and other epithelia. Patients often have associated vomiting and abdominal cramps.

Seafood is a common source of food poisoning, particularly fin fish and bivalve shellfish. Most of these toxins cause varying combinations of gastrointestinal (nausea, vomiting, diarrhea) and neurologic symptoms (tingling and burning around the mouth, facial flushing, sweating, headache, palpitations, and dizziness) within hours of seafood ingestion (Chapter 114). Similar symptoms are reported in patients with scombroid poisoning, which is caused by ingestion of decaying flesh of blood fish (tuna, mahi-mahi, marlin, or mackerel) that release large amounts of histamine (Chapter 114).

Marine dinoflagellates (algae) produce toxins that can cause paralytic shellfish poisoning, diarrhetic shellfish poisoning, and ciguatera (Chapter 114). Sporadic outbreaks of diarrhetic shellfish poisoning "red tides" occur when bivalve mollusks ingest dinoflagellates that produce saxitoxins (voltage-sensitive sodium-channel blocker) and okadaic acid (a lipid-soluble toxin that inhibits serine and threonine protein phosphatases 1 and 2A). Ingestion of contaminated mollusks by humans results in diarrhea and neurologic symptoms. Saxitoxins cause predominantly neurologic symptoms (paralytic, neurotoxic, or amnestic shellfish poisonings) and okadaic acid gastrointestinal symptoms (diarrhetic shellfish poisoning).

Food-chain passage of another dinoflagellate species (*Gambierdiscus toxicus*) to fin fish (mackerel, amberjack, snapper, grouper, or barracuda) results in the accumulation of ciguatoxin (Chapter 114) that causes a seafood poisoning called ciguatera. Ciguatoxin activates voltage-sensitive sodium channels and causes neurologic and gastrointestinal symptoms. Fish from the Albemarle-Pamlico estuary (eastern United States) ingest toxic dinoflagellates that cause *Pfiesteria piscicida* poisoning. The dinoflagellate toxins cause nausea, vomiting, abdominal pain, diarrhea, and neurologic symptoms such as fatigue, myalgias, pruritus, circumoral paresthesias, reversal of hot and cold sensation, psychiatric abnormalities, and memory loss. The neurologic symptoms may persist for months to years. Puffer fish poisoning by tetrodotoxin, a voltage-sensitive sodium-channel blocker produced by the fish, causes neurologic symptoms, respiratory paralysis, and death.

Traveler's Diarrhea

North American travelers to developing countries and travelers on airplanes and cruise ships are at high risk for acute infectious diarrhea. Most traveler's diarrhea (85%) is due to enterotoxic *E. coli. E. coli* heat-stable toxin binds to guanylate cyclase in the enterocyte brush-border membrane, where it results in elevation of intracellular cGMP. *E. coli* heat-labile toxin, similar to cholera toxin, binds to the monosialoganglioside GM_1 in the brush-border membrane, thereby resulting in the activation of adenylate cyclase and the elevation of intracellular cAMP. Cyclic AMP and cGMP stimulate intestinal chloride secretion (see Fig. 142-1C) and inhibit the nutrient-independent absorption of sodium and chloride (see Fig. 142-1B). Sodium-glucose absorption is not affected, hence the basis for oral rehydration therapy. Cholera toxin permanently binds to adenylate cyclase until the natural turnover of the intestinal epithelium in 5 to 7 days, thereby resulting in persistent secretion and severe diarrhea. Of the 10 to 15 cases of cholera reported in the United States each year, about 60% are travel associated.

Antibiotic-Associated Diarrheas

Antibiotics are a common cause of hospital-acquired diarrheas that occur in about 20% of patients receiving broad-spectrum antibiotics; about 30% of these diarrheas are due to *Clostridium difficile* (Chapter 304). Hypervirulent, fluoroquinolone-resistant strains that produce increased levels of toxins A and B and a binary toxin have emerged. These strains are associated with an increase in the incidence and severity of *C. difficile* infections, including fulminant *C. difficile* colitis that can lead to colectomy or even death. The A and B toxins produced by *C. difficile* can cause diarrhea. In animal models, IL-8, substance P, and leukotriene B_4 were found to mediate toxin A–stimulated intestinal fluid secretion. *C. difficile* can cause severe diarrhea, pseudomembranous colitis, or toxic megacolon. Patients may have a relapsing course after seemingly successful therapy with metronidazole or vancomycin.

Nosocomial Hospital Diarrhea

Diarrhea is the most common nosocomial illness among hospitalized patients and residents in long-term care facilities. Common causes include antibiotic-associated diarrhea, *C. difficile* infection, medications, fecal impaction, tube feeding, and underlying illness. Magnesium-containing laxatives, antacids, and lactulose cause osmotic diarrheas. Bisacodyl laxatives cause secretory diarrhea. Colchicine, neomycin, methotrexate, and para-aminosalicylic acid damage the enterocyte membrane. Cholestyramine, colestipol, and colesevelam bind bile salts and can result in malabsorption. Gold therapy causes intestinal inflammation and diarrhea. Liquid formulations of medications cause diarrhea (elixir diarrhea) because of the high content of sorbitol or other nonabsorbable sugars (e.g., mannitol) used to sweeten the elixir; patients prescribed liquid medications through feeding tubes may receive more than 20 g of sorbitol daily. An important but poorly understood cause of diarrhea is enteral (tube) feeding (Chapter 223), particularly in critically ill patients, who often develop diarrhea. Dysmotility, increased intestinal permeability, and low sodium content in enteral formulas may be contributing factors.

Patients in mental health institutions and nursing homes have a high incidence of nosocomial infectious diarrhea (e.g., *C. difficile* and less commonly *Shigella, Salmonella,* hemorrhagic *E. coli, Giardia, Entamoeba histolytica*). Infectious diarrhea, 50% or more of which is caused by *C. difficile,* is also common in acute-care hospitals. Severe *C. difficile* infection has also been reported among peripartum women. If outside foods are not brought to hospitalized patients, the likelihood of a nosocomial infection caused by *Salmonella* or *Shigella* is extremely rare. Immunosuppressed patients are also susceptible to nosocomial viral infections (rotavirus, norovirus, adenovirus, and coxsackievirus).

Cancer Treatment–Related Diarrhea

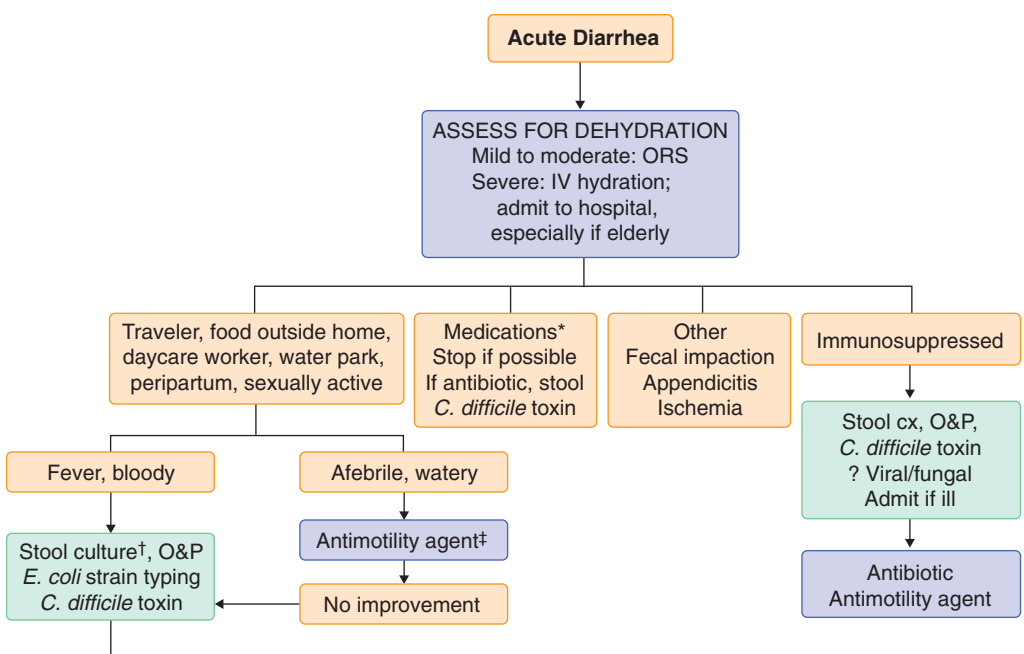
Abdominal or whole body radiation virtually always causes an increased frequency of bowel movements that are often watery. Cancer chemotherapy with amsacrine, azacitidine, cytarabine, dactinomycin, daunorubicin, doxorubicin, floxuridine, 5-fluorouracil, 6-mercaptopurine, methotrexate, plicamycin, IL-2, and resveratrol may cause mild to moderate diarrhea. Irinotecan (CPT-11) and the combination of 5-fluorouracil plus leucovorin are frequent causes of severe watery diarrhea.

Daycare Diarrhea

More than 7 million children in the United States attend daycare, where diarrhea is extremely common, and secondary infection of family members occurs in 10 to 20% of cases. Most outbreaks of diarrhea are due to rotavirus or norovirus; less common causes are *Shigella* (Chapter 317), *Giardia* (Chapter 359), and *Cryptosporidium* (Chapter 358).

Runner's Diarrhea

Diarrhea occurs in 10 to 25% of individuals who exercise vigorously, especially women marathon runners and triathletes. Some athletes have associated abdominal cramps, urgency, nausea, or vomiting. The pathophysiology of runner's diarrhea is unknown. Release of intestinal secretogogues, especially prostaglandins, hormones, or ischemia, may be involved.



Report to Public Health and save blood/stool

FIGURE 142-2. Approach to the diagnosis of acute diarrhea. *More than 700 medications cause diarrhea, including furosemide, caffeine, protease inhibitors, thyroid preparations, metformin, mycophenolate mofetil, sirolimus, cholinergic drugs, colchicine, theophylline, selective serotonin reuptake inhibitors, proton pump inhibitors, histamine-2 blockers, 5-ASA derivatives, angiotensin-converting enzyme inhibitors, bisacodyl, senna, aloe, anthraquinones, and magnesium- or phosphorus-containing medications. †Specifically request culture for *Yersinia, Plesiomonas,* enterohemorrhagic *Escherichia coli* serotype O157:H7, and *Aeromonas* if suspected. ‡If high suspicion for *Clostridium difficile* or invasive bacterial infection, wait for stool culture and toxin studies before starting. Racecadotril has antisecretory effects without paralyzing intestinal motility and can be used if available. §Not recommended for patients with bloody diarrhea due to *E. coli* O157:H7. CX = culture; IV therapy = intravenous rehydration; O&P = ova and parasites; ORS = oral rehydration solution.

DIAGNOSIS

Acute watery diarrhea may be due to infections, food toxins, or medications, or the acute diarrhea may signal the onset of a chronic disease (Fig. 142-2; see Tables 142-1 and 142-2) (Chapters 310 through 320, 344, 345, 359, 360, 364, 365, 387, and 388). The diagnostic approach in patients with fever and watery or bloody diarrhea should focus on stool cultures for *Campylobacter, Salmonella,* and *Shigella* species. Routine stool culture is not indicated when diarrhea occurs after 3 to 5 days of hospitalization, except in patients with neutropenia, human immunodeficiency virus infection, or signs of enteric infection. In patients with a history of recent antibiotic use, hospitalization, or peripartum, stools for *C. difficile* toxin should be obtained. Organisms that cause diarrhea but are not routinely tested by clinical microbiology laboratories include *Yersinia, Plesiomonas,* enterohemorrhagic *E. coli* serotype O157:H7, *Aeromonas, Cyclospora,* microsporidia, and noncholera *Vibrio.* Parasites such as *Giardia, Cryptosporidium,* and *Strongyloides* can be difficult to detect in stool but may be diagnosed by stool antigen testing or intestinal biopsy. Despite all testing techniques available, 20 to 40% of acute infectious diarrheas remain undiagnosed.

TREATMENT Rx

Goals for the treatment of diarrhea include fluid replacement, antidiarrheal agents, nutritional support, and antimicrobial therapy when indicated. Because death in patients with acute diarrhea is caused by dehydration, the first task is to assess the degree of dehydration and to replace fluid and electrolyte deficits.

Fluid Replacement

Severely dehydrated patients should be treated with intravenous Ringer's lactate or saline solution, with additional potassium and bicarbonate as needed. Oral rehydration solutions, which are used extensively to replace diarrheal fluid and electrolyte losses, are effective because they contain sodium, sugars, and, often, amino acids that use nutrient-dependent sodium uptake transporters. In alert patients with mild to moderate dehydration, oral rehydration solution is equally effective as intravenous hydration in repairing fluid and electrolyte losses. Oral rehydration solutions can be given to infants and children in volumes of 50 to 100 mL/kg over 4 to 6 hours; adults may need to drink 1000 mL/hr. Reduced-osmolarity solutions (Na^{++} 75 mmol/L, osmolarity 245 mmol/L versus Na^{++} 90 mmol/L, osmolarity 311 mmol/L in standard solutions) are better tolerated and effective in noncholera diarrhea but may cause hyponatremia in patients with high-volume diarrhea, particularly children. Glucose-based solutions, although effective in rehydrating the patient, may worsen the diarrhea. In contrast to glucose-based solutions, polymeric rice-based solutions decrease diarrhea in cholera victims; rice is digested to many glucose monomers that aid in the absorption of intestinal secretions. These solutions may not decrease stool output in acute diarrhea, but they will effectively rehydrate the patient despite continued diarrhea. After rehydration has been accomplished, oral rehydration solutions are given at rates equaling stool loss plus insensible losses until the diarrhea ceases.

Reducing Diarrhea

Bismuth subsalicylate (Pepto-Bismol, 525 mg orally every 30 minutes to 1 hour for five doses, may repeat on day 2) is safe and efficacious in bacterial infectious diarrheas. Opiates and anticholinergic drugs are not recommended for invasive bacterial infectious diarrheas because these drugs paralyze intestinal motility and predispose to increased colonization, invasion, and prolonged excretion of infectious organisms. The opiate loperamide is safe in acute or traveler's diarrhea, provided that it is not given to patients with dysentery (high fever, with blood or pus in the stool), and especially when administered concomitantly with effective antibiotics. A combination of loperamide (2 mg orally four times a day) plus simethicone (125 mg orally four times a day) may reduce the abdominal cramps and duration of traveler's diarrhea. Racecadotril (100 mg orally three times a day in adults, 1.5 mg/kg of body weight orally three times a day in children), an intestinal enkephalinase inhibitor that is antisecretory but does not paralyze intestinal motility, is effective in the treatment of acute diarrhea in children and adults. The diarrhea associated with enteral nutrition (Chapter 223) often can be managed with pectin (4 g/kg body weight daily) or, if there are no contraindications, with loperamide (2 mg orally four times a day for 3 to 7 days, maximal dose 16 mg daily), and diarrhea is not a reason to stop tube feeding unless stool volumes exceed 1 L/day.

Anxiolytics (e.g., diazepam 2 mg orally two to four times daily) and antiemetics (e.g., promethazine 12.5 to 25 mg orally once or twice daily) that decrease sensory perception may make symptoms more tolerable and are safe. Some foods or food-derived substances (green bananas, pectins [amylase-resistant starch], zinc) lessen the amount or duration of diarrhea in children. Unabsorbed amylase-resistant starches are metabolized in the colon to short-chain fatty acids that enhance fluid absorption. Zinc supplementation (20 mg of elemental zinc orally once a day) is effective in preventing recurrences of diarrhea in malnourished children; copper deficiency is a potential complication of prolonged zinc therapy.

Probiotics may be of benefit in children with acute diarrhea, predominantly that due to rotavirus infection. *Lactobacillus* GG (10^{10} colony-forming units [CFU]/250 mL daily until diarrhea stops) added to an oral rehydration solution decreases the duration of diarrhea.

Antibiotics

While the clinician is awaiting stool culture results to guide specific therapy (Chapter 295), the fluoroquinolones (e.g., ciprofloxacin, 500 mg orally twice

a day for 1 to 3 days, or levofloxacin, 500 mg orally daily for 1 to 3 days) are the treatment of choice when antibiotics are indicated (see Fig. 142-2). Trimethoprim-sulfamethoxazole (one double-strength tablet orally twice a day for 5 days or two single-strength tablets orally twice a day for 5 days) is second-line therapy. If the symptom complex suggests *Campylobacter* infection, azithromycin (500 mg orally once a day for 3 days) should be added. Regardless of the cause of infectious diarrhea, patients should be treated with antibiotics if they are immunosuppressed; have valvular, vascular, or orthopedic prostheses; have congenital hemolytic anemias (especially if salmonellosis is involved); or are extremely young or old.

Certain infectious diarrheas should be treated with antibiotics, including those associated with shigellosis (Chapter 317), cholera (Chapter 310), pseudomembranous enterocolitis (Chapter 304), parasitic infestations (Chapters 358 to 360 and 365), and sexually transmitted diseases (Chapter 293). Treatment of *E. coli* serotype O157:H7 infection is not recommended at present because current antibiotics do not appear to be helpful and the incidence of complications (hemolytic-uremic syndrome) may be greater after antibiotic therapy. Antibiotics are not effective for viral diarrhea or cryptosporidiosis.

For traveler's diarrhea, ciprofloxacin (500 mg orally two times a day for 3 days) is an effective treatment. The nonabsorbable antibiotic rifaximin (200 mg taken orally three times a day or 400 mg two times a day for 3 days) is safe and effective for treatment of traveler's diarrhea in Mexico, but it may not be effective against *Campylobacter* and *Shigella* infections.

Fluoroquinolone-resistant and trimethoprim-sulfamethoxazole-resistant strains of *Shigella, E. coli, Salmonella, Campylobacter,* and *C. difficile* have emerged. Azithromycin, 500 mg orally on day 1 and 250 mg orally once a day for 4 days, may be an effective alternative treatment for resistant strains of *Shigella* and *Campylobacter* and for traveler's diarrhea acquired in Mexico.

If *C. difficile* is suspected on an epidemiologic basis, metronidazole (250 mg orally four times a day or 500 mg orally three times a day for 10 days) or oral vancomycin (125 to 250 mg orally four times a day for 10 days) should be prescribed. In patients with recurrent *C. difficile* infection that is associated with low serum antibody titers to toxin A, immunotherapy with monoclonal antibodies against toxin A and B[1] or fecal bacteriotherapy may decrease recurrence rates. Non–*C. difficile* antibiotic-induced diarrhea is generally mild and self-limited, and it usually clears spontaneously or in response to cholestyramine therapy (4 g orally four times a day for 2 weeks).

Treatment for chemotherapy-induced and radiation-induced mild to moderate diarrhea includes loperamide (2 mg orally four times a day) and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., naproxen, 250 to 500 mg orally twice daily). Octreotide may be an effective treatment in those with severe diarrhea in doses up to 700 µg administered subcutaneously daily.

PREVENTION

Rotavirus vaccination (Chapter 388) reduces the risk of infection and generally results in milder symptoms among those infected.[2,3] Travelers to high-risk countries (Central America and parts of Latin America, Africa, Asia, the Middle East) should avoid ingestion of tap water and ice and of raw meat, raw seafood, and raw vegetables. An oral cholera vaccine against recombinant toxin B subunit and killed whole-cell (rBS-WC) is effective in preventing infection from the O1 El Tor strain and partially effective against enterotoxigenic *E. coli* strains.[4] Cholera vaccination is recommended for relief workers and health professionals who work in endemic countries and for individuals who are immunocompromised or have chronic illnesses or hypochlorhydria. Rifaximin (200 mg orally per day for 2 weeks) is safe and effective for preventing traveler's diarrhea in Mexico,[5] and the combination of rifaximin plus loperamide is better than either one alone. Bismuth subsalicylate (525 mg orally four times a day for up to 3 weeks) is also effective. Loperamide and NSAIDs are taken prophylactically by many runners who are susceptible to runner's diarrhea, but it is not clear whether they are effective.

CHRONIC DIARRHEA

An estimated 5% of the U.S. population suffers from chronic diarrhea, and about 40% of these individuals are older than 60 years of age. In 25 to 50% of cases, expert history and physical examination may be sufficient to make a definitive diagnosis (Fig. 142-3). The addition of stool culture and examination for ova and parasites, determination of stool fat, and flexible sigmoidoscopy or colonoscopy with biopsy raises the diagnostic rate to about 75%. The remaining 25% of patients with chronic diarrhea may need extensive testing and perhaps hospitalization to make a diagnosis.

Prolonged, Persistent Infectious Diarrheas

Prolonged infectious diarrheas (>2 weeks) may be due to persistent or recurrent infections. These diarrheas occur most commonly in children exposed to unsafe drinking water in developing countries, patients who have acquired immunodeficiency syndrome (AIDS) or are immunosuppressed for other reasons, and recent travelers. The most common causes in children in developing countries are enteropathogenic and enteroadherent *E. coli* infections (Chapter 312). Other common organisms include *Giardia* (Chapter 359), *Cryptosporidium* (Chapter 358), *Entamoeba* (Chapter 360), *Isospora* (Chapter 361), and microsporidia (Chapter 358). Recurrent or prolonged infectious diarrhea may lead to severe malnutrition and death (mortality rate, 50%). Treatment includes nutrition support with supplemental vitamin A (200,000

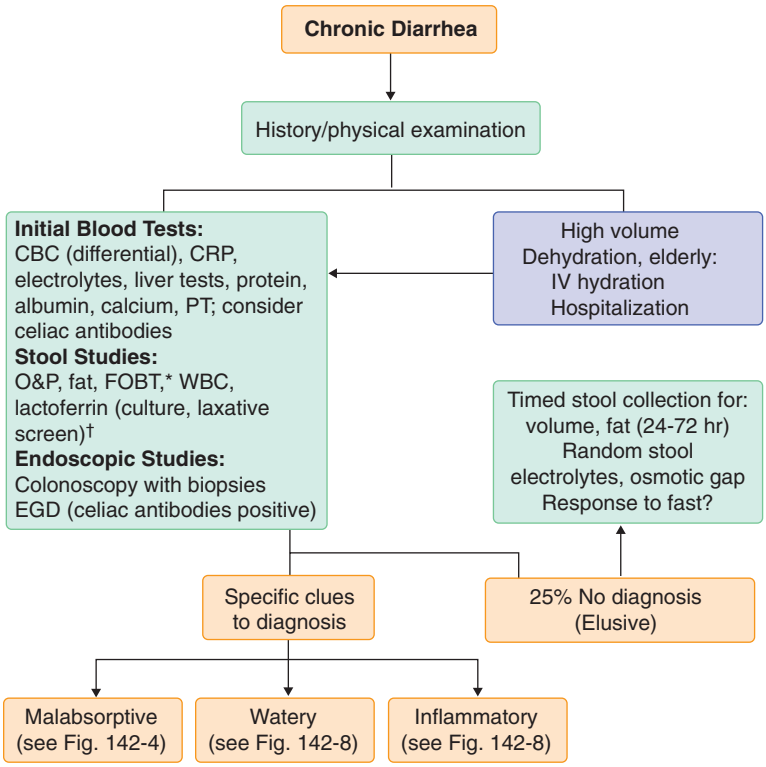


FIGURE 142-3. Initial approach to chronic diarrhea. *Fecal occult blood testing (FOBT) is a sensitive test for underlying bowel inflammation. †Perform stool culture in those who are immunosuppressed; perform laxative screen if laxative abuse is suspected. CBC = complete blood count; CRP = C-reactive protein; EGD = esophagogastroduodenoscopy; IV = intravenous; O&P = ova and parasites; PT = prothrombin time; WBC = white blood cells.

IU twice yearly) and zinc (20 mg elemental daily for 14 days). Severe disease may require total parenteral nutrition.

In AIDS patients, protracted diarrhea may be caused by treatable agents such as *Entamoeba histolytica, Giardia,* or *Strongyloides* or by organisms such as *Cryptosporidium, Isospora belli,* and microsporidia that are difficult to treat or untreatable. The most effective treatment is retroviral therapy to improve the immune system (Chapter 396).

Up to 10% of travelers returning from developing countries have infectious diarrhea that persists for longer than 3 to 4 weeks. Stool should be examined for culture and for ova and parasites; in patients with a recent history of antibiotic use, stool should also be sent for *C. difficile* toxin. Any specific organisms that are identified should be treated. If treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone has been unsuccessful, tetracycline (250 mg orally four times a day for 7 to 10 days) or metronidazole (250 mg orally three times a day for 7 to 10 days) can be tried. After documented infectious diarrhea, 25% of patients experience pain, bloating, urgency, a sense of incomplete evacuation, and loose stools for 6 months or longer; some of these patients have celiac disease, so screening (see later) is warranted in this setting. When no other cause is found, these patients are deemed to have postinfectious irritable bowel syndrome (Chapter 139).

Sporadic outbreaks of severe, prolonged diarrhea, often greater than 1 year in duration, occasionally have been reported. This form of prolonged diarrhea is called *Brainerd's diarrhea*. The organism has yet to be identified. The diarrhea is difficult to treat; cholestyramine (4 g orally three times a day) may be helpful.

Malabsorptive Syndromes

Malabsorption is caused by many different diseases, drugs (e.g., the lipase inhibitor orlistat; Chapter 227), and nutritional products (the nonabsorbable fat olestra) that impair intraluminal digestion, mucosal absorption, or delivery of the nutrient to the systemic circulation (Fig. 142-5; Table 142-3). Dietary fat is the nutrient most difficult to absorb. Fatty stools (steatorrhea) are the hallmark of malabsorption; a stool test for fat is the best screening test. Malabsorption does not always cause diarrhea. Clinical signs of vitamin or mineral deficiencies may occur in the absence of diarrhea. A careful history is crucial in guiding further testing to confirm the suspicion of malabsorption and to make a specific diagnosis (see Fig. 142-4). The goals of treatment are to correct or treat the underlying disease and to replenish losses of water, electrolytes, and nutrients.

Conditions That Impair Intraluminal Digestion

Most digestion and absorption of nutrients occur in the small intestine (Fig. 142-5). Carbohydrates and most dietary proteins are water soluble and readily digested by pancreatic enzymes. Pancreatic proteases (trypsinogen, chymotrypsinogen, procarboxypeptidases) are secreted from acinar cells in inactive forms. The cleavage of trypsinogen to trypsin by the duodenal brush-border peptidase enteropeptidase (enterokinase) allows trypsin to cleave the remaining trypsinogen and other proteases to their active form.

Most dietary lipids (long-chain triglycerides, cholesterol, and fat-soluble vitamins) are water insoluble and must undergo lipolysis and incorporation into mixed micelles before they can be absorbed across the intestinal mucosa. Pancreatic lipase, in the presence of its cofactor, colipase, cleaves long-chain triglycerides into fatty acids and monoglycerides. The products of lipolysis interact with bile salts and phospholipids to form mixed micelles, which also incorporate cholesterol and fat-soluble vitamins (D, A, K, and E) in their hydrophobic centers. Bicarbonate secreted from pancreatic duct cells is physiologically important because pancreatic enzyme activity and bile salt micelle formation are optimum at a luminal pH of 6 to 8.

IMPAIRED MIXING

Surgical alterations, such as partial gastrectomy with gastrojejunostomy (Billroth II anastomosis) or gastrointestinal bypass surgeries for obesity, result in the release of biliary and pancreatic secretions into the intestine at a site remote from the site of entry of gastric contents. This imbalance can result in impaired lipolysis and impaired micelle formation, with subsequent fat malabsorption. Bypass of the duodenum also impairs absorption of iron, folate, and calcium. Rapid transit through the jejunum contributes to the malabsorption of nutrients. Individuals with these conditions also have surgical anastomoses that predispose to bacterial overgrowth.

DUMPING SYNDROME

After esophageal (distal esophagectomy, myomectomy for achalasia), gastric (Nissan wrap, hiatal hernia repair, gastrojejunostomy), and bariatric (Roux-en-Y and duodenal switch gastric bypass) surgeries, the unregulated delivery of concentrated sugars and food into the duodenum and jejunum results in altered insulin regulation, maldigestion, osmotic movement of fluid into the intestinal lumen, and rapid transit such that intestinal contact time is insufficient for absorption of nutrients.

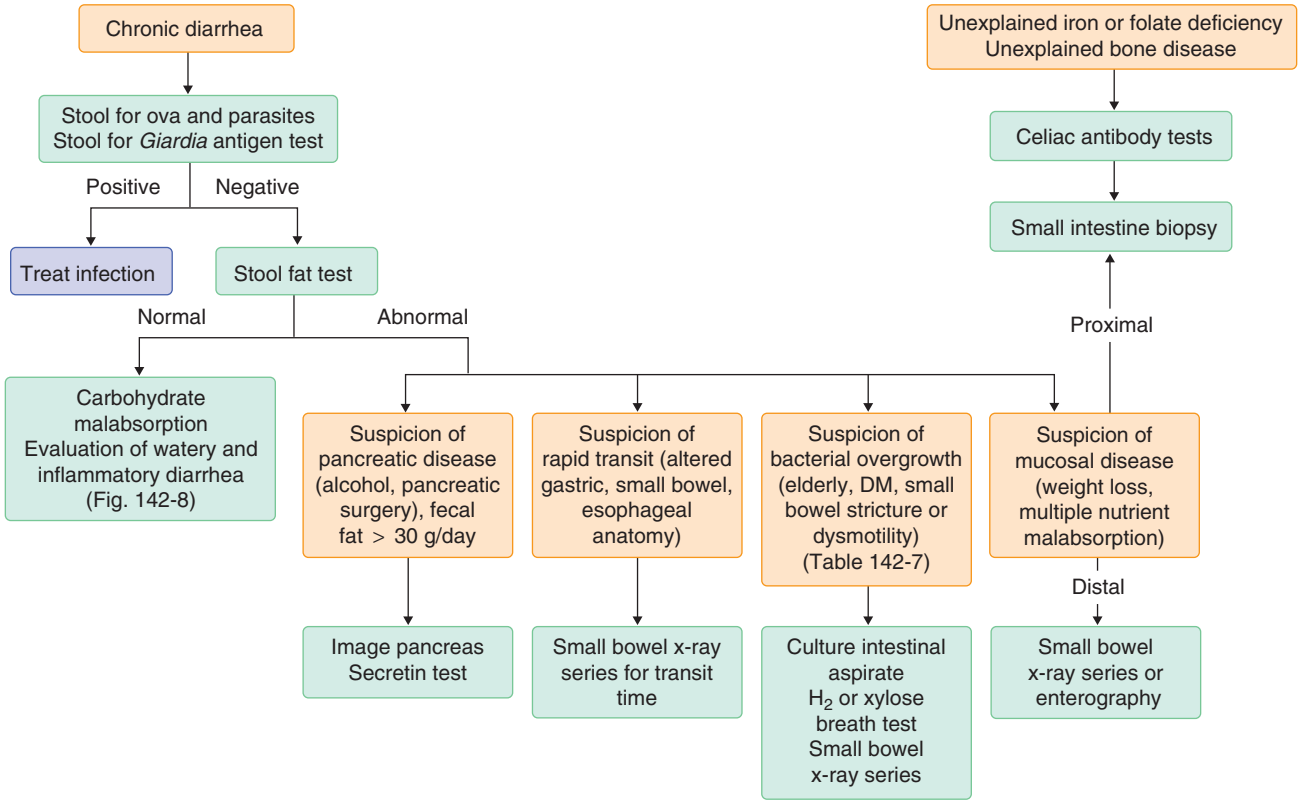

FIGURE 142-4. Approach to the diagnosis of malabsorption. DM = diabetes mellitus.

TABLE 142-3 CAUSES OF MALABSORPTION

MECHANISM OF MALABSORPTION	CONDITIONS
Impaired mixing	Partial/total gastrectomy Gastric bypass surgery
Impaired lipolysis	Chronic pancreatitis Pancreatic cancer Congenital pancreatic insufficiency Congenital colipase deficiency Gastrinoma
Impaired micelle formation	Severe chronic liver disease Cholestatic liver disease Bacterial overgrowth Crohn's disease Ileal resection Gastrinoma
Impaired mucosal absorption	Lactase deficiency Congenital enterokinase deficiency Abetalipoproteinemia Giardiasis Celiac disease Tropical sprue Agammaglobulinemia Amyloidosis AIDS-related (infections, enteropathy) Radiation enteritis Graft-versus-host disease Whipple's disease Eosinophilic gastroenteritis Megaloblastic gut Collagenous sprue Ulcerative jejunitis Lymphoma Bacterial overgrowth Short-bowel syndrome Mastocytosis
Impaired nutrient delivery	Congenital lymphangiectasia Lymphoma Tuberculosis Constrictive pericarditis Severe congestive heart failure
Unknown	Hypoparathyroidism Adrenal insufficiency Hyperthyroidism Carcinoid syndrome

AIDS = acquired immunodeficiency syndrome.

IMPAIRED LIPOLYSIS

A deficiency in pancreatic lipase may be caused by the congenital absence of pancreatic lipase or by destruction of the pancreatic gland due to alcohol-related pancreatitis, cystic fibrosis, or pancreatic cancer. Pancreatic lipase also can be denatured by excess secretion of gastric acid (e.g., Zollinger-Ellison syndrome; Chapter 201).

CHRONIC PANCREATITIS

Chronic pancreatitis (Chapter 146) is the most common cause of pancreatic insufficiency and impaired lipolysis. In the United States, chronic pancreatitis most commonly results from alcohol abuse; in contrast, tropical (nutritional) pancreatitis is most common worldwide. Malabsorption of fat does not occur until more than 90% of the pancreas is destroyed.

CLINICAL MANIFESTATIONS

Individuals with pancreatic causes of malabsorption typically present with bulky, fat-laden stools (usually >30 g of fat per day), abdominal pain, and diabetes, although some present with diabetes in the absence of gastrointestinal symptoms. Stools usually are not watery because undigested triglycerides form large emulsion droplets with little osmotic force and, in contrast to fatty acids, do not stimulate water and electrolyte secretion in the colon. Deficiency of fat-soluble vitamins is seen only rarely, presumably because gastric and residual pancreatic lipase generates enough fatty acids for some micelle formation. In severe disease, subclinical protein malabsorption, manifested by the presence of undigested meat fibers in the stool, and subclinical carbohydrate malabsorption, manifested by gas-filled, floating stools, can occur. Weight loss, when it occurs, is most often caused by decreased oral intake to avoid abdominal pain or diarrhea and less commonly by malabsorption.

In the dumping syndrome, patients may present with severe diarrhea, malabsorption, abdominal cramping, gas, and weight loss. Some have associated sweatiness, dizziness, and altered cognition due to postprandial hypoglycemia.

DIAGNOSIS

Between 30 and 40% of individuals with alcohol-related chronic pancreatitis have calcifications on abdominal radiographs. A qualitative or quantitative test for fecal fat is positive in individuals whose pancreas is more than 90% destroyed. Noninvasive tests of pancreatic function are not sensitive enough to detect mild to moderate insufficiency, so the secretin stimulation test is preferred (Table 142-4) if it can be obtained. A modified oral glucose tolerance test that shows late (120 to 180 minutes) hypoglycemia and an early (30 minutes) rise in hematocrit with an increased pulse rate suggests the dumping syndrome in patients with consistent symptoms. Small bowel barium study to assess transit time may be helpful in the diagnosis.

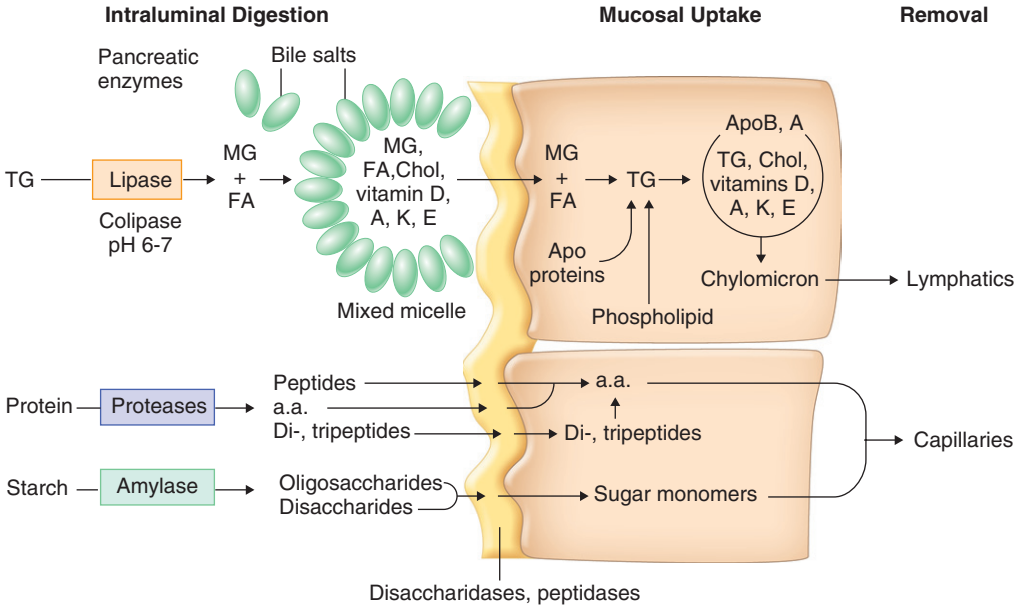

FIGURE 142-5. Phases of intestinal digestion and absorption of dietary fat, protein, and carbohydrate. a.a. = Amino acids; ApoB, A = apolipoproteins B and A; Chol = cholesterol; FA = fatty acids; MG = monoglycerides; TG = triglycerides.

TABLE 142-4 TESTS FOR THE EVALUATION OF MALABSORPTION*

TEST	COMMENTS
GENERAL TESTS OF ABSORPTION	
Quantitative stool fat test	Gold standard test of fat malabsorption, with which all other tests are compared. Requires ingestion of a high-fat diet (100 g) for 2 days before and during the collection. Stool is collected for 3 days. Normally, <7 g/24 hr is excreted on a high-fat diet. Borderline abnormalities of 8-14 g/24 hr may be seen in secretory or osmotic diarrheas that are not caused by malabsorption. There are false-negative findings if fat intake is inadequate. False-positive results can occur if mineral oil laxatives or rectal suppositories (e.g., cocoa butter) are given to the patient before stool collection.
Qualitative stool fat test	Sudan stain of a stool sample for fat. Many fat droplets per medium-power field (×40) constitute a positive test result. The nuclear magnetic resonance method determines the percentage of fat in the stool (normal, <20%). The test depends on an adequate fat intake (100 g/day). There is high sensitivity (90%) and specificity (90%) with fat malabsorption of >10 g/24 hr. Sensitivity drops with stool fat in the range of 6-10 g/24 hr.
D-Xylose test	A test of small intestinal mucosal absorption, used to distinguish mucosal malabsorption from malabsorption due to pancreatic insufficiency. An oral dose of D-xylose (25 g/500 mL water) is administered, and D-xylose excretion is measured in a 5-hr urine collection. Normally, >4 g of D-xylose is excreted in the urine over 5 hr. The test also may be positive in bacterial overgrowth owing to metabolism of D-xylose by bacteria in the intestinal lumen. False-positive test results occur with renal failure, ascites, and an incomplete urine collection. Blood levels at 1 and 3 hr improve sensitivity. May be normal with mild or limited mucosal disease.
Hydrogen breath test	Most useful in the diagnosis of lactase deficiency. An oral dose of lactose (1 g/kg body weight) is administered after measurement of basal breath H_2 levels. The sole source of H_2 in the mammal is bacterial fermentation; unabsorbed lactose makes its way to colonic bacteria, resulting in excess breath H_2. A *late peak* (within 3-6 hr) of >20 ppm of exhaled H_2 after lactose ingestion suggests lactose malabsorption. Absorption of other carbohydrates (e.g., sucrose, glucose, fructose) also can be tested.
SPECIFIC TESTS FOR MALABSORPTION	
Tests for Pancreatic Function	
Secretin stimulation test	The gold standard test of pancreatic function. Requires duodenal test intubation with a double-lumen tube and collection of pancreatic juice in response to IV secretin. Allows measurement of bicarbonate (HCO_3^-) and pancreatic enzymes. A sensitive test of pancreatic function, but labor intensive and invasive.
Fecal elastase-1 test	Stool test for pancreatic function. Equal sensitivity to the secretin stimulation test for the diagnosis of moderate-to-severe pancreatic insufficiency. More specific than the fecal chymotrypsin test. Unreliable with mild insufficiency. False-positive results occur with increased stool volume and intestinal mucosal diseases.
Tests for Bacterial Overgrowth	
Quantitative culture of small intestinal aspirate	Gold standard test for bacterial overgrowth. Greater than 10^5 colony-forming units (CFU)/mL in the jejunum suggests bacterial overgrowth. Requires special anaerobic sample collection, rapid anaerobic and aerobic plating, and care to avoid oropharyngeal contamination. False-negative results occur with focal jejunal diverticula and when overgrowth is distal to the site aspirated.
Hydrogen breath test	The 50-g glucose breath test has a sensitivity of 90% for growth of 10^5 colonic-type bacteria in the small intestine. If bacterial overgrowth is present, increased H_2 is excreted in the breath. A hydrogen level (within 2 hr) of >20 ppm suggests bacterial overgrowth. False-negative results occur with non-hydrogen-producing organisms.
^{14}C-D-xylose breath test	This test uses 1 g of carbon 14–labeled D-xylose. It has a sensitivity and specificity >90% for growth of 10^5 test colonic-type bacteria in the small intestine. Bacteria metabolize D-xylose with release of $^{14}CO_2$, which is absorbed and exhaled. Non-degraded D-xylose is absorbed in the small bowel and does not reach the colon, yielding a greater specificity than the lactulose H_2 breath test. A nonradioactive ^{13}C-D-xylose breath test is suitable for children and pregnant women.
Tests for Mucosal Disease	
Small bowel biopsy	Obtained for a specific diagnosis when there is a high index of suspicion for small intestinal disease. Several biopsy specimens (4-5) must be obtained to maximize the diagnostic yield. Distal duodenal biopsy specimens are usually adequate for diagnosis, but occasionally enteroscopy with jejunal biopsy specimens is necessary. Small intestinal biopsy provides a specific diagnosis in some diseases (e.g., intestinal infection, Whipple's disease, abetalipoproteinemia, agammaglobulinemia, lymphangiectasia, lymphoma, amyloidosis). In other conditions, such as celiac disease and tropical sprue, the biopsy specimens show characteristic findings, but the diagnosis is made on improvement after treatment.
Tests of Ileal Function	
Schilling test	A test of vitamin B_{12} absorption (see Table 167-1 in Chapter 167).
^{75}SeHCAT test	This is a test of bile acid absorption. Seven days after ingestion of radiolabeled synthetic selenium-homocholic acid conjugated with taurine (^{75}SeHCAT), whole body retention is measured by a gamma-counting device. The result is expressed as a fraction of baseline ingestion. Retention values of less than 10% are abnormal and indicate bile acid malabsorption with a sensitivity of 80-90% and specificity of 70-100%. The radiation dose is equivalent to a plain chest x-ray. Liver disease and bacterial overgrowth may give false results. Not approved for use in the United States.

*Not all these tests are readily available. A strong suspicion for any disease may warrant foregoing an extensive work-up and obtaining the test with highest diagnostic yield. In some cases, empirical treatment, such as removing lactose from the diet of an otherwise healthy individual with lactose intolerance, is warranted without any testing.

TREATMENT

Rx

Pancreatic enzyme replacement and analgesics are the mainstays of treatment for chronic pancreatitis (Chapter 146). It is difficult to correct fat malabsorption completely with exogenous pancreatic enzymes because of their inactivation by acid and pepsin in the stomach. Normally, 28,000 U of lipase is present in the duodenal lumen with each meal. A high lipase-containing pancreatic enzyme preparation (25,000 to 40,000 U of lipase in the form of uncoated enzymes or enteric-coated, pH-sensitive microspheres) should be prescribed with each meal. Mini-microsphere preparations (e.g., 20,000 U of lipase taken orally with each meal) may be best tolerated owing to their small capsule size. Pancreatic proteases present in enzyme preparations may reduce abdominal pain by inactivating cholecystokinin-releasing factor in the duodenum. Uncoated preparations may be more effective in pain relief because coated preparations release enzymes predominantly distal to the duodenum.

A histamine-2 receptor antagonist (e.g., ranitidine, 150 mg orally taken two times a day) or a proton pump inhibitor (e.g., lansoprazole, 15 to 30 mg orally once a day) should be added to uncoated pancreatic enzyme replacement therapy in patients with a poor response.

In the dumping syndrome, treatment is with a diet that is low in concentrated sugars divided into six small meals. Administration of pectin (15 g with each meal) may slow gastric emptying. In patients who are refractory to dietary measures, a short-acting somatostatin analogue (e.g., octreotide, 25 to 200 µg subcutaneously three times a day) or the better tolerated long-acting octreotide preparation (10 to 20 mg subcutaneously monthly) improves dumping symptoms. In patients with predominant reactive hypoglycemia 1 to 3 hours after a meal (late dumping), an α-glycosidase hydrolase inhibitor (e.g., acarbose, 50 to 100 mg orally three times daily) that blocks carbohydrate absorption in the small bowel may be beneficial. Continuous tube feeding is also effective.

IMPAIRED MICELLE FORMATION

PATHOBIOLOGY

Bile salt concentrations in the intestinal lumen can fall to less than the critical concentration (2 to 3 mmol/L) needed for micelle formation because of decreased bile salt synthesis (severe liver disease), decreased bile salt delivery (cholestasis), or removal of luminal bile salts (bacterial overgrowth, terminal ileal disease or resection, cholestyramine therapy, acid hypersecretion). Fat malabsorption resulting from impaired micelle formation is generally not as severe as malabsorption resulting from pancreatic lipase deficiency, presumably because fatty acids and monoglycerides can form lamellar structures, which to a certain extent can be absorbed. Malabsorption of fat-soluble vitamins (D, A, K, and E) may be marked, however, because micelle formation is required for their absorption.

Decreased Bile Salt Synthesis and Delivery

Malabsorption can occur in individuals with cholestatic liver disease or bile duct obstruction. The clinical consequences of malabsorption are seen most often in women with primary biliary cirrhosis because of the prolonged nature of the illness. Although these individuals can present with steatorrhea, osteoporosis or, less commonly, osteomalacia is the most common presentation. The cause of bone disease in these patients is poorly understood and often is not related to vitamin D deficiency. Bone disease is treated with calcium supplements (and vitamin D if a deficiency is documented), weight-bearing exercise, and a bisphosphonate (e.g., alendronate, 10 mg orally once daily or 70 mg orally once weekly).

Intestinal Bacterial Overgrowth

In health, only small numbers of lactobacilli, enterococci, gram-positive aerobes, or facultative anaerobes can be cultured from the upper small bowel lumen. Motility and acid are the most important factors in keeping the number of bacteria in the upper small bowel low. Any condition that produces local stasis or recirculation of colonic luminal contents allows development of a predominantly "colonic" flora (coliforms and anaerobes, such as *Bacteroides* and *Clostridium*) in the small intestine (see Table 142-4). Anaerobic bacteria cause impaired micelle formation by releasing cholylamidases, which deconjugate bile salts. The unconjugated bile salts, with their higher pK_a, are more likely to be in the protonated form at the normal upper small intestinal pH of 6 to 7 and can be absorbed passively. As a result, the concentration of bile salts decreases in the intestinal lumen and can fall to less than the critical micellar concentration, causing malabsorption of fats and fat-soluble vitamins. Vitamin B_{12} deficiency and carbohydrate malabsorption also can occur with generalized bacterial overgrowth. Anaerobic bacteria ingest vitamin B_{12} and release proteases that degrade brush-border disaccharidases. Although anaerobic bacteria use vitamin B_{12}, they synthesize folate. Individuals with bacterial overgrowth usually have low serum vitamin B_{12} levels but normal or high folate levels; this helps distinguish bacterial overgrowth from tropical sprue, in which vitamin B_{12} and folate levels are usually low because of decreased mucosal uptake.

CLINICAL MANIFESTATIONS

Individuals with bacterial overgrowth can present with diarrhea, abdominal cramps, gas and bloating, weight loss, and signs and symptoms of vitamin B_{12} and fat-soluble vitamin deficiency. Watery diarrhea occurs because of the osmotic load of unabsorbed carbohydrates and stimulation of colonic secretion by unabsorbed fatty acids.

DIAGNOSIS

The diagnosis of bacterial overgrowth should be considered in elderly people and in individuals with predisposing underlying disorders (see Table 142-4). Bacterial overgrowth may be associated with the irritable bowel syndrome (Chapter 139). The identification of greater than 10^5 CFU/mL in a culture of small intestinal aspirate is the "gold standard" in diagnosis but is not readily available. The noninvasive tests with a sensitivity and specificity comparable to intestinal culture are the glucose hydrogen breath test and the ^{14}C- or ^{13}C-D-xylose breath test; in individuals with low vitamin B_{12} levels, a Schilling test before and after antibiotic therapy can be diagnostic (Chapter 167).

TREATMENT Rx

The goals of treatment are to correct the structural or motility defect, if possible; to eradicate offending bacteria; and to provide nutritional support. Acid-reducing agents should be stopped, if possible. Treatment with antibiotics should be based on culture results whenever possible; otherwise, empirical treatment is given. Rifaximin (400 mg orally three times a day) is effective,■ but less so in individuals with an excluded (blind) intestinal loop. Tetracycline (250 to 500 mg orally four times a day) or a broad-spectrum antibiotic against aerobes and enteric anaerobes (ciprofloxacin, 500 mg orally twice a day; amoxicillin–clavulanic acid, 250 to 500 mg orally three times a day; cephalexin, 250 mg orally four times a day with metronidazole, 250 mg three times a day) should be given for 14 days. Prokinetic agents such as metoclopramide (10 mg orally four times a day) or erythromycin (250 to 500 mg orally four times a day) can be tried to treat small bowel motility disorders, but often they are not efficacious. Octreotide (50 µg subcutaneously every day) may improve motility and reduce bacterial overgrowth in individuals with scleroderma. If the structural abnormality or motility disturbance cannot be corrected, the patient is at risk for malnutrition and deficiencies of vitamin B_{12} and fat-soluble vitamins. Cyclic treatment (1 to 3 weeks out of every 4 to 6 weeks) with rotating antibiotics may be required in these patients to prevent recurrent bouts of bacterial overgrowth. If supplemental calories are needed, medium-chain triglycerides should be given because they are not dependent on micelle formation for their absorption. Monthly treatment with vitamin B_{12} should be considered, along with supplemental vitamins D, A, K, and E and calcium.

ILEAL DISEASE OR RESECTION

Disease of the terminal ileum is most commonly due to Crohn's disease (Chapter 143), which also may lead to ileal resection, but it also can be caused by radiation enteritis, tropical sprue, tuberculosis, *Yersinia* infection, or idiopathic bile salt malabsorption. These diseases cause bile salt wasting in the colon.

The clinical consequences of bile salt malabsorption are related directly to the length of the diseased or resected terminal ileum. In an adult, if less than 100 cm of ileum is diseased or resected, watery diarrhea results because of stimulation of colonic fluid secretion by unabsorbed bile salts. Bile acid diarrhea responds to cholestyramine (2 to 4 g taken at breakfast, lunch, and dinner). If more than 100 cm of ileum is diseased or resected, bile salt losses (>3 g/day) in the colon exceed the capacity for increased bile salt synthesis in the liver, the bile salt pool shrinks, and micelle formation is impaired. As a result, steatorrhea ensues, and fatty acid–induced intestinal secretion synergizes with the bile acid–induced secretion to cause diarrhea. Treatment is with a low-fat diet, vitamin B_{12} (300 to 1000 µg subcutaneously once every month or 2 mg orally once a day), dietary supplements of calcium (500 mg orally two to three times a day, monitor 24-hour urine calcium for adequacy of dose), and a multiple vitamin and mineral supplement. An antimotility agent should be given for diarrhea. Bile salt binders may worsen diarrhea. Screening for fat-soluble vitamin deficiencies (vitamins A and E, 25-OH vitamin D, and prothrombin time) and bone disease (bone densitometry, serum calcium, intact parathyroid hormone, 24-hour urine for calcium) should be done.

Three long-term complications of chronic bile salt wasting and fat malabsorption are renal stones, bone disease (osteoporosis and osteomalacia), and gallstones. Oxalate renal stones occur as a consequence of excess free oxalate absorption in the colon. Free oxalate is generated when unabsorbed fatty acids bind luminal calcium, which is then unavailable for binding oxalate. Renal oxalate stones sometimes can be avoided with a low-fat, low-oxalate diet and calcium supplements. Bone disease is caused by impaired micelle formation with a resulting decrease in absorption of vitamin D; year-round sun exposure reduces this complication. Vitamin D (50,000 U orally one to three times a week) and calcium supplements (500 mg orally two to three times a day) should be given to susceptible individuals, but vitamin D levels and serum and urinary calcium must be monitored for response to treatment because excess vitamin D can be toxic. The mechanism of gallstone formation in these individuals is unclear; pigmented gallstones are most common.

Conditions that Impair Mucosal Absorption

PATHOBIOLOGY

Nutrients are absorbed along the entire length of the small intestine, with the exception of iron and folate, which are absorbed in the duodenum and proximal jejunum, and bile salts and cobalamin, which are absorbed in the distal ileum. The efficiency of nutrient uptake at the mucosa is influenced by the

number of villus absorptive cells, the presence of functional hydrolases and specific nutrient transport proteins on the brush-border membrane, and transit time. Transit time determines the contact time of luminal contents with the brush-border membrane and influences the efficiency of nutrient uptake across the mucosa.

Mucosal malabsorption can be caused by specific (usually congenital) brush-border enzyme or nutrient transporter deficiencies or by generalized diseases that damage the small intestinal mucosa or result in surgical resection or bypass of small intestine. The nutrients malabsorbed in these general malabsorptive diseases depend on the site of intestinal injury (proximal, distal, or diffuse) and the severity of damage. The main mechanism of malabsorption in these conditions is a decrease in surface area available for absorption. Some conditions (infection, celiac disease, tropical sprue, food allergies, and graft-versus-host disease) are characterized by intestinal inflammation and villus flattening; others are characterized by ulceration (ulcerative jejunitis, NSAIDs, Crohn's disease), infiltration (amyloidosis), or ischemia (radiation enteritis, mesenteric ischemia).

Long-chain fatty acids are transported across the microvillus membrane of villus epithelial cells by the fatty acid transport protein FATP4. The bile salts from mixed micelles remain in the intestinal lumen and are absorbed in the distal ileum by sodium-dependent cotransport. Oligosaccharides and larger oligopeptides (products of pancreatic enzyme digestion), sucrose, and lactose are hydrolyzed further by enzymes present in the brush-border membrane of villus epithelial cells before they are absorbed. Although only sugar monomers (glucose, galactose, fructose) can be taken up at the apical epithelial cell membrane, dipeptides and tripeptides are readily taken into the cell.

Water-soluble vitamins are readily absorbed throughout the small intestine. Fat-soluble vitamins, minerals, and cobalamin are more difficult to absorb because of the requirement for micelle formation (vitamins D, A, K, and E), a divalent charge (magnesium, calcium, iron), or selected sites of uptake in the intestine (iron, cobalamin). Calcium is absorbed best in the proximal small intestine by a vitamin D–dependent calcium channel. Magnesium is absorbed by the small intestine (throughout its length) by a poorly understood mechanism. Ferrous iron is transported into intestinal epithelial cells by a proton-coupled metal-ion transporter (Nramp2) that has specificity for Fe^{2++} and other divalent cations (Zn^{2++}, Mn^{2++}, Co^{2++}, Cd^{2++}, Cu^{2++}, Ni^{2++}, and Pb^{2++}). The absorption of calcium and nonheme iron is enhanced by solubilization with hydrochloric acid. Intraluminal compounds such as oxalate, phytate, and long-chain fatty acids bind to calcium and magnesium, decreasing their absorption. Individuals with severe mucosal disease or short-bowel syndrome with high fecal fluid outputs lose magnesium and zinc from endogenous secretions.

Folates (Chapters 167 and 225) are both taken in the diet and produced by bacteria in the colon. Dietary folates are absorbed in the proximal small intestine through a reduced folate carrier (RFC1). Deficiency can be caused by poor intake or malabsorption secondary to intestinal disease or drugs. The cobalamins (Chapters 167 and 225) are abundant in foods containing animal proteins (e.g., meat, seafood, eggs, milk). Cobalamin deficiency in industrialized countries is rarely due to poor dietary intake but rather reflects the inability to absorb cobalamin. This inability may be caused by a lack of intrinsic factor, consumption of cobalamin by overgrowth of anaerobic bacteria in the small bowel lumen, ileal disease or resection, or defective transcobalamin II. Large amounts of cobalamin are present in the liver (2 to 5 mg), and cobalamin is reabsorbed from bile through the enterohepatic circulation, thereby limiting daily losses to less than 1 µg. It usually takes 10 to 12 years for cobalamin deficiency to develop after it is eliminated from the diet, but deficiency can occur more rapidly (2 to 5 years) with malabsorptive syndromes. If lack of gastric acid causes food-cobalamin malabsorption, treatment with oral cyanocobalamin supplementation (Chapter 167) is curative.

LACTASE DEFICIENCY

EPIDEMIOLOGY

Acquired lactase deficiency is the most common cause of selective carbohydrate malabsorption. Most individuals, except those of northern European descent, begin to lose lactase activity by the age of 2 years. The prevalence of lactase deficiency is highest (85 to 100%) in persons of Asian, African, and Native-American descent.

PATHOBIOLOGY

The persistence or nonpersistence of lactase activity is associated with a single nucleotide polymorphism C/T_{-13910} that is found upstream of the lactase gene on chromosome 2q21-22. Hypolactasia is associated with the C/C_{-13910} genotype in diverse ethnic groups. The mechanism by which this variant downregulates the lactase gene is not known, but functional studies suggest genotype-dependent alterations in levels of messenger RNA.

CLINICAL MANIFESTATIONS

Adults with lactase deficiency typically complain of gas, bloating, and diarrhea after the ingestion of milk or dairy products but do not lose weight. Unabsorbed lactose is osmotically active, drawing water followed by ions into the intestinal lumen. On reaching the colon, bacteria metabolize lactose to short-chain fatty acids, carbon dioxide, and hydrogen gas. Short-chain fatty acids are transported with sodium into colonic epithelial cells, facilitating the reabsorption of fluid in the colon. If the colonic capacity for the reabsorption of short-chain fatty acids is exceeded, an osmotic diarrhea results (see later discussion of carbohydrate malabsorption in watery diarrheas).

DIAGNOSIS

The diagnosis of acquired lactase deficiency can be made by empirical treatment with a lactose-free diet, which results in resolution of symptoms; by the hydrogen breath test after oral administration of lactose; or by genetic testing. Many intestinal diseases cause secondary reversible lactase deficiency, including viral gastroenteritis, celiac disease, giardiasis, and bacterial overgrowth.

Congenital Enteropeptidase (Enterokinase) Deficiency

Enteropeptidase is a brush-border protease that cleaves trypsinogen to trypsin, triggering the cascade of pancreatic protease activation in the intestinal lumen. The rare congenital deficiency of enteropeptidase results in inability to activate all pancreatic proteases and leads to severe protein malabsorption. It manifests in infancy as diarrhea, growth retardation, and hypoproteinemic edema.

Abetalipoproteinemia

Formation and exocytosis of chylomicrons at the basolateral membrane of intestinal epithelial cells are necessary for the delivery of lipids to the systemic circulation. One of the proteins required for assembly and secretion of chylomicrons is the microsomal triglyceride transfer protein, which is mutated in individuals with abetalipoproteinemia. Children with this disorder have fat malabsorption and the consequences of vitamin E deficiency (retinopathy and spinocerebellar degeneration). Biochemical tests show low plasma levels of apoprotein B, triglyceride, and cholesterol. Membrane lipid abnormalities result in red blood cell acanthosis (burr cells). Intestinal biopsy is diagnostic; the tissue is characterized by engorgement of epithelial cells with lipid droplets. Calories are provided by treatment with a low-fat diet containing medium-chain triglycerides. Poor absorption of long-chain fatty acids sometimes can result in essential fatty acid deficiency. High doses of fat-soluble vitamins, especially vitamin E, often are needed. Mutations in the apolipoprotein B gene (hypobetalipoproteinemia) and intracellular retention of chylomicrons (Anderson's disease) cause a similar although less severe clinical syndrome.

CELIAC DISEASE

DEFINITION AND EPIDEMIOLOGY

Celiac disease is an inflammatory condition of the small intestine precipitated by the ingestion of wheat, rye, and barley in individuals with certain genetic predispositions. Screening studies for the antiendomysial (EMA) and anti–tissue transglutaminase (anti-tTG) antibodies that are associated with celiac disease suggest a prevalence in white populations of about 1%. High-risk groups for celiac disease include first-degree relatives and individuals with type 1 diabetes mellitus, autoimmune thyroid disease, primary biliary cirrhosis, Turner's syndrome, or Down syndrome. About 20% of patients diagnosed with irritable bowel syndrome or with microscopic (lymphocytic) colitis have celiac disease.

PATHOBIOLOGY

Environmental and genetic factors are important in the development of celiac disease. The alcohol-soluble protein fraction of wheat gluten, the gliadins, and similar prolamins in rye and barley trigger intestinal inflammation in susceptible individuals. Oat grains, which have prolamins rich in glutamine but not proline, are rarely toxic. Gliadins and similar prolamins with high proline content are relatively resistant to digestion by human proteases. A 33-mer peptide that is a natural digestion product of α_2-gliadin may be important in

the pathogenesis of celiac disease. This peptide resists terminal digestion by intestinal brush-border proteases and contains three previously identified antigenic epitopes. It also reacts with tissue transglutaminase and stimulates human leukocyte antigen (HLA)-DQ2-restricted intestinal T-cell clones from individuals with celiac disease.

Approximately 15% of first-degree relatives of affected individuals are found to have celiac disease. Predisposition has been mapped to the HLA-D region on chromosome 6. More than 90% of northern Europeans with celiac disease have the DQ2 heterodimer encoded by alleles *DQA1*0501* and *DQB1*0201,* compared with 20 to 30% of controls. A smaller celiac group carries HLA DQ8. The strongest candidate non-HLA alleles identified in genome-wide association studies are 4q27 and 3q28. The DQ2 protein expressed on antigen-presenting cells has positively charged binding pockets; tTG (the autoantigen recognized by EMA) may enhance intestinal inflammation by deamidation of select glutamine residues in gliadin to negatively charged glutamic acid. In the deamidated form, most gliadin peptides have a higher binding affinity for DQ2 and are more potent stimulants of gluten-sensitized T cells. Villous atrophy may be caused by inflammation that is triggered by γ-interferon released from DQ2- or DQ8-restricted CD4 T cells in the lamina propria. Alternatively, intraepithelial lymphocytes may directly kill intestinal epithelial cells under the influence of IL-15 released from stressed enterocytes.

CLINICAL MANIFESTATIONS

Celiac disease usually manifests early in life, at about 2 years of age (after wheat has been introduced into the diet), or later in the second to fourth decades of life, but it can occur at any age. It may first manifest clinically after abdominal surgery or an episode of infectious diarrhea.

Breast-feeding and the time of introduction of wheat in the diet may lessen the risk or delay the onset of celiac disease in children at risk. Adults with celiac disease in the United States often present with anemia or osteoporosis without diarrhea or other gastrointestinal symptoms. These individuals most likely have proximal disease that impairs iron, folate, and calcium absorption but an adequate surface area in the remaining intestine for absorption of other nutrients. Other extraintestinal manifestations of celiac disease include rash (dermatitis herpetiformis), neurologic disorders (peripheral neuropathy, ataxia, epilepsy), psychiatric disorders (depression, paranoia), reproductive disorders (infertility, spontaneous abortion), short stature, dental enamel hypoplasia, chronic hepatitis, or cardiomyopathy.

Individuals with significant mucosal involvement present with watery diarrhea, weight loss or growth retardation, and the clinical manifestations of vitamin and mineral deficiencies. Cobalamin deficiency is more common (10% of patients) than previously thought and usually corrects itself on a gluten-free diet. Symptomatic individuals require supplementation of vitamin B_{12}. Diarrhea is caused by many mechanisms, including a decreased surface area for water and electrolyte absorption, the osmotic effect of unabsorbed luminal nutrients, an increased surface area for chloride secretion (crypt hyperplasia), and the stimulation of intestinal fluid secretion by inflammatory mediators and unabsorbed fatty acids. Some individuals have impaired pancreatic enzyme secretion caused by decreased mucosal cholecystokinin release or bacterial overgrowth that may contribute to diarrhea.

DIAGNOSIS

The diagnosis of celiac disease is made by characteristic changes found on a small intestinal biopsy specimen and improvement when a gluten-free diet is instituted (Figs. 142-6 and 142-7). Mucosal flattening may be observed endoscopically as scalloped or reduced duodenal folds. Characteristic features found on intestinal biopsy include blunted or absent villi, crypt hyperplasia, increased intraepithelial lymphocytes, and infiltration of the lamina propria with plasma cells and lymphocytes. In some individuals, the only abnormal biopsy finding is increased intraepithelial lymphocytes. A hypoplastic mucosa indicates irreversible (end-stage) intestinal disease.

Serologic markers for celiac disease are useful in supporting the diagnosis, in screening first-degree relatives, and in monitoring the response to a gluten-free diet. EMA immunoglobulin A (IgA) antibodies, detected by indirect immunofluorescence, are highly sensitive (90%) and specific (90 to 100%) for active celiac disease in skilled laboratory testing. An enzyme-linked immunosorbent assay (ELISA) test to detect antibodies against tTG has equal sensitivity to the EMA test but is less specific. The newer anti-deamidated gliadin (a biotinylated synthetic γ-gliadin peptide with glutamic acid substituted for glutamine) IgA and IgG antibody immunofluorometric assay has a sensitivity and specificity that approaches that of EMA.

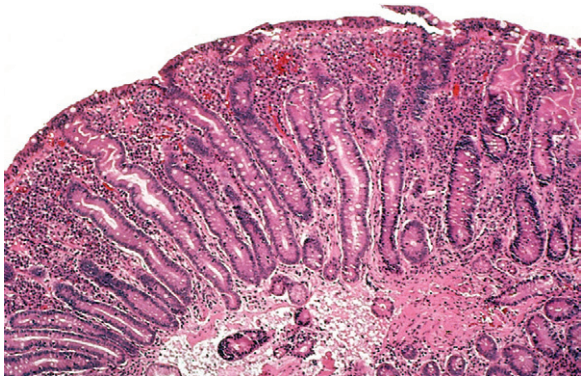

FIGURE 142-6. Intestinal biopsy appearance of flattened villi, hyperplastic crypts, and increased intraepithelial lymphocytes. (Courtesy of John Hart, MD.)

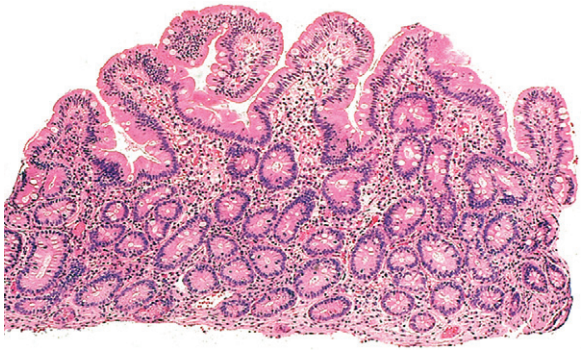

FIGURE 142-7. Regeneration of villi after initiation of a gluten-free diet. (Courtesy of John Hart, MD.)

The anti-tTG IgA antibody test, when obtained with a serum IgA level, is a cost-effective strategy for screening high-risk groups; very high titers of the anti-tTG IgA and EMA antibodies are virtually diagnostic of celiac disease. Patients with mild disease may have negative antibody studies. Anti-tTG, gliadin peptide, and EMA IgA antibodies tests are negative in individuals with selective IgA deficiency (present in up to 2.6% of individuals with celiac disease). In these patients, anti-tTG or gliadin peptide IgG antibodies may be helpful in diagnosis. In equivocal cases (negative serology and equivocal biopsy or positive serology and normal biopsy), HLA genotyping is useful to exclude the diagnosis of celiac disease in persons who lack the DQ2 or DQ8 gene.

TREATMENT

Rx

Treatment consists of a lifelong gluten-free diet. Wheat, rye, and barley grains should be excluded from the diet. Rice and corn grains are tolerated. Oats (if not contaminated by wheat grain) are tolerated by most. Early referral to a reputable celiac support group or website is often helpful in maintaining dietary compliance. Owing to secondary lactase deficiency, a lactose-free diet should be recommended until symptoms improve. Bone densitometry should be performed on all individuals with celiac disease because up to 70% have osteopenia or osteoporosis. Patients with diarrhea and weight loss should be screened for vitamin and mineral deficiencies. Documented deficiencies of vitamins and minerals should be replenished (see Table 142-4), and women of childbearing age should take folic acid supplements. Bone mass often improves on a gluten-free diet alone. Patients with vitamin D or calcium deficiency should receive supplements (Chapter 225), with the dose monitored by 25-OH vitamin D levels and a 24-hour urine test for calcium.

PROGNOSIS

Of patients with celiac disease treated with a gluten-free diet, 90% experience symptomatic improvement within 2 weeks. The most common cause of a poor dietary response is continued ingestion of gluten. Other possibilities include a missed intestinal infection (see later), an alternative diagnosis (e.g., agammaglobulinemia [diagnosed by hypogammaglobulinemia and lack of

plasma cells on small bowel biopsy], autoimmune enteritis [diagnosed by a positive antienterocyte antibody and crypt apoptosis or loss of goblet cells on small bowel biopsy]), bacterial overgrowth, pancreatic insufficiency, microscopic colitis, or other food allergies (cow's milk, soy protein).

In a small percentage of patients, symptoms and enteropathy persist despite a strict gluten-free diet. In such patients, repeat intestinal biopsy is indicated. Some patients will have collagen deposition beneath the surface epithelium (collagenous sprue). Others will have ulcerative jejunitis or a monoclonal population of intraepithelial T cells with an aberrant phenotype or clonal T-cell receptor-γ gene rearrangements, which are predictive of enteropathy-associated T-cell lymphoma (Chapter 191) that portends a poor prognosis. Video capsule endoscopy and balloon-assisted enteroscopy may be helpful in establishing these diagnoses. Patients with collagenous sprue, autoimmune enteritis, or refractory sprue with a polyclonal population of intraepithelial T lymphocytes often respond to prednisone (20 to 40 mg orally daily) or budesonide (3 mg orally three times a day).

Individuals with celiac disease are at increased risk for B-cell lymphoma (Chapter 191), gastrointestinal tract carcinomas (esophageal, small bowel, and colonic adenocarcinomas), and increased mortality; a strict gluten-free diet for life may lessen these risks. Intestinal T-cell lymphoma is rare and should be suspected in individuals who have abdominal pain, recurrence of symptoms after initial response to a gluten-free diet, or refractory celiac disease.

TROPICAL SPRUE

Tropical sprue is an inflammatory disease of the small intestine associated with the overgrowth of predominantly coliform bacteria. It occurs in residents or travelers to the tropics, especially India and Southeast Asia. Individuals classically present with diarrhea and megaloblastic anemia secondary to vitamin B_{12} and folate deficiency, but some have anemia only. Intestinal biopsy characteristically shows subtotal and patchy villous atrophy in the proximal and distal small intestine, which may be caused by the effect of bacterial toxins on gut structure or by the secondary effects of vitamin B_{12} deficiency on the gut (megaloblastic gut). Diagnosis is based on history, documentation of vitamin B_{12} or folate deficiency, and the presence of an abnormal small intestinal biopsy report. Treatment is a prolonged course of broad-spectrum antibiotics, oral folate, and vitamin B_{12} injections until symptoms resolve. Relapses occur mainly in natives of the tropics.

Infection

GIARDIA LAMBLIA

Giardia lamblia (Chapter 359) infection, the most common protozoal infection in the United States, can cause malabsorption in individuals infected with many trophozoites, especially the immunocompromised or IgA-deficient hosts. Malabsorption occurs when many organisms cover the epithelium and cause mucosal inflammation, which results in villous flattening and a decrease in absorptive surface area. Stool for ova and parasites at this stage of infection is often negative because of the attachment of organisms in the proximal small intestine. Diagnosis can be made by a stool antigen-capture ELISA test but may require duodenal aspiration and biopsies.

HUMAN IMMUNODEFICIENCY VIRUS

Diarrhea, malabsorption, and wasting are common in individuals with AIDS but are seen less frequently with improved antiretroviral therapy (Chapter 397). In patients who are receiving highly active antiretroviral therapy, diarrhea is more likely to be due to protease inhibitors than to enteric infection.

Malabsorption is usually due to infection with cryptosporidia, *Mycobacterium avium-intracellulare* complex, *I. belli,* or microsporidia. An organism can be identified by stool examination or intestinal biopsy about 50% of the time. *AIDS enteropathy* (a term used if no organism is identified) also can cause malabsorption. Mechanisms of malabsorption and diarrhea include villous atrophy, increased intestinal permeability, rapid small bowel transit (in patients with protozoal infection), and ultrastructural damage of enterocytes (in AIDS enteropathy). Among individuals with AIDS and diarrhea, results of fecal fat and D-xylose absorption are frequently abnormal. Serum albumin, vitamin B_{12}, and zinc levels are often low. Vitamin B_{12} deficiency is caused mainly by ileal disease, but low intrinsic factor and decreased transcobalamin II may be contributing factors. Management of malabsorption should focus on restoring the immune system by treating the underlying HIV infection with antiviral therapy. If possible, the offending organism should be treated with antibiotics. If the organism cannot be eradicated, chronic diarrhea and malabsorption result; treatment in these cases consists of antimotility agents and a lactose-free, low-fat diet. Pancreatic enzyme replacement therapy can be tried in HIV-infected individuals who are taking highly active antiretroviral therapy or nucleoside analogues and who have fat malabsorption of obscure origin. If supplemental calories are needed, liquid oral supplements that are predigested and high in medium-chain triglycerides (semi-elemental) are tolerated best. Vitamin and mineral deficiencies should be screened for and treated.

WHIPPLE'S DISEASE

Whipple's disease (Chapters 144 and 283), a rare cause of malabsorption, manifests with gastrointestinal complaints in association with systemic symptoms, such as fever, joint pain, or neurologic manifestations. About one third of patients have cardiac involvement, most commonly culture-negative endocarditis. Occasionally, individuals present with ocular or neurologic disease without gastrointestinal symptoms. Men are affected more commonly than women, particularly white men. The organism responsible for causing Whipple's disease is a gram-positive actinomycete, *Tropheryma whippelii.* The epidemiology and pathogenesis of Whipple's disease are poorly understood. The prevalence of the disease is higher in farmers compared with other workers, which suggests that the organism lives in the soil. Using the polymerase chain reaction, *T. whippelii* has been detected in sewage and in duodenal biopsy specimens, gastric juice, saliva, and stool of individuals without clinical disease. Whether the latter represents a carrier state or the presence of nonpathogenic organisms is not known. Immunologic defects and an association with the HLA-B27 gene may be disease factors. Small intestinal biopsy shows villous blunting and infiltration of the lamina propria with large macrophages that stain positive with the periodic acid–Schiff method and are filled with the organism. It is important to distinguish these macrophages from macrophages infected with *M. avium-intracellulare* complex, which stain positive on acid-fast staining and are found in individuals with AIDS. Treatment is with a prolonged course of broad-spectrum antibiotics (e.g., 10 to 14 days of parenteral penicillin G, 1.2 million U every day and streptomycin, 1 g every day; ceftriaxone, 2 g intravenously daily, or meropenem, 1 g intravenously three times daily; then, 160 mg of trimethoprim and 800 mg of sulfamethoxazole orally two times a day for 1 year or 160 mg of trimethoprim and 800 mg of sulfamethoxazole orally two times a day for 1 year). Relapses occur, but initial treatment with parenteral ceftriaxone or meropenem appears to be associated with a low relapse rate.

GRAFT-VERSUS-HOST DISEASE

Diarrhea occurs frequently after allogeneic bone marrow or stem cell transplantation (Chapter 181). Immediately after transplantation, diarrhea is caused by the toxic effects of cytoreductive therapy on the intestinal epithelium. Twenty to 100 days after transplantation, diarrhea is usually due to graft-versus-host disease (GVHD) or infection. Patients with GVHD present clinically with a skin rash, hepatic cholestasis, buccal mucositis, anorexia, nausea, vomiting, abdominal cramps, and diarrhea. The diagnosis of GVHD in the gastrointestinal tract can be made on biopsy of the stomach, small intestine, or colon. In mild cases, the mucosa appears normal on inspection at endoscopy, but apoptosis of gastric gland or crypt cells can be found on biopsy. In severe cases, denudation of the intestinal epithelium results in diarrhea and malabsorption and often requires parenteral nutritional support. Octreotide (50 to 250 μg subcutaneously three times a day) may be helpful in controlling voluminous diarrhea. Treatment of GVHD is with steroids and antithymocyte globulin combined with parenteral nutritional support until intestinal function returns.

SHORT-BOWEL SYNDROME

Malabsorption caused by small bowel resection or surgical bypass is called the short-bowel syndrome. The most common causes in the United States are massive resection due to adhesions, volvulus, ischemia (mesenteric or after intra-abdominal surgery), and gastric bypass surgery. Short-bowel syndrome due to Crohn's disease and radiation enteritis now is less common because of improved medical and radiation therapies. The severity of malabsorption depends on the site and extent of resection; the capacity for hyperplasia, dilation, and elongation; and the function of the residual bowel. Mechanisms of malabsorption after small bowel resection include a decreased absorptive surface area, decreased luminal bile salt concentration, rapid transit, and bacterial overgrowth. Limited jejunal resection usually is tolerated best because bile salt and vitamin B_{12} absorption remain normal. Ileal resection is less well tolerated because of the consequences of bile

salt wasting and the limited capacity of the jejunum to undergo adaptive hyperplasia.

When less than 100 cm of jejunum remains, the colon takes on an important role in caloric salvage and fluid reabsorption. Malabsorbed carbohydrates are digested by colonic bacteria to short-chain fatty acids, which are absorbed in the colon.

TREATMENT

Rx

Parenteral nutrition may be avoided by a diet rich in complex carbohydrates, oral rehydration solutions, and an antimotility agent. In comparison, individuals with fewer than 100 cm of jejunum and no colon have high jejunostomy outputs and often require intravenous fluids or parenteral nutrition to survive. These individuals waste sodium, chloride, bicarbonate, magnesium, zinc, and water in their ostomy effluent. Dietary modifications should include a high-salt, nutrient-rich diet given in small meals. An oral rehydration solution with a sodium concentration greater than 90 mmol/L is absorbed best. Oral vitamin and mineral doses higher than the usual U.S. recommended daily allowances are required (Table 142-5). Vitamin B_{12} should be given parenterally (500 to 1000 µg subcutaneously every month). Magnesium deficiencies are often difficult to replenish with oral magnesium because of its osmotic effect in the intestinal lumen. A liquid magnesium preparation added to an oral rehydration solution and sipped throughout the day may minimize magnesium-induced fluid losses. Potent antimotility agents, such as tincture of opium (0.5 to 1 mL orally four times a day), often are needed to slow transit and maximize contact time for nutrient absorption. High-volume jejunostomy outputs can be lessened by inhibiting endogenous secretions with a proton pump inhibitor (e.g., omeprazole, 40 mg orally one to two times a day, or lansoprazole, 30 mg orally one to two times a day) and, in severe cases, octreotide (100 to 250 µg subcutaneously three times a day; if effective, convert to an equivalent long-acting monthly dosage). The benefit of octreotide may be offset by its potential to inhibit intestinal adaptation and impair pancreatic enzyme secretion with doses greater than 300 µg/day.

In the most severe cases, supplemental calories must be provided by nocturnal tube feeding or parenteral nutrition. Treatment with growth hormone (0.1 mg/kg/day subcutaneously) with or without glutamine (30 g once a day orally) for 4 weeks may reduce parenteral nutrition requirements in patients who have had massive intestinal resections.■ Teduglutide (0.05 mg/kg/day subcutaneously), a glucagon-like peptide-2 analogue that stimulates adaptive hyperplasia in remnant intestine after resection, reduces parenteral nutrition requirements.■

TABLE 142-5 VITAMIN AND MINERAL DOSES USED IN THE TREATMENT OF MALABSORPTION

VITAMIN	ORAL DOSE	PARENTERAL DOSE
Vitamin A*	Water-soluble A, 25,000 U/day†	
Vitamin E	Water-soluble E, 400-800 U/day†	
Vitamin D‡	25,000-50,000 U/day	
Vitamin K	5 mg/day	
Folic acid	1 mg/day	
Calcium§	1500-2000 mg elemental calcium/day Calcium citrate, 500 mg calcium/tablet† Calcium carbonate, 500 mg calcium/tablet†	
Magnesium	Liquid magnesium gluconate† 1-3 tbsp (12-36 mEq magnesium) in 1-2 L of ORS or sports drink sipped throughout the day Magnesium chloride hexahydrate† 100-600 mg elemental magnesium/day	2 mL of a 50% solution (8 mEq) both buttocks IM
Zinc	Zinc gluconate† 20-50 mg elemental zinc/day‖	
Iron	150-300 mg elemental iron/day Polysaccharide-iron complex† Iron sulfate or gluconate	Iron sucrose¶ Sodium ferric gluconate complex¶ Iron dextran (as calculated for anemia) (IV or IM¶; Chapter 162)
B-complex vitamins	1 megadose tablet/day	
Vitamin B_{12}	2 mg/day	1 mg IM or SC/mo**

*Monitor serum vitamin A level to avoid toxicity, especially in patients with hypertriglyceridemia.
†Form best absorbed or with least side effects.
‡Monitor serum calcium and 25-OH vitamin D levels to avoid toxicity.
§Monitor 24-hr urine calcium to assess adequacy of dose.
‖If intestinal output is high, additional zinc should be given. Monitor for copper deficiency with high doses.
¶Parenteral therapy should be given in a supervised outpatient setting because of the risk of fatal reactions. Decreased risk of fatal reactions when compared with iron dextran.
**For vitamin B_{12} deficiency, 1 mg IM or SC twice a week for 4 wk, then once a month.
ORS = oral rehydration solution.

PROGNOSIS

Long-term complications include bone disease, renal stones (oxalate stones if the colon is present, urate stones with a jejunostomy), gallstones, bacterial overgrowth, fat-soluble vitamin deficiencies, essential fatty acid deficiency, and D-lactic acidosis. Small bowel transplantation should be considered for individuals who require parenteral nutrition to survive and then develop liver disease or venous access problems.

Conditions That Impair Nutrient Delivery to the Systemic Circulation

Insoluble lipids (present in chylomicrons) are exocytosed across the basolateral membrane of epithelial cells into the intestinal lymphatics. From there, they enter the mesenteric lymphatics and the general circulation through the thoracic duct. Sugar monomers, amino acids, and medium-chain fatty acids are transported across the basolateral membrane of intestinal epithelial cells into capillaries and into the portal circulation. Sugar monomers are transported across the basolateral membrane by the facilitative glucose transporter isoform (GLUT2) and amino acids by facilitative amino acid carriers (see Fig. 142-1A).

IMPAIRED LYMPHATIC DRAINAGE

Diseases that cause intestinal lymphatic obstruction, such as primary congenital lymphangiectasia (malunion of intestinal lymphatics), and diseases that result in secondary lymphangiectasia (lymphoma, tuberculosis, Kaposi's sarcoma, retroperitoneal fibrosis, constrictive pericarditis, severe heart failure) result in fat malabsorption. The increased pressure in the intestinal lymphatics leads to leakage and sometimes rupture of lymph into the intestinal lumen, with the loss of lipids, γ-globulins, albumin, and lymphocytes. The diagnosis of lymphangiectasia can be made by intestinal biopsy, but the specific cause may be more difficult to identify. Individuals with lymphangiectasia malabsorb fat and fat-soluble vitamins and have protein loss into the intestinal lumen. The most common presentation is hypoproteinemic edema. Nutritional management includes a low-fat diet and supplementation with medium-chain triglycerides, which are absorbed directly into the portal circulation. Fat-soluble vitamins should be given if deficiencies develop.

WATERY DIARRHEA

Watery diarrhea may be due to osmotic, secretory, inflammatory, or often combined mechanisms (Fig. 142-8).

Ingestion of Nonabsorbable or Poorly Absorbable Solutes

MAGNESIUM AND SODIUM PHOSPHATE AND SULFATE DIARRHEAS

Magnesium, phosphate, and sulfate are poorly absorbed minerals. Individuals who ingest significant amounts of magnesium-based antacids or high-potency multimineral and multivitamin supplements or those who surreptitiously ingest magnesium-containing laxatives or nonabsorbable anion laxatives, such as Na_2PO_4 (neutral phosphate) or Na_2SO_4 (Glauber's or Carlsbad salt) may develop osmotically induced, watery diarrhea that may be high volume.

SORBITOL AND FRUCTOSE DIARRHEA

Dietetic food, chewing gum, candies, and medication elixirs that are sweetened with sorbitol, which is an unabsorbable carbohydrate, can cause diarrhea. Excessive consumption of pears, prunes, peaches, and apple juice, which also contain sorbitol and fructose, a poorly absorbable sugar, can result in diarrhea. Most soft drinks are now sweetened with fructose-containing corn syrup and may be a cause of diarrhea when ingested in high concentrations.

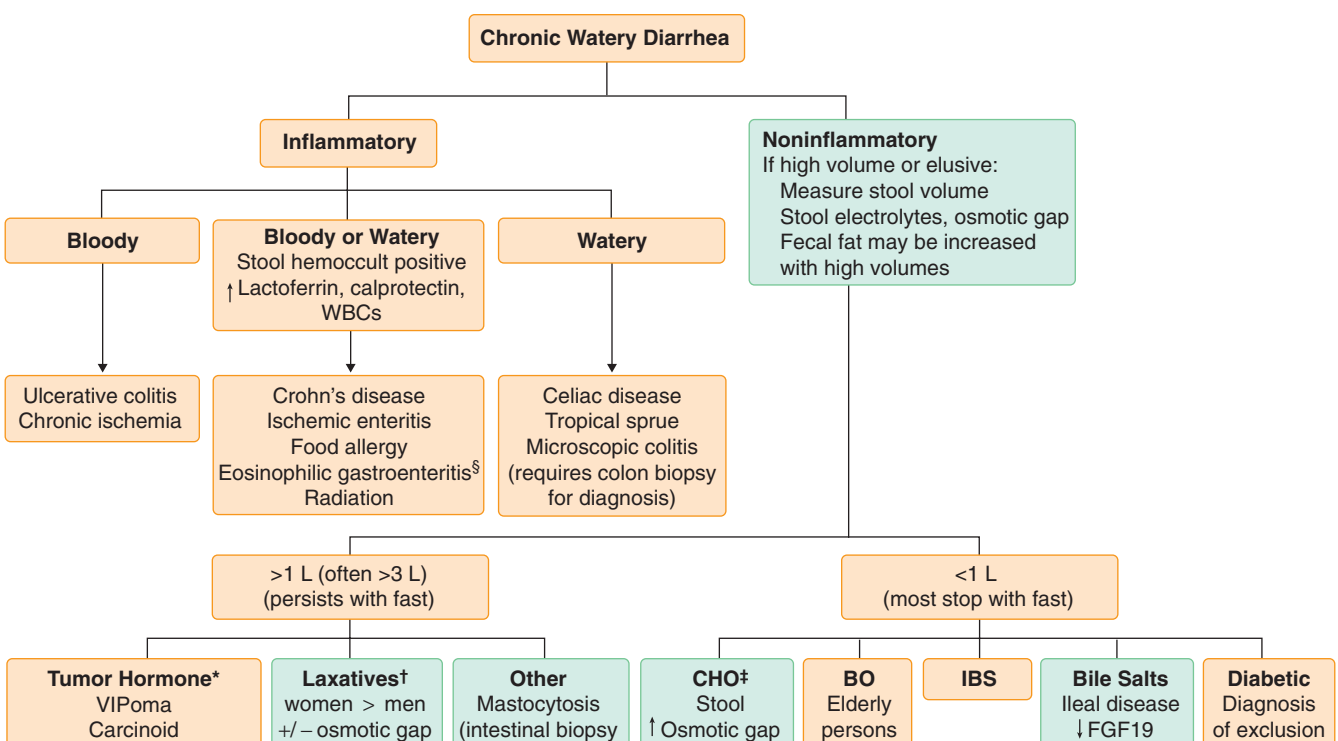

FIGURE 142-8. Approach to the evaluation of watery diarrheas. Many diarrheas have more than one mechanism (i.e., osmotic, secretory, inflammatory). Other causes include medications, postsurgical (vagotomy, Nissan wrap, cholecystectomy), hyperthyroidism, and alcohol. *VIPoma: >3 L output daily "pancreatic cholera," elevated VIP level. Carcinoid: elevated urine 5-hydroxyindole acetic acid, positive OctreoScan. Gastrinoma (Zollinger-Ellison syndrome): elevated gastrin level, positive secretin stimulation test, diarrhea due to high volume of acid secretion. Thyroid medullary cancer: elevated calcitonin level. †May be high or low volume depending on dose ingested, may respond to fast. ‡Carbohydrate malabsorption (CHO) may be due to lactase deficiency, dietary fructose, sorbitol in diabetic candies or liquid medications. §Full-thickness biopsy may be needed for diagnosis. BO = bacterial overgrowth; FGF = fibroblast growth factor; IBS = irritable bowel syndrome; WBCs = white blood cells.

GLUCOSE-GALACTOSE MALABSORPTION AND DISACCHARIDASE DEFICIENCIES

Primary and secondary lactase deficiency is the most common cause of disaccharidase deficiency (see malabsorption). Congenital lactase deficiency causes diarrhea at birth with the first breast feed. Congenital sucrose-isomaltose deficiency presents in infancy when table sugar is introduced into the diet. Glucose-galactose malabsorption is due to mutations in the *SGLT1* gene and causes diarrhea at birth. The mechanism of diarrhea in these disorders is osmotic. Stools are acidic owing to conversion of unabsorbed sugars to short-chain fatty acids in the colon. Treatment is the substitution of fructose for other sugars in the diet. Patients who develop gas, bloating, or diarrhea after the ingestion of mushrooms may have a deficiency in the disaccharidase trehalase.

RAPID INTESTINAL TRANSIT

A small amount of carbohydrate in the diet is unabsorbed by the normal small intestine. Diets that are high in carbohydrate and low in fat may allow rapid gastric emptying and rapid small intestinal motility, thereby leading to carbohydrate malabsorption and osmotic diarrhea. Rapid transit time also occurs in thyrotoxicosis (Chapter 233). Because of the production of H_2 and CO_2 gas by colonic bacteria, abdominal gas and cramping may be the predominant symptoms.

BILE ACID MALABSORPTION

Ileal malabsorption of bile salts results in the stimulation of colonic fluid secretion and watery diarrhea. Three types of bile acid malabsorption induce diarrhea. Type 1 results when severe disease (e.g., Crohn's disease), resection, or bypass of the distal ileum allows bile salts to escape absorption (see earlier). Type 2 may rarely be congenital, owing to a defect in the apical sodium bile acid transporter, or may more commonly be idiopathic. The idiopathic type has been associated with decreased levels of FGF19, an intestinal fibroblast growth factor that normally downregulates bile salt synthesis in the liver. The result is increased bile salt production that overwhelms reabsorption in the ileum. Type 3 is caused by various conditions, including prior cholecystectomy, celiac disease, pancreatic insufficiency, microscopic colitis, bacterial overgrowth, gastric surgery, or vagotomy. Postulated mechanisms include a bile salt storage problem, increased production, decreased recycling, or saturation of absorption.

TREATMENT

Rx

Diarrhea due to types 1 and 2 often responds to cholestyramine, 2 to 4 g given orally two to four times daily, or the more potent and better tolerated bile salt binder, colesevelam, 625 mg tablet orally two to six times daily. Fat-soluble vitamin deficiency is a potential risk with chronic use of bile salt binders.

Although many patients with type 3 respond to cholestyramine, some do not. In these patients, motility-altering drugs such as opiates (e.g., loperamide, 2 to 4 mg orally two to four times daily) and anticholinergics (e.g., hyoscyamine sulfate, 0.125 to 0.250 mg orally two to four times daily) may be of benefit.

Functional Watery Diarrhea (Irritable Bowel Syndrome)

See Chapter 139.

TRUE SECRETORY DIARRHEAS

Endocrine diseases that can cause secretory diarrheas (see Fig. 142-8) include carcinoid tumors (Chapter 240), gastrinomas (Chapter 201), VIPomas of the pancreas (Chapter 201), and medullary carcinoma of the thyroid (Chapter 254). Diarrhea is also seen in 60 to 80% of patients with systemic mastocytosis (Chapter 263). Diarrhea due to gastrinoma is distinct in that it is caused by high volumes of hydrochloric acid secretion that overwhelm the reabsorptive capacity of the colon and by maldigestion of fat owing to pH inactivation of pancreatic lipase and precipitation of bile salts.

Villous Adenomas

Large (4 to 18 cm) villous adenomas (Chapter 199), particularly in the rectum or occasionally the sigmoid colon, may cause secretory diarrhea of 500 to 3000 mL/24 hours characterized by hypokalemia, chloride-rich stool, and metabolic alkalosis. Increased numbers of goblet cells and increased prostaglandin E_2 are responsible for the diarrhea. Chloride wasting in the stool and metabolic alkalosis are also found in congenital chloridorrhea, which is caused by a defect in the intestinal Cl^-/HCO_3^- transporter. The metabolic alkalosis distinguishes these two diarrheas from most other diarrheas that cause metabolic acidosis. A villous adenoma is usually diagnosed by colonoscopy. The prostaglandin antagonist indomethacin (25 to 100 mg orally daily) reduces the diarrhea in some patients; resection is curative.

Diabetes Mellitus–Related Diarrhea

Constipation is more common than diarrhea in patients with diabetes. High-volume, watery diarrhea, often with nocturnal incontinence, occurs in 20% of poorly controlled type 1 diabetic patients. These patients usually have concomitant neuropathy, nephropathy, and retinopathy. The diarrhea may be due to several causes, including celiac disease, anal incontinence, bacterial overgrowth related to dysmotility, medications (metformin, acarbose), and autonomic neuropathy. If no specific cause is found, clonidine (initial dose 0.1 mg orally twice daily and titrated slowly to a maximal dose of 0.5 to 0.6 mg orally twice daily) may be helpful. Patients with neuropathy frequently have impaired anal sphincter function, and high-dose loperamide (4 mg orally four times a day) may improve the incontinence.

Alcoholic Diarrhea

Diarrhea related to alcohol ingestion (Chapter 32) may be due to rapid intestinal transit, decreased bile and pancreatic secretion, nutritional deficiencies such as folate or vitamin B_{12}, or alcohol-related enteric neuropathy. Diarrhea may be acute with binge drinking, or it may be chronic and watery and persist for days or weeks. The diarrhea slowly resolves with abstinence from alcohol, proper nutrition, and the repletion of vitamin deficiencies.

Factitious Diarrhea

Approximately 30% of patients referred to tertiary centers have chronic diarrhea due to laxative abuse. The diarrhea is usually severe and watery, often with nocturnal symptoms. Some patients may have abdominal pain, weight loss, nausea, vomiting, hypokalemic myopathy, and acidosis. Stool volumes range from 300 to 3000 mL a day depending on the dose of laxative ingested. In the United States, bisacodyl is the most common cause. Other culprits include anthraquinone (senna, cascara, aloe, rhubarb) or osmotic laxatives (neutral phosphate, Epsom salts, and magnesium citrate). Some patients abuse other agents that cause diarrhea, such as the diuretics furosemide and ethacrynic acid.

More than 90% of laxative abusers are women who have underlying eating disorders such as anorexia nervosa or bulimia (Chapter 226) or middle-aged women who have complicated medical histories and who often work in health care. In patients with unexplained diarrhea, laxative screening of stool and urine (see later) should be performed to exclude this syndrome before an extensive medical evaluation is performed for other causes of chronic diarrhea.

Chronic Idiopathic Secretory Diarrhea

In a small subset of patients with secretory diarrhea, no cause is found despite an extensive evaluation. These cases are labeled as chronic idiopathic secretory diarrhea. In most patients, the diarrhea resolves within 6 to 24 months, which suggests a possible postinfectious or Brainerd's diarrhea. If no diagnosis is found after thorough testing and a search for surreptitious laxative abuse, a therapeutic trial with bile salt–binding drugs (e.g., cholestyramine, 4 g orally before meals three times a day, or the more potent colesevelam, 625-mg tablet two to six times daily) or opiates (e.g., loperamide, 2 mg orally four times a day, maximal dose 16 mg a day) is warranted.

INFLAMMATORY DIARRHEAS

Diarrhea due to inflammation is characterized by watery or bloody stools, fecal leukocytes, and loss of protein in the stool (see Fig. 142-8).

Inflammatory Bowel Disease

See Chapter 143.

Eosinophilic Gastroenteritis

Eosinophilic gastroenteritis is an increasingly recognized condition of unknown etiology characterized by infiltration of eosinophils in the mucosa, muscle, or serosal layers of the gastrointestinal tract. Approximately 50% of patients have atopic histories. Infestation with nematodes (Chapter 365) must be excluded before this diagnosis is made. Diarrhea occurs in 30 to 60% of patients with mucosal disease. Patients with involvement of the muscle layer often present with abdominal pain, nausea, and vomiting indicative of gastric outlet or intestinal obstruction. Peripheral eosinophilia is present in most patients. The disease may involve the entire gastrointestinal tract from esophagus to anus, or it may be isolated to a segment. With diffuse involvement, patients may have steatorrhea, protein-losing enteropathy, and blood loss.

COLLAGENOUS COLITIS AND LYMPHOCYTIC COLITIS

These two conditions, collectively known as *microscopic colitis*, may or may not be the same disease or variants of the same disease. Lymphocytic colitis is equally prevalent in men and women, whereas collagenous colitis occurs ten times more often in middle-aged or elderly women. These conditions may be associated with autoimmune disease or with NSAID use. There is an increased prevalence (15%) of microscopic colitis among individuals with celiac sprue. These diseases may be categorized as either inflammatory or secretory diarrheas. An epidemiologic relationship to medications such as NSAIDs, H_2-receptor blockers, proton pump inhibitors, selective serotonin reuptake inhibitors, and others has been reported, and increased luminal prostaglandin levels may cause the diarrhea. Enteric infections, food hypersensitivity, or intraluminal bile has been proposed as a trigger for prostaglandin release from lymphocytes. The disease disappears with fecal stream diversion. Antidiarrheal agents such as loperamide (2 mg orally four times a day) are the mainstay of therapy. Budesonide (9 mg orally once a day),[9,10] bismuth subsalicylate therapy (eight chewable 262-mg tablets orally once a day), and 5-aminosalicylates (e.g., mesalamine, 400 to 800 mg orally three times daily) may be useful. Those with refractory disease may require corticosteroids (e.g., prednisone, 40 mg orally once a day).

FOOD ALLERGY

Food allergies or sensitivities, especially to cow's milk and soy protein, are a well established cause of enterocolitis in children, with an estimated frequency of 5%. Symptoms of abdominal cramps, diarrhea, and sometimes vomiting occur shortly after ingestion of the allergen (Chapter 261). The role of food allergy in causing diarrhea in adults is less clear owing to the lack of a reliable diagnostic test. Allergy testing correlates poorly with intestinal allergy. The most common food allergens are milk, soy, eggs, seafood, nuts, and wheat. Sequential elimination diets can be diagnostic and therapeutic.

Protein-Losing Enteropathy

Severe protein loss through the gastrointestinal tract can be caused by mucosal diseases such as lymphangiectasia, lymphatic obstruction, bacterial or parasitic infection, gastritis (Chapter 141), gastric cancer, collagenous colitis, inflammatory bowel disease (Chapter 143), celiac disease, sarcoidosis (Chapter 95), lymphoma (Chapter 191), tuberculosis (Chapter 332), Ménétrier's disease (Chapter 198), eosinophilic gastroenteritis, and food allergies. A variety of extraintestinal diseases, including systemic lupus erythematosus (Chapter 274), heart failure (Chapter 58), and constrictive pericarditis (Chapter 77), also can be causative. Patients with systemic lupus erythematosus (Chapter 274) may present with protein-losing enteropathy as the only manifestation of their disease. Treatment focuses on the underlying disease.

Radiation Enteritis

Patients who receive pelvic radiation for malignancies of the female urogenital tract or the male prostate may develop chronic radiation enterocolitis 6 to 12 months after total doses of radiation greater than 40 to 60 Gy (Chapters 19 and 144). Symptoms can develop 20 years after treatment, however. Early abnormalities include an increase in inflammatory mediators, an increase in cholinergic stimulation of intestinal tissue, and endothelial cell apoptosis that precedes epithelial cell apoptosis. The last finding suggests that vascular injury is the primary event. Vascular endothelial growth factor, basic fibroblast growth factor, and IL-11 protect animal intestine from experimental radiation damage. Diarrhea may be caused by bile acid malabsorption if the ileum is damaged, by bacterial overgrowth if radiation causes small intestinal strictures or bypass, or by radiation-induced chronic inflammation of the

small intestine and colon. Rapid transit also may contribute to malabsorption and diarrhea.

TREATMENT

Rx

Treatment is often unsatisfactory. Anti-inflammatory drugs (sulfasalazine, corticosteroids) and antibiotics have been tried with little success. Cholestyramine (4 g orally three times a day) and NSAIDs (e.g., naproxen, 250 to 500 mg orally twice daily) may help, as may opiates (loperamide, 2 mg orally four times a day, or loperamide-*N*-oxide, 3 mg orally two times a day).

Miscellaneous Diseases

Although acute mesenteric arterial or venous thrombosis manifests as an acute bloody diarrhea, chronic mesenteric vascular ischemia (Chapter 145) may manifest as watery diarrhea. Gastrointestinal tuberculosis (Chapter 332) and histoplasmosis (Chapter 340) manifest as diarrhea that may be either bloody or watery, as do certain immunologic diseases, such as Behçet's syndrome or Churg-Strauss syndrome. All of these diseases may be misdiagnosed as inflammatory bowel disease (Chapter 143). Neutropenic enterocolitis, an ileocolitis that occurs in neutropenic leukemic patients, sometimes is caused by *C. difficile* infection.

CLINICAL MANIFESTATIONS OF CHRONIC DIARRHEA

Patients with malabsorption can present with a variety of gastrointestinal or extraintestinal manifestations (Table 142-6). Significant malabsorption of fat and carbohydrate usually causes chronic diarrhea, abdominal cramps, gas, bloating, and weight loss. Steatorrhea (fat in the stool) manifests as oily, foul-smelling stools that are difficult to flush down the toilet. Stools may be large and bulky (e.g., pancreatic insufficiency) or watery (e.g., bacterial overgrowth, mucosal diseases). Individuals with malabsorption also can present with manifestations of vitamin and mineral deficiencies. Dyspnea can be caused by anemia from iron, folate, or vitamin B_{12} deficiency. Manifestations of calcium, magnesium, or vitamin D malabsorption include paresthesias and tetany due to hypocalcemia or hypomagnesemia and bone pain due to osteomalacia or osteoporosis-related fractures. Paresthesias and ataxia are manifestations of cobalamin and vitamin E deficiency. Dermatitis herpetiformis is a blistering, burning, itchy rash on the extensor surfaces and buttocks that is associated with celiac disease.

Inflammatory diarrheas may present with fever and abdominal pain or with edema to suggest chronic protein loss. Patients may have multiple, low-volume, bloody stools with tenesmus to suggest proctitis, or have severe diarrhea due to GVHD or celiac disease. Systemic manifestations of inflammatory bowel disease include polymigratory arthritis, sacroiliitis, erythema nodosum, pyoderma gangrenosum, leukocytoclastic angiitis, uveitis, and oral aphthous ulcers.

TABLE 142-6 CLINICAL CONSEQUENCES OF MALABSORPTION OF NUTRIENTS, WATER, AND ELECTROLYTES

NUTRIENT MALABSORBED	CLINICAL MANIFESTATION
Protein	Wasting, edema
Carbohydrate and fat	Diarrhea, abdominal cramps and bloating, weight loss and growth retardation
Fluid and electrolytes	Diarrhea, dehydration
Iron	Anemia, cheilosis, angular stomatitis
Calcium and vitamin D	Bone pain, fractures, tetany
Magnesium	Paresthesias, tetany
Vitamin B_{12} and folate	Anemia, glossitis, cheilosis, paresthesias, ataxia (vitamin B_{12} only)
Vitamin E	Paresthesias, ataxia, retinopathy
Vitamin A	Night blindness, xerophthalmia, hyperkeratosis, diarrhea
Vitamin K	Ecchymoses
Riboflavin	Angular stomatitis, cheilosis
Zinc	Dermatitis, hypogeusia, diarrhea
Selenium	Cardiomyopathy
Essential fatty acids	Dermatitis

DIAGNOSIS OF CHRONIC DIARRHEA

A detailed history, physical examination, and certain screening tests lead to a diagnosis in 75 to 80% of patients with chronic diarrheas (see Table 142-1 and Fig. 142-3). A history of 10 to 20 daily bowel movements that do not respond to fasting suggests secretory diarrhea (see Fig. 142-8). A history of peptic ulcer should suggest gastrinoma (Chapter 201) or systemic mastocytosis (Chapter 263). Physical examination is helpful only if the thyromegaly of medullary carcinoma (Chapter 254), the cutaneous flushing of the neuroendocrine tumors and systemic mastocytosis, the dermatographism of systemic mastocytosis, or the migratory necrolytic erythema of glucagonoma (Chapter 201) is evident. Autonomic dysfunction (e.g., postural hypotension, impotence, gustatory sweating) is almost invariably present in diabetic diarrhea.

Evaluation for malabsorption begins with a careful elicitation of bowel habits, a description of the stool, weight loss, travel, food or milk tolerance, underlying gastrointestinal or liver diseases, abdominal surgery, radiation or chemotherapy treatments, family history, and drug and alcohol use.

Blood Tests

Blood measurements (see Fig. 142-3) of iron, folate, vitamin B_{12}, vitamin D, or prothrombin time (vitamin K) help evaluate malabsorption. Peripheral blood findings of leukocytosis, eosinophilia, elevated erythrocyte sedimentation rate, hypoalbuminemia, or low total serum protein suggests an inflammatory diarrhea, whose hallmark is the presence of blood, either gross or occult, and leukocytes in the stool. There are no bedside screening tests to establish the diagnosis in watery diarrheas.

Imaging

Malabsorption may be suggested if a flat plate radiograph of the abdomen shows pancreatic calcification (Chapter 135). Some diseases (e.g., previous gastric surgery, gastrocolic fistulas, blind loops from previous intestinal anastomoses, small intestine strictures, multiple jejunal diverticula, abnormal intestinal motility that could lead to bacterial overgrowth) may be shown by computed tomography or magnetic resonance imaging of the abdomen after administration of oral contrast agents or by a traditional upper gastrointestinal radiographic series with small intestine follow-through. A small bowel barium study may show thickening of the intestinal folds (e.g., amyloidosis, lymphoma or Whipple's disease), uniform or patchy abnormalities (e.g., lymphoma or lymphangiectasia), or flocculation of barium and ilealization of jejunum to suggest celiac disease. Routine contrast radiographs of the gastrointestinal tract usually are not helpful in the diagnosis of watery diarrheas, unless they show extensive small bowel resection, the presence of a tumor (carcinoid or villous adenoma), or a bowel filled with fluid (endocrine tumor). Abdominal contrast imaging may show diagnostic evidence of advanced inflammatory bowel disease or changes suggestive of eosinophilic gastroenteritis or radiation enterocolitis. Somatostatin receptor scintigraphy with indium-111-labeled octreotide can be useful in localizing gastrinomas, pancreatic endocrine tumors, and carcinoid tumors.

Endoscopy and Biopsy

Upper endoscopy with distal duodenal biopsy should be undertaken if serologic tests for celiac disease are positive or diagnostic clues suggest small bowel mucosal malabsorption (Chapter 136). Small bowel biopsy is virtually always abnormal when the tTG IgA antibody level is very high (more than five-fold the normal range), and EMA is positive. A biopsy may be avoided in this setting. Some patients may have patchy mucosal disease and require enteroscopy with jejunal biopsies for diagnosis. Wireless video capsule endoscopy (Chapter 136) and balloon-assisted enteroscopy are increasingly used to diagnose diseases that reside deep in the small bowel. Patients with severe watery or elusive diarrhea should have a colonoscopy to assess for villous adenomas, microscopic colitis, mastocytosis, or early inflammatory bowel disease. Colonoscopy may also show brown pigmentation suggestive of melanosis coli due to chronic use of anthracene laxatives. Terminal ileal biopsy may indicate infectious or inflammatory bowel disease.

Other Laboratory Tests

Malabsorption

If chronic diarrhea is the presenting symptom, a stool examination for ova and parasites and a stool antigen-capture ELISA test for *Giardia* should be

TABLE 142-7 ABNORMALITIES CONDUCIVE TO BACTERIAL OVERGROWTH

obtained. A stool test for fat on a high-fat diet (70 to 100 g/day) is the best available screening test for malabsorption (see Table 142-6). If the fecal fat test result is negative, selective carbohydrate malabsorption or other causes of watery diarrhea should be considered. If the fecal fat test result is positive, further testing should be based on clinical suspicion for particular diseases. If pancreatic insufficiency is suspected, imaging studies of the pancreas should be performed. If proximal mucosal damage is suspected, multiple small intestinal biopsy specimens should be obtained. If there are no clues to the cause of malabsorption, a D-xylose test may help to distinguish mucosal disease from pancreatic insufficiency. However, the D-xylose test result also can be abnormal in individuals with bacterial overgrowth; if this condition is suspected, culture of an intestinal aspirate or a breath test should be obtained (see Table 142-6). Small bowel contrast imaging is useful in detecting ileal disease and structural abnormalities that predispose to bacterial overgrowth (Table 142-7). Some individuals with celiac disease present with selective nutrient deficiencies without diarrhea. In these cases, tTG antibody tests and intestinal biopsy should be performed. In patients hospitalized for severe diarrhea or malnutrition, a more streamlined evaluation usually includes a stool for culture, ova and parasites, and fat; an abdominal imaging study; and a biopsy of the small intestine and colon.

Watery Diarrhea

Breath tests to measure the respiratory excretion of labeled CO_2 after oral administration and metabolism of radioactive carbon-labeled substrates, or of H_2 after administration of carbohydrates, can assess carbohydrate and bile salt malabsorption or bacterial overgrowth (see Table 142-6).

The diagnosis of endocrine tumors, such as carcinoids, gastrinoma, VIPoma, medullary carcinoma of the thyroid, glucagonoma, somatostatinoma, and systemic mastocytosis, is made by showing elevated blood levels of serotonin or urinary 5-hydroxyindoleacetic acid and serum levels for gastrin, vasoactive intestinal peptide, calcitonin, glucagon, somatostatin, histamine, or prostaglandins (Chapter 201). Somatostatin receptor scintigraphy has proved to be sensitive and useful in the diagnosis and evaluation of Zollinger-Ellison syndrome (Chapter 201).

Inflammatory Diarrhea

Stool occult blood, white blood cells, or lactoferrin and calprotectin (components of leukocytes) are helpful tests for bowel inflammation. Video capsule endoscopy (Chapter 136) of the small bowel may detect ulcerations deep in the small bowel not reachable by standard upper or lower endoscopy and not detected with conventional barium contrast radiography. However, the risk of capsule retention in the small bowel is high in patients with Crohn's disease or NSAID use, particularly when there is a history of obstructive symptoms. The most sensitive test for protein-losing enteropathy is measurement of intestinal protein loss by 24-hour stool excretion or clearance of α_1-antitrypsin.

Stool Examination in Elusive Diarrhea

An important adjunct to diagnosing the cause of diarrhea is to examine the stool. The greasy, bulky stool of steatorrhea and the bloody stool of gut inflammation are distinctive. Stool collections (see Table 142-6) can be analyzed for weight, volume, fat, electrolytes ($^{+}Na^{++}$, K^{++}, Cl^{-}), osmolality, pH, and a laxative screen (SO_4^{2-}, PO_4^{2-}, Mg^{2+}). Stool or urine can be analyzed for emetine (a component of ipecac), bisacodyl, castor oil, or anthraquinone.

Carbohydrate malabsorption lowers stool pH because of colonic fermentation of carbohydrate to short-chain fatty acids. Stool pH less than 5.3 usually means pure carbohydrate malabsorption, whereas in the generalized malabsorptive diseases, stool pH is greater than 5.6 and usually greater than 6.0.

The normal stool osmotic gap, which is the difference between stool osmolality (or 290 mOsm) and twice the stool Na^{++} and K^{++} concentrations, is 50 to 125. In secretory diarrheas, the colon's capacity for adjusting electrolyte concentrations is overwhelmed, the stool osmotic gap is less than 50, and stool electrolytes more nearly resemble plasma electrolytes ($^{+}Na^{++}$ concentrations are usually >90 mmol/L, K^{+} concentrations usually <10 mmol/L), except for higher HCO_3^{-} concentrations (usually >50 mmol/L). In osmotic diarrhea, the presence of uncharged solute or unmeasured cation in the colonic lumen draws in water, depresses stool Na^{++} (usually <60 mmol/L) and K^{+} concentrations, and results in a stool osmotic gap >125. Stools with Na^{++} concentrations between 60 and 90 mmol/L and calculated osmotic gaps between 50 and 100 can result from either secretory or malabsorptive abnormalities. Patients with Mg^{2++}-induced diarrhea may be diagnosed by fecal Mg^{2+} values of more than 50 mmol/L. Sodium anion–induced diarrheas (Na_2SO_4, Na_2PO_4) mimic secretory diarrhea because the stool Na^{++} content is high (>90 mmol/L), and there is no osmotic gap; this diarrhea may be diagnosed by determining stool Cl^{-} concentration because these anions displace stool Cl^{-} resulting in a depressed stool Cl^{-} value (usually <20 mmol/L).

TREATMENT OF CHRONIC DIARRHEA Rx

Antidiarrheal Therapy

Antidiarrheal agents are of two types: those used for mild to moderate diarrheas and those used for severe secretory diarrheas. A major shortcoming of opiates, the most commonly prescribed antidiarrheal agents, is that they have no antisecretory effect. Rather, they act by decreasing intestinal motility, thereby allowing longer contact time with the mucosa for improved fluid absorption. The exception is racecadotril, an enkephalinase inhibitor, that blocks intestinal fluid secretion without affecting motility.

Bulk-forming agents (psyllium [7 g in 8 ounces water orally up to five times a day] and methylcellulose [three to six tablets twice a day with 300 mL of water]) act by binding water and increasing the consistency of stool. Pectin has been shown to have proabsorptive activity. These agents may be useful in patients with fecal incontinence. Bismuth subsalicylates (524 mg orally every hour up to eight doses a day) have mild antisecretory and antimotility effects and are effective and safe in mild diarrheas. Agents that bind bile salts (e.g., cholestyramine, 2 to 4 g orally two to four times a day) are effective in the treatment of bile acid diarrheas but may worsen diarrhea in patients with ileal resection or disease of more than 100 cm of ileum.

The opiates may be symptomatically useful in mild to moderate diarrheas. Paregoric, deodorized tincture of opium, codeine, and diphenoxylate with atropine largely have been supplanted by loperamide. Loperamide does not pass the blood-brain barrier and has a high first-pass metabolism in the liver; it has a high therapeutic-to-toxic ratio and is essentially devoid of addiction potential. It is safe in adults, even in total doses of 24 mg/day. The usual dose is 2 to 4 mg two to four times daily. Opiates may be harmful in patients with severe diarrheas because large volumes of fluid may pool in the intestinal lumen (third space), and stool output is no longer a reliable gauge for replacing fluid losses. The antimotility effects are a problem in infectious diarrheas because stasis may enhance bacterial invasion and delay clearance of microorganisms from the bowel. Opiates and anticholinergics also are dangerous in severe inflammatory bowel disease or severe *C. difficile* infection, where they may precipitate megacolon.

Antidiarrhea agents that are used for the treatment of severe secretory and inflammatory diarrheas generally have profiles with more serious side effects. The somatostatin analogue octreotide (initial dose, 100 to 600 µg subcutaneously in two to four divided doses daily; maximal dose, 1500 µg daily) lessens diarrhea in the carcinoid syndrome and in neuroendocrine tumors because it inhibits hormone secretion by the tumor. It is also effective in the treatment of dumping syndrome and chemotherapy-related diarrheas. Long-acting subcutaneous octreotide preparations (20 to 30 mg intramuscularly intragluteally every month) are now available for once-a-month dosing. Octreotide can

suppress pancreatic enzyme secretion and make diarrhea worse; it also may be of only limited usefulness in short-bowel syndrome and AIDS diarrhea. Agents such as phenothiazine and calcium-channel blockers have mild antisecretory effects, but side effects limit their use. Clonidine (initial dose, 0.1 mg orally twice daily, titrated slowly to a maximal dose of 0.5 to 0.6 mg twice daily) is most useful in opiate withdrawal diarrhea and is sometimes useful in diabetic diarrhea; postural hypotension may limit its use, particularly in patients with diabetes. Alosetron (0.5 mg orally twice daily for four weeks, maximal dose 1 mg orally twice daily) may be justified for severe diarrhea-predominant irritable bowel syndrome; associations with ischemic colitis and severe constipation have limited its use. Indomethacin (250 to 500 mg orally twice daily), a cyclooxygenase blocker that inhibits prostaglandin production, is useful in the treatment of diarrheas caused by acute radiation, AIDS, or villous adenomas of the rectum or colon; occasionally, it may be useful in neuroendocrine tumors and food allergy. For eosinophilic gastroenteritis, corticosteroids (prednisone, 20 to 40 mg orally once a day for 7 to 10 days) are the mainstay of therapy, but disodium cromoglycate (200 mg orally four times daily) also may be useful; food elimination diets are not usually effective. Treatment of inflammatory bowel disease is described in Chapter 143.

INFLAMMATORY BOWEL DISEASE

GARY R. LICHTENSTEIN

DEFINITION

Inflammatory bowel disease refers to two chronic idiopathic inflammatory disorders, ulcerative colitis and Crohn's disease. These disorders are diagnosed by characteristic clinical, endoscopic, and histologic features, but no single individual finding is absolutely diagnostic for one disease or the other. Ulceration from Crohn's disease may be transmural and may occur anywhere in the gastrointestinal tract, most commonly in the distal ileum and proximal colon. The hallmark of ulcerative colitis is continuous ulceration starting in the rectum and limited to the colon. Approximately 10% of patients with inflammatory bowel disease have indeterminant colitis, a term used when Crohn's colitis cannot be differentiated from ulcerative colitis.

EPIDEMIOLOGY

Inflammatory bowel disease occurs worldwide, but the highest incidence is found in North America, the United Kingdom, and northern Europe. The incidence of Crohn's disease has risen slowly over time, although ulcerative colitis remains slightly more prevalent than Crohn's disease. The incidence of ulcerative colitis in North America is estimated to be 2.2 to 14.3 per 100,000 person years, with a prevalence of 37 to 246 per 100,000. The incidence of Crohn's disease in North America is estimated to be 3.1 to 14.6 per 100,000 person years, with a prevalence of 26 to 199 per 100,000.

Crohn's disease and ulcerative colitis may occur at any age. The peak incidence of Crohn's disease occurs between age 15 and 30 years of age, with a second peak in the seventh decade. There is a 1.2 : 1 female-to-male ratio. Ulcerative colitis also has a bimodal peak age distribution, with an initial peak between 20 and 40 years of age and second smaller peak beyond the seventh decade. There is an equal gender distribution in ulcerative colitis.

Crohn's disease and ulcerative colitis are polygenic disorders, for which family history is a risk factor. Crohn's disease and ulcerative colitis occur in all ethnic groups and races, but their incidence is highest in whites and Jewish people of Eastern European (Ashkenazi Jews) descent. In North America and the United Kingdom, however, the incidence of Crohn's disease in African Americans and African Caribbeans appears to be approaching that of whites. Studies of migrants from underdeveloped countries in South Asia to the United Kingdom suggest an increased prevalence of inflammatory bowel disease in subsequent generations, presumably as a result of environmental influences.

Cigarette smoking is associated with a worse prognosis in patients with Crohn's disease but an improved course in ulcerative colitis. Nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be associated with exacerbations of disease, although evidence for this is less definitive. Appendectomy has been suggested as protective against the development of ulcerative colitis. Diet does not clearly affect the course of inflammatory bowel disease.

PATHOBIOLOGY

Although the trigger for inflammatory bowel disease is not known, three major pathways likely activate the disease: a genetic predisposition, immune dysregulation, and an environmental antigen. A possible explanation is that the inability of the innate immune system to clear microbial antigens, combined with increased intestinal epithelial permeability to antigens, eventually leads to an overactive adaptive immune response.

Genetics

Of patients with inflammatory bowel disease, 5 to 20% have a positive family history. First-degree relatives have a 10- to 15-fold increased risk for developing inflammatory bowel disease. The concordance rate of developing Crohn's disease in identical twins, siblings, and first-degree relatives is 50%, 0 to 3%, and 5 to 10%, respectively. Ulcerative colitis follows similar genetic patterns but with slightly lower risk rates. Twenty percent of patients with a positive family history of inflammatory bowel disease will have discordant disease type: one family member with Crohn's disease and another with ulcerative colitis.

The initial gene associated with Crohn's disease is *NOD2/CARD15*, located on chromosome 16 (16q12), and is expressed in intestinal epithelial Paneth cells, macrophages, and dendritic cells. This gene is involved in the expression of an intracellular receptor that senses muramyl dipeptide, a peptidoglycan component of gram-positive bacteria. Activation of *NOD2* leads to activation of NF-κB, which mediates transcription of numerous proinflammatory cytokines. A mutation in the leucine-rich domain of the NOD2 protein, which interacts with bacterial lipopolysaccharide, leads to failure in activation of NF-κB and is associated with the development of Crohn's disease.

Toll-like receptor-4 gene polymorphisms are associated with both Crohn's disease and ulcerative colitis. Polymorphisms of the interleukin-23 (IL-23) receptor gene are associated with ulcerative colitis and a varied risk of Crohn's disease. Human leukocyte antigen (HLA) class II polymorphisms, especially in HLA-DR molecules, may confer increased risk for ulcerative colitis and possibly Crohn's as well. The *OCTN1* gene, located on chromosome 5, and the *DLG5* gene, located on chromosome 10, have also been associated with

Crohn's disease. *DLG5*, which encodes a scaffolding protein that is important for maintaining epithelial integrity in various organs, may interact with the *NOD2/CARD15* gene to increase susceptibility to Crohn's disease. Gene *OCTN1*, located on chromosome 5q31, codes for an ion channel and also increases the risk of Crohn's disease; mutations in this gene may disrupt ion channels through altered function of cation transporters and cell-to-cell signaling in the intestinal epithelium.

PATHOPHYSIOLOGY

Microbes likely play a part in the development of inflammatory bowel disease. In several animal models of colitis, colitis does not develop in a sterile environment but can be induced after the introduction of commensal bacteria. Diverting the fecal stream away from active mucosal inflammation, such as in an ileostomy, also helps alleviate inflammation in Crohn's disease. Antibiotics, particularly antibiotics with broad-spectrum anaerobic coverage, are helpful in the treatment of Crohn's disease. More recently, several genetic polymorphisms associated with sensing the intestinal microbial environment and triggering an immune response have been linked to inflammatory bowel disease.

Both Crohn's disease and ulcerative colitis are products of a dysregulated innate immune system that triggers T cells and a humoral response. T_H17 cells, which are activated in Crohn's disease and ulcerative colitis, are stimulated by IL-23, which is produced by antigen-presenting cells. Variations in single-nucleotide polymorphisms of the gene encoding the receptor for IL-23 are associated with Crohn's disease.

Pathology

Crohn's Disease

As a result of a dysregulated immune system, patients with Crohn's disease develop aphthous ulcers, which are superficial mucosal ulcers. As the disease progresses, the ulceration becomes deeper, transmural, and discrete; it may form a serpiginous pattern and may occur anywhere from the esophagus to the anus in a noncontinuous pattern. The most common location for ulceration is the ileocecal region. In some patients, chronic disease leads to the formation of fibrotic strictures, and approximately 30% of patients may develop fistulas.

In early Crohn's disease, the histopathology is characterized by an acute inflammatory infiltrate in the lamina propria, with cryptitis, and crypt abscesses. Later in the disease process, the crypt architecture becomes distorted, with a lymphocytic infiltrate and a resulting branching and shortening of the crypts. Noncaseating granulomas, which are present in up to 15% of endoscopic biopsy specimens and as many as 70% of surgical specimens, are not unique to Crohn's disease but help confirm the diagnosis when other classic features are present.

Surgical specimens also may show transmural intestinal wall inflammation and fat creeping on the serosal surface.

Ulcerative Colitis

In mild ulcerative colitis, the mucosa is granular, hyperemic, and edematous in appearance. As the disease becomes more severe, the mucosa ulcerates, and the ulcers may extend into the lamina propria. Ulcerative colitis starts in the rectum and may extend proximally in a continuous pattern, but it affects only the colon. Pseudopolyps may form owing to epithelial regeneration after recurrent acute attacks. With chronic disease, the colonic mucosa may lose the normal fold pattern, the colon may shorten, and the colon may appear narrowed.

In early ulcerative colitis, the histopathology is characterized by epithelial necrosis, an acute inflammatory infiltrate in the lamina propria, cryptitis, and crypt abscesses. In chronic disease, a predominant lymphocytic infiltrate and distortion of crypt architecture are seen.

CLINICAL MANIFESTATIONS

Symptoms of inflammatory bowel disease are varied and may be a consequence of the location of the disease, the duration of disease, and any anatomic complications of the disease, such as strictures and fistulas in Crohn's disease (Table 143-1).

TABLE 143-1 CLINICAL CHARACTERISTICS OF CROHN'S DISEASE AND ULCERATIVE COLITIS

	CROHN'S DISEASE	ULCERATIVE COLITIS
Peak age of onset (years of age)	15-30, 2nd peak in the 7th decade	20-40, 2nd smaller peak beyond the 7th decade
Sex distribution (F/M)	1.2/1	1/1
Potential sites of gastrointestinal involvement	Esophagus to anus	colon
Skipped areas of involvement	+	–
Transmural inflammation	+	–
Type of ulceration	Usually discrete	Continuous
Fistula	+	–
Stricture	–	–
Perianal disease (fissure, skin tags)	+	–

Symptoms

Crohn's Disease

The terminal ileum is affected in about 70% of patients with Crohn's disease. Primary ileal disease occurs in 30% of patients, whereas ileocolonic disease occurs in 40%. Symptoms may include abdominal pain, typically in the right lower quadrant, diarrhea, hematochezia, and fatigue. With more severe disease, fever and weight loss may be present. Some patients may present with obstructive symptoms, such as abdominal pain, abdominal distention, and nausea.

Only approximately 5% of patients develop Crohn's disease in the upper gastrointestinal tract, and esophageal Crohn's disease occurs in less than 2% of patients. Subjects with upper gastrointestinal Crohn's disease may present with dysphagia, odynophagia, chest pain, or heartburn. Gastroduodenal disease occurs in 0.5 to 4% of patients and commonly occurs along with distal disease. Symptoms may include upper abdominal pain. Isolated jejunal disease is rare; if the jejunum is involved, there is also distal small bowel involvement. Up to 30% of patients have perianal disease (Chapter 147) that may include the development of fistulas, abscesses, fissures, and skin tags. Symptoms of perianal disease include pain and discharge. Fever may be present if there is an abscess.

Fistulas, which are internal tracks that can occur anywhere in the gastrointestinal tract and connect to various sites, occur in 20 to 40% of Crohn's patients. Penetrating Crohn's disease may also cause intra-abdominal and perianal abscesses owing to a fistula with a blind end or intestinal perforation. External fistulas, which present with symptoms of fluid discharge from the cutaneous opening, can be enterocutaneous, or perianal. Internal fistulas can be enteroenteric, rectovaginal, or enterocolonic. Patients may present with persistent abdominal pain and fever with an abscess in this location.

Ulcerative Colitis

As with Crohn's disease, symptoms and signs of ulcerative colitis depend on the extent and severity of disease. At the time of diagnosis, 14 to 37% of patients have pancolitis, 36 to 41% have disease extending beyond the rectum, and 44 to 49% have proctosigmoiditis. Symptoms include hematochezia, diarrhea, tenesmus, passage of mucus, urgency to defecate, and abdominal pain. In the setting of proctitis or proctosigmoiditis, patients may have constipation with difficulty defecating. With more extensive and severe colonic involvement, patients may also have weight loss and fever. Patients may also have nausea and vomiting because of abdominal pain, fatigue because of anemia, and peripheral edema because of hypoalbuminemia.

Physical Examination

Signs on physical examination are representative of the type of disease as well as its location and severity. Oral ulcers may be present in Crohn's disease. The location of abdominal tenderness usually reflects the location of intestinal involvement. In Crohn's disease, abdominal tenderness is classically in the right lower quadrant and may include fullness or a mass depending on the severity of inflammation. Peritoneal signs may occur when penetrating Crohn's disease causes intestinal perforation. Rectal examination may reveal skin tags, hemorrhoids, fissure, and fistulas.

Extraintestinal Manifestations

Arthropathy, the most common extraintestinal manifestation (Table 143-2), affects up to 10 to 20% of subjects. Peripheral arthralgias, arthritis, ankylosing spondylitis (Chapter 273), and sacroiliitis may exacerbate with

TABLE 143-2 EXTRAINTESTINAL COMPLICATIONS OF INFLAMMATORY BOWEL DISEASE

	CROHN'S DISEASE	ULCERATIVE COLITIS

gastrointestinal symptoms. Dermatologic disorders, such as erythema nodosum (10 to 15%; see Fig. 448-23 in Chapter 448) and pyoderma gangrenosum (1 to 2%; Chapter 269), develop in up to 15% of patients. Eye disorders, especially uveitis and episcleritis (Chapter 431), may occur in 5 to 15%. Patients with inflammatory bowel disease also have up to a 10% risk of renal calculi, especially calcium oxalate stones (Chapter 128), in the setting of fat malabsorption with Crohn's disease in the small bowel. Uric acid stones can occur in the setting of severe volume depletion. Inflammatory bowel disease patients, especially patients with ulcerative colitis, are at increased risk for primary sclerosing cholangitis (Chapter 158).

Extraintestinal Complications

Patients with inflammatory bowel disease are susceptible to extraintestinal complications from the disease itself or medications used to treat disease. These complications include osteoporosis, osteomalacia, arthritic complications, thromboembolic events, pulmonary disease, and renal, dermatologic, and neurologic complications. Osteoporosis occurs in about 15% of patients, and steroid therapy (Chapter 34) is the major risk factor; avascular necrosis of the hip and septic arthritis are unusual complications of steroids or other immunosuppressive therapies. Cheilitis may be a result of iron deficiency anemia (Chapter 162). Patients with inflammatory bowel disease are at an increased risk for thromboembolic disease, especially in the setting of active intestinal disease, even when compared with other autoimmune diseases such as rheumatoid arthritis and celiac disease. Renal amyloidosis can be a consequence of chronic inflammation. Asthma is the most common pulmonary disorder in Crohn's disease. Patients also are at risk for multiple sclerosis (Chapter 419) and for peripheral neuropathy (Chapter 428) from vitamin B_{12} deficiency, which may occur as a result of poor absorption owing to active small bowel disease or surgical resection.

DIAGNOSIS

When diarrhea (Chapter 142) is the predominant symptom, the initial evaluation should include a thorough medical history, testing for infectious colitis (Chapter 142), and screening for endocrine-metabolic disorders such as hyperthyroidism (Chapter 233) and hypocalcemia (Chapter 253). Infections with organisms such as *Shigella* (Chapter 317), *Amoeba* (Chapter 360), *Giardia* (Chapter 359), *Escherichia coli* O157:H7 (Chapter 312), and *Campylobacter* (Chapter 311) can be accompanied by bloody diarrhea, abdominal cramps, and an endoscopic picture identical to ulcerative colitis. Stool studies are needed to diagnose or exclude these infections. If hematochezia or abdominal pain are the predominant symptom, the differential diagnosis is broad (Table 143-3).

Diagnostic Evaluation

Endoscopic Evaluation

In a patient with symptoms suggestive of inflammatory bowel disease and no evidence for an infection to explain their symptoms, endoscopic evaluation is essential. Colonoscopy is the initial endoscopic test for patients who present with lower gastrointestinal symptoms such as diarrhea and hematochezia, except in the presence of acute severe peritoneal symptoms. Colonoscopy to the terminal ileum is important if there is a potential diagnosis of inflammatory bowel disease. Small bowel imaging (such as small bowel follow-through or computed tomography [CT] enterography) may also be needed to determine whether there is small bowel disease or to determine the distribution of disease. Capsule endoscopy is useful if all other endoscopic and radiologic testing is nondiagnostic, but Crohn's disease of the small bowel is still suspected. Findings on capsule endoscopy should be followed by endoscopy to obtain biopsies. Capsule endoscopy should not be performed if Crohn's disease is complicated by a known small bowel stricture.

Crohn's Disease

Early endoscopic findings in Crohn's disease include superficial small mucosal ulcers, also called aphthous ulcers. As the severity of Crohn's disease progresses, the ulceration becomes deeper and may become round, linear, or serpiginous. A cobblestone appearance of the mucosa is caused by intersecting longitudinal and transverse ulcers, with "stone" areas representing normal mucosa (Fig. 143-1). Areas of ulceration, which are typically interspersed with normal "skip" areas, may occur anywhere from the esophagus to anus but are most common in the ileocecal region. Isolated colonic disease occurs in 25% of patients, and 60% will have rectal involvement, thereby making it at times difficult to differentiate from ulcerative colitis.

The diagnosis of inflammatory bowel disease is contingent on accurate histopathology, so biopsy of the affected area is key. Findings of an inflammatory infiltrate in the lamina propria and distortion of the crypt architecture support the diagnosis (Fig. 143-2). The diagnosis of Crohn's disease may be made by histopathology alone if noncaseating granulomas are seen, but

FIGURE 143-1. Endoscopic appearance of Crohn's disease with cobblestoning.

FIGURE 143-2. Colonic biopsy histopathology showing features of inflammatory bowel disease with crypt distortion and lymphocytic infiltration in the mucosa. (Adapted from AGA Institute GastroSlides 2010.)

granulomas are rarely found on endoscopic biopsies. The diagnosis of Crohn's disease is usually based on a combination of information gleaned from histopathology, colonoscopy, and small bowel imaging. A skipped pattern of ulceration, ulceration in the small bowel or upper gastrointestinal tract or the presence of fistulas supports the diagnosis of Crohn's disease. Colonic and small bowel ulceration occur in several other disorders, including infections that may not be detected by routine stool studies (such as enterohemorrhagic *Escherichia coli*), vascular disorders, immune-related enterocolitis, neoplasia, diverticulitis, radiation, and medications such as NSAIDs (see Table 143-3).

Ulcerative Colitis

The diagnosis of ulcerative colitis is based on endoscopic findings and histopathology. Early in the disease process, patients develop diffuse mucosal erythema with loss of the normal mucosal vascular pattern. In mild disease, the mucosa may have a granular and edematous appearance. As the disease becomes more severe, the mucosa becomes more friable, bleeds easily when the mucosa is touched, and may eventually ulcerate (Fig. 143-3). Endoscopic findings, which start in the rectum and may extend proximally in a continuous pattern, affect only the colon. Pseudopolyps may form owing to epithelial regeneration after recurrent attacks in patients with long-standing disease. With chronic disease, the colonic mucosa may lose its normal fold pattern, and the colon may shorten and appear narrowed.

Features such as crypt distortion, continuous mucosal inflammation starting from the rectum, absence of granulomas, and absence of small bowel disease are all consistent with ulcerative colitis. Early in the disease process, chronic inflammatory findings, such as crypt distortion, may not be present, and the diagnosis may be more difficult to confirm.

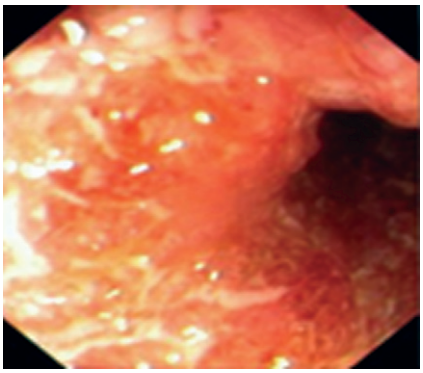

FIGURE 143-3. Endoscopic appearance of ulcerative colitis.

Radiology

Radiologic imaging is vital and should almost always be obtained when inflammatory bowel disease, particularly Crohn's disease, is suspected. Barium studies such as an upper gastrointestinal series, small bowel follow-through, and barium enema are usually necessary to diagnose fistulas and strictures in Crohn's disease. If Crohn's disease is suspected by colonoscopic examination, a small bowel follow-through is generally obtained to assess the extent, severity, and type of disease (strictures and fistulas) in the small intestine. CT enterography and magnetic resonance imaging (MRI) enterography are alternatives to a small bowel follow-through. CT enterography may be preferred for the detection of abdominal abscesses, whereas MRI may be preferred for the detection of perineal abscesses and strictures.

Laboratory Findings

Anemia may result from chronic disease, blood loss or nutritional deficiencies of iron, folate, or vitamin B_{12}. A modestly elevated leukocyte count is indicative of active disease, but a marked elevation suggests an abscess or another suppurative complication. The erythrocyte sedimentation rate and C-reactive protein are nonspecific serum inflammatory markers that are sometimes used to monitor the activity of disease. Hypoalbuminemia is an indication of malnutrition. Ileal disease or resection of more than 100 cm of distal ileum results in a diminished serum vitamin B_{12} level because of malabsorption.

Serologic Markers

Serologic markers are supportive but may not be used independently to diagnose inflammatory bowel disease. Anti–*Saccharomyces cerevisiae* antibodies (ASCA), which are antibodies to yeast, are present in 40 to 70% of patients with Crohn's disease and in less than 15% of patients with ulcerative colitis. The combination of elevated ASCA immunoglobulin A (IgA) and IgG titers is highly specific for Crohn's disease, ranging from 89 to 100%. Perinuclear antineutrophil cytoplasmic antibodies (pANCA) are present in 20% of Crohn's patients, primarily in colon-predominant disease, and in 55% of patients with ulcerative colitis. ASCA-positive and pANCA-negative disease is associated with a sensitivity of 55% and specificity of 93% for Crohn's disease. The antimicrobial antibodies anti-I2 (Crohn's disease–related protein from *Pseudomonas fluorescens*), anti-Cbir1 (flagellin-like antigen), and anti-OmpC (*E. coli* outer membrane porin C) are also associated with Crohn's disease, but the utility of these additional markers has yet to be determined.

TREATMENT

Rx

The aim of medical therapy is to reduce inflammation and subsequently induce and maintain clinical remission. Medications used to treat inflammatory bowel disease include the categories of 5-aminosalicylate (5-ASA), antibiotics, corticosteroids, immunomodulators, and biologics (infliximab, adalimumab, certolizumab pegol, and natalizumab) (Table 143-4). The specific medical therapy selected is based on the location, extent (nonpenetrating and nonstricturing, stricturing, and penetrating and fistulizing disease), and severity of disease (Fig. 143-4; see Fig. 143-3). Supportive medical therapy, such as antidiarrheal and antispasmodic medications, may also be used.

Categories of Medical Therapy

5-Aminosalicylate

5-ASA, which acts as a topical anti-inflammatory within the lumen of the intestine, is used to treat mild to moderate ulcerative colitis and also has a

TABLE 143-4 MEDICAL THERAPIES FOR INFLAMMATORY BOWEL DISEASE

DRUG	DOSE	RELEASE SITE
5-AMINOSALICYLATES		
Sulfasalazine (Azulfidine)	2-6 g/day	Colon
Mesalamine (Asacol, Lialda, Apriso)	2.4-4.8 g/day	Distal ileum, colon
Olsalazine (Dipentum)	1-3 g/day	Colon
Balsalazide (Colazal)	6.25 g/day	Colon
Mesalamine (Pentasa)	2-4 g/day	Duodenum, jejunum, ileum, colon
Mesalamine (Rowasa), enema, suppository	4 g/day (enema) 1 g/day (suppository)	Rectum/sigmoid Rectum
Mesalamine (Canasa), suppository	1 g/day (suppository)	Rectum
CORTICOSTEROIDS		
Budesonide (Entocort)	Induction: 9 mg PO qd Maintenance: 6 mg PO qd	Small intestine
Prednisone	0.25-0.75 mg/kg PO qd	Systemic
Methylprednisolone	40-60 mg IV qd	Systemic
IMMUNOMODULATORS		
6-Mercaptopurine	1.5 mg/kg/day	Systemic
Azathioprine	2.5 mg/kg/day	Systemic
Methotrexate	Induction: 25 mg SC q wk × 4 mo Maintenance: 15 mg SC q wk	Systemic
Cyclosporine	2-4 mg/kg/day	Systemic
BIOLOGICS		
Infliximab	Induction: 5 mg/kg IV weeks 0, 2, 6 Maintenance: 5 mg/kg IV q 8 wk	Systemic
Adalimumab	Induction: 160 mg SC week 0, 80 mg week 2 Maintenance: 40 mg SC every other week	Systemic
Certolizumab pegol	Induction: 400 mg SC weeks 0, 2, 4 Maintenance: 400 mg SC q 4 wk	Systemic
Natalizumab	300 mg IV q 4 wk	Systemic

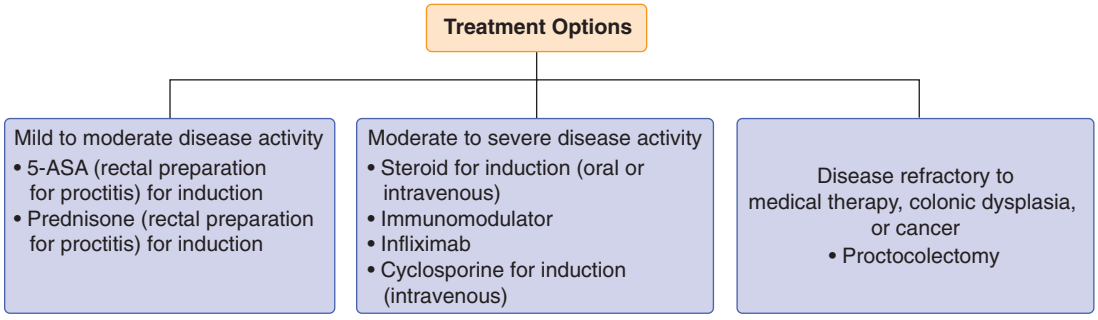

FIGURE 143-4. Ulcerative colitis treatment algorithm.

limited role in Crohn's disease. Sulfasalazine is the combination of a sulfapyridine with 5-ASA; 5-ASA is responsible for the anti-inflammatory property of this drug, whereas sulfapyridine is the carrier that allows 5-ASA to be delivered into the colon. Other oral formulations of 5-ASA allow it to be delivered to the intestine by different mechanisms. Mesalamine is released in the intestine based on a pH delivery model, whereas sulfasalazine, olsalazine, and balsalazide are released in the intestine by bacterial cleavage of a covalent bond between 5-ASA and a prodrug. For rectal and sigmoid disease, 5-ASA suppository and enema preparations are also available. Adverse events associated with 5-ASAs are rare and may include nausea, dyspepsia, hair loss, headache, worsening diarrhea, and hypersensitivity reactions.

Corticosteroids

Corticosteroids are primarily used to treat flares of ulcerative colitis and Crohn's disease. Oral formulations may be used for mild to moderate disease, whereas systemic corticosteroids are used for moderate to severe disease.

Enteric coated budesonide, a pH-dependent ileal release formulation, is an oral corticosteroid with high topical activity and low systemic bioavailability (10%). Enteric coated budesonide is indicated for treatment of active mild to moderate Crohn's disease. Oral corticosteroids such as prednisone and methylprednisolone are used for moderate to severe disease, starting at doses ranging from 40 to 60 mg once a day. Intravenous methylprednisolone is used for severe disease, with dosing ranging from 40 to 60 mg once a day. Maintenance with systemic corticosteroids is not recommended because of their substantial side effects (Chapter 34).

Immune Modulators

In patients who remain symptomatic despite 5-ASA therapy or who have moderate to severe Crohn's disease or ulcerative colitis, the thiopurine analogues (6-mercaptopurine and azathioprine) may be used; methotrexate also may be used for moderate to severe Crohn's disease. Azathioprine, the prodrug of 6-mercaptopurine, typically is prescribed at a dose of 2 to 3 mg/kg/day; the equivalent dose of 6-mercaptopurine is 1.5 mg/kg/day. A disadvantage of the thiopurine analogs is the slow clinical response that may not be evident for as long as 12 weeks. Their side effects include allergic reactions, pancreatitis, myelosuppression, nausea, infections, hepatotoxicity, and malignancy, especially lymphoma. The white blood cell count and liver chemistries must be monitored routinely. Methotrexate, which is a folic acid antagonist, is given as 25 mg intramuscularly or subcutaneously once per week for 16 weeks for active Crohn's disease and, 15 mg to 25 mg intramuscularly or subcutaneously once per week for maintaining remission.

Antibiotics

The exact mechanism for the beneficial effect of broad-spectrum antibiotics in the treatment of inflammatory bowel disease is not known. Potential mechanisms include eliminating bacterial overgrowth, eradicating a bacterially mediated antigenic trigger, and potential immunosuppressive properties (e.g., metronidazole). The primary role of antibiotics is in Crohn's disease, where metronidazole (10 to 20 mg/kg daily for 4 to 8 weeks), ciprofloxacin (500 mg orally twice daily for 4 to 8 weeks), or both are primary inductive therapies for perianal fistulas and fissures. Metronidazole may also be a helpful adjunctive treatment for colonic Crohn's disease.

Biologicals

Anti–Tumor Necrosis Factor-α Agents

Antibodies to tumor necrosis factor-α (anti-TNF-α) include infliximab, which is a chimeric mouse-human IgG1 monoclonal antibody that is approved to treat moderate to severe Crohn's disease, fistulizing Crohn's disease, and moderate to severe ulcerative colitis that has failed to respond to conventional therapy. Adalimumab (Humira) and certolizumab pegol (Cimzia) have been approved to treat moderate to severe Crohn's disease that has failed to respond to conventional therapy. Adalimumab is a fully humanized IgG1 antibody that is self-administered subcutaneously. Certolizumab pegol, which is a chimeric pegylated Fab fragment to TNF-α, also is administered subcutaneously.

Antiadhesion molecules

Natalizumab, a humanized IgG4 monoclonal antibody, binds to the α_4 subunit of $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins expressed on all leukocytes except neutrophils. Natalizumab inhibits the interactions between α_4 integrins on the surface of leukocytes and adhesion molecules on vascular endothelial cells in the gastrointestinal tract, thereby preventing adhesion and recruitment of leukocytes. Natalizumab is approved for the treatment of moderate to severe Crohn's disease that is refractory to conventional therapy, but there are strict guidelines for prescribing natalizumab because of its associated risk of progressive multifocal leukoencephalopathy (Chapter 378).

Crohn's Disease Medical Therapy

Mild to Moderate Crohn's Disease

Sulfasalazine, 3 to 6 g/day, is superior to placebo for treating active ileocolonic and colonic Crohn's disease, with response rates ranging from 45 to 55% for mild to moderate disease, but is not clearly effective for small bowel disease alone (Fig. 143-5). Mesalamine also has a modest benefit compared with placebo for mild to moderate disease.[1] However, the 5-ASAs are not effective for maintaining remission.

For mild to moderate Crohn's disease involving the distal small intestine or proximal colon budesonide (9 mg by mouth once a day) provides about a 70% response rate after 8 weeks and is significantly more effective than mesalamine, 4 g once a day, for distal ileal and right colonic disease.[2] As a maintenance agent at 3 or 6 mg, the effects of budesonide wane and disappear within 1 year.

Upper gastrointestinal Crohn's disease (jejunal, duodenal, gastric, and esophageal) is uncommon, so few clinical trials are available to assess therapies for this location. Because local therapies such as 5-ASAs and budesonide are not released in these locations, systemic immunosuppressants (azathioprine, mercaptopurine, infliximab, adalimumab, and certolizumab pegol) are the mainstays of therapy.

Moderate to Severe Crohn's Disease

Patients with moderate to severe disease are initially treated with systemic corticosteroids, but corticosteroids should not be used as maintenance therapy. Options to induce a remission or maintain a steroid-induced remission include 6-mercaptopurine, azathioprine, methotrexate, infliximab, adalimumab, and certolizumab.[3–5] After 1 year, approximately 20% more patients treated with combined therapy (corticosteroids, daily azathioprine, and infliximab, 5 mg/kg at weeks 1, 2, and 6) will be in remission compared with conventional treatment (corticosteroids plus azathioprine and then infliximab as needed according to current guidelines).[6] In a randomized trial, infliximab (5 mg/kg at 0, 2, and 6 weeks and then every 8 weeks) alone or infliximab plus azathioprine (2.5 mg/kg/day) was more effective than azathioprine alone.[7] Patients who have not responded to conventional therapy may be considered for natalizumab.

For severe Crohn's disease, patients should be hospitalized, given nothing by mouth, rehydrated with intravenous fluids, and administered parenteral corticosteroids. Patients who respond to parenteral corticosteroids should be switched to high-dose oral corticosteroids (prednisone, 40 to 60 mg/day), with the dose of prednisone gradually reduced. Patients who have severe Crohn's disease and who do not respond to parenteral corticosteroids within a week should be considered for either infliximab or surgery. A course of total parenteral nutrition (Chapter 224) may be useful as adjunctive therapy.

Fistulizing Crohn's disease

Fistulas occur in one third of patients with Crohn's disease, and perianal fistulas represent the most common location. Asymptomatic internal fistulas rarely require therapy. A concomitant abscess, which may occur in the setting of a fistula, must be excluded before initiating immunosuppressive therapy. Surgery may be required. Medical treatment depends on the location and associated complications.

High-output enterocutaneous fistulas in the setting of proximal small bowel involvement can lead to outputs of more than 500 mL/day and can cause severe volume depletion. Initial management requires volume repletion. In the postoperative setting, a fistulous opening is usually in the area of a wound, and it is imperative to protect the healing skin from infection caused by the drainage from either an ostomy bag or a catheter used for a high-output fistula. High-output fistulas will rarely close spontaneously and typically will require surgical closure. Low-output fistulas may be treated initially with azathioprine (or 6-mercaptopurine), methotrexate, or anti-TNF-α therapy (infliximab, adalimumab, or certolizumab).[8]

Perianal fistulas are classified into simple and complex fistulas. A simple fistula is located below most of the anal sphincter and has one track. A complex

fistula passes through the intersphincteric (high location), transsphincteric, or suprasphincteric region and may have multiple tracks. Simple fistulas respond well to medical therapy, initially with metronidazole (10 to 20 mg/kg orally daily for 4 to 8 weeks) and ciprofloxacin (500 mg orally twice daily for 4 to 8 weeks) for the fistula and treatment of concurrent mucosal disease. Treatment with immunomodulators or anti-TNF-α agents is also beneficial.[9] Patients with fistulas without rectal mucosal Crohn's disease may respond well to fistulotomy, whereas patients with mucosal involvement may benefit from seton placement rather than fistulotomy. Complex fistulas usually require a combination of surgical and medical therapy. In the setting of intractable disease, colonic or ileal diversion may allow for rectal and perianal healing; in severe cases, proctocolectomy may be necessary.

For Crohn's disease–related rectovaginal fistulas, medical therapy with antimetabolite therapy, or anti-TNF-α agents is usually considered before surgery. Surgical therapy such as fistulotomy and mucosal flap may be considered.

Enterovesicular or colovesicular fistulas may be treated with antimetabolite therapy or anti- TNF-α agents, or both, but recurrent urinary tract infection is an indication for surgery. Surgery usually involves resection of involved bowel and closure of the bladder defect.

Asymptomatic internal fistulas, such as enteroenteric fistulas, do not require surgical intervention, but treatment with an immunomodulator may be considered. Internal fistulas, such as cologastric and coloduodenal, may cause substantial symptoms because of bypass of part of the intestine. If medical management fails or if an abscess forms, surgery is recommended.

Medical Management of Ulcerative Colitis

The anatomic distribution of ulcerative colitis guides therapy. Options include suppositories, retention enemas, topical foam, oral therapy, and parenteral therapy. Suppositories are effective to treat proctitis in the distal 20 cm of the colon. Topical foam and enemas are effective for distal and left-sided colitis. Oral therapy and parenteral therapy are effective for all locations of disease.

Proctitis

For active ulcerative proctitis, topical 5-ASA (enema and suppository) in combination with oral treatment is superior to oral treatment alone.[9] Topical 5-ASA is superior to topical corticosteroids for treatment of active ulcerative proctitis, rectal 5-ASA therapy produces a faster response when given with oral 5-ASA. Corticosteroid enemas, suppositories, or foam can also be used if 5-ASA fails. 5-ASA or corticosteroid retention enemas can be used for active disease up to the splenic flexure (i.e., the rectum, sigmoid colon, and descending colon). Another approach to proctitis or distal colitis is an oral aminosalicylate, although a response may not be evident for 3 to 4 weeks.

Extensive Colitis

In patients with ulcerative colitis of mild to moderate activity and extension of disease proximal to the splenic flexure, the initial drug of choice is an oral 5-ASA; efficacy increases with increasing doses.[10] Even with more extensive disease, supplementation of oral 5-ASA with 5-ASA enemas or suppositories may help reduce the symptoms of urgency that result from rectal involvement. In patients with more than five or six bowel movements per day, in patients in whom a more rapid response is desired, or in patients who have not responded to 3 to 4 weeks of 5-ASA, the treatment of choice is oral prednisone. Patients with severe diarrhea, systemic symptoms, or significant amounts of blood in stool should be started on 40 mg/day; most patients respond to oral corticosteroids within a few days. After the symptoms are controlled, prednisone can be tapered gradually by 5 mg every 1 to 2 weeks. Patients who respond to oral prednisone and can be fully withdrawn from it should be maintained on 5-ASA.

If patients with severe ulcerative colitis do not begin to respond to corticosteroids at the equivalent dose of 60 mg of intravenous methylprednisolone within 5 days or do not completely respond within 7 to 10 days, options include colectomy, infliximab, or cyclosporine. For patients whose disease flares whenever the corticosteroids are withdrawn or their corticosteroid dose is lowered, the continuation of high-dose corticosteroid therapy is the most common management error. If the patient requires a substantial dose (>15 mg/day of prednisone) for more than 6 months, a trial of an immunomodulator, infliximab, or colectomy should be given serious consideration.

The most common indication for hospitalization in patients with ulcerative colitis is intractable diarrhea, although blood loss is also common. Patients with severely active ulcerative colitis should be evaluated for toxic megacolon by abdominal radiography or CT. Antidiarrheal medications and anticholinergic medications are contraindicated in patients with severe ulcerative colitis because of the risk for precipitating toxic megacolon. The mainstays of therapy for severe ulcerative colitis are rehydration with intravenous fluids and intravenous corticosteroids (hydrocortisone, 300 mg/day; prednisolone, 60 to 80 mg/day; or methylprednisolone, 40 to 60 mg/day). Total parenteral nutrition (Chapter 224) may be necessary in patients with malnutrition. Patients with peritoneal signs or signs of systemic infection should be treated with parenteral antibiotics (Chapter 144). Patients who do not improve in 7 to 10 days should be considered for either colectomy, a trial of intravenous cyclosporine,[11] or a trial of infliximab.

Maintenance Therapy

Aminosalicylates reduce recurrent disease in patients with ulcerative colitis, and essentially all patients should receive maintenance therapy[12] with original or newer 5-ASA preparations. Corticosteroids are not effective as maintenance therapy and should not be used. Azathioprine, 6-mercaptopurine, and infliximab are effective for maintenance therapy in patients whose ulcerative colitis has not responded to 5-ASA.

Surgical Therapy

Crohn's Disease

Surgical resection does not cure Crohn's disease, and recurrences are likely after resection, so the approach should be conservative in terms of the amount of tissue removed. Nevertheless, about 40% of patients with Crohn's disease undergo surgery within 10 years of their diagnosis. Failure of medical management is a common cause for resection in patients with Crohn's disease, but complications (e.g., obstruction, fistula, abscess) are often the indications for resection. For Crohn's disease of the small bowel, the most common surgical procedure is segmental resection for obstruction or fistula; the incidence of a recurrence severe enough to require repeat surgery after ileal or ileocolic resection is about 25% after 10 years and 35% after 15 years. For patients with extensive colonic disease that includes the rectum, the procedure of choice is total proctocolectomy with a Brooke (end) ileostomy. Total colectomy with ileal pouch anal anastomosis is not appropriate in Crohn's colitis because recurrence of Crohn's disease in the ileal segment of the new pouch would require a repeat operation and loss of a long segment of ileum.

Ulcerative Colitis

For ulcerative colitis, colectomy is a curative procedure. Approximately 40% of patients with extensive ulcerative colitis eventually undergo colectomy, usually because their disease has not responded adequately to medical therapy. Emergency colectomy may be required in patients with toxic megacolon or a severe fulminant attack without toxic megacolon. The standard operation for ulcerative colitis is proctocolectomy and a Brooke ileostomy. The most popular alternative operation is total proctocolectomy with an ileal pouch anal anastomosis; in this procedure, a pouch is constructed from the terminal 30 cm of ileum, and the distal end of the pouch is pulled through the anal canal. Ileoanal anastomosis is sometimes complicated by inflammation in the ileal pouch (termed *pouchitis*), which can be treated with antibiotics (typically, metronidazole, 500 mg three times daily or 20 mg/kg daily, or ciprofloxacin, 500 mg twice daily for a duration of 2 weeks). The decision for or against colectomy and among types of surgery is influenced by the patient's age, social circumstances, and duration of disease, and this decision requires expert consultation. When other indications are equivocal, the risk of malignancy (see later) may be an indication for colectomy.

Complications

Crohn's Disease

Abscesses

Abscesses, which are common complications in Crohn's disease, result from extension of a mucosal fissure or ulcer through the intestinal wall and into extraintestinal tissue. Leakage of intestinal contents through a fissure into the peritoneal cavity results in an abscess. Abscesses occur in 15 to 20% of patients with Crohn's disease, especially in the terminal ileum. The typical clinical manifestation of an intra-abdominal abscess is fever, abdominal pain, abdominal tenderness, and leukocytosis. Abdominal abscess is most often diagnosed by a CT scan. Broad-spectrum antibiotic therapy, including anaerobic coverage, is indicated. Percutaneous drainage of abscesses in patients with Crohn's disease may improve the clinical picture but does not provide adequate therapy because of persistent communication between the abscess cavity and the intestinal lumen. Resection of the involved intestine is usually required for definitive therapy.

Obstruction

Obstruction is a common complication of Crohn's disease, particularly in the small intestine, and is a leading indication for surgery. Small bowel obstruction in Crohn's disease may be caused by mucosal thickening from acute inflammation, by muscular hyperplasia and scarring as a result of previous inflammation, or by adhesions. Obstruction may also occur because of impaction of a bolus of fibrous food in a stable, long-standing stricture. Obstruction is marked by cramping abdominal pain and diarrhea that worsen after meals and resolve with fasting. Strictures may be evaluated by CT enterography, MRI enterography, oral contrast studies, barium enema, or colonoscopy, depending on the anatomic location. Corticosteroids (e.g., intravenous methylprednisolone, 40 to 60 mg once a day, or intravenous hydrocortisone, 200 to 300 mg once a day, for 5 to 14 days) are useful if acute inflammation is an important component of the obstructive process, but not if the obstruction is caused by fibrosis. A common error in the management of Crohn's disease is inappropriate treatment with long courses of corticosteroids in patients who have obstructive symptoms from fixed anatomic lesions. If the obstruction does not resolve with nasogastric suction and corticosteroids, surgery is necessary.

Perianal Disease

Perianal disease is a potentially disabling complication of Crohn's disease. Ulcerations in the anal canal may coalesce and result in fistula formation. The fistulous openings are most commonly found in the perianal skin but can occur in the groin, the vulva, or the scrotum. Fistulas are accompanied by drainage of serous or purulent material. If the fistula does not drain freely, there is local accumulation of pus (perianal abscess) with redness, pain, and induration. The pain of a perianal abscess is exacerbated by local pressure that may result from defecation, sitting, or walking. The typical physical manifestation of an abscess is redness with tenderness on digital examination; fluctuance also may be present. Adequate evaluation of perianal disease generally requires proctoscopic examination under anesthesia. Cross-sectional CT or MRI can define the presence and extent of perianal abscesses. The goals of therapy for perianal disease are relief of local symptoms and preservation of the sphincter. Limited disease can be approached with sitz baths and metronidazole, but most cases also require adequate external drainage. Azathioprine, infliximab, adalimumab, or certolizumab pegol may be useful in healing perianal disease, but the disease may reactivate when the drug is stopped. Persistent severe perianal Crohn's disease can result in destruction of the anal sphincter and subsequent fecal incontinence.

Ulcerative Colitis

One of the most significant complications of ulcerative colitis is toxic megacolon, which is dilation of the colon to a diameter greater than 6 cm associated with worsening of the patient's clinical condition and the development of fever, tachycardia, and leukocytosis. Physical examination may reveal postural hypotension, abdominal tenderness over the distribution of the colon, and absent or hypoactive bowel sounds. Agents that reduce gastrointestinal motility, such as antispasmodics and antidiarrheal agents, are likely to initiate or exacerbate toxic megacolon. Medical therapy is designed to reduce the likelihood of perforation and return the colon to normal motor activity as rapidly as possible. The patient is given nothing by mouth, and nasogastric suction is begun. Intravenous fluids should be administered to replete water and electrolyte abnormalities, broad-spectrum antibiotics (e.g., ampicillin-sulbactam, given as 1 g ampicillin plus 0.5 g sulbactam, 1.5 to 3 g every 6 hours for 5 to 14 days; levofloxacin, 500 mg intravenously once daily plus metronidazole, 500 mg intravenously or orally twice daily; cefazolin, 500 mg intravenously three times daily plus metronidazole, 500 mg intravenously or orally twice daily; or trimethoprim-sulfamethoxazole, 8 to 10 mg/kg/day intravenously or orally in two to four divided doses plus metronidazole, 500 mg intravenously or orally twice daily for approximately 7 days or until symptomatic improvement) are given in anticipation of possible peritonitis as a result of perforation, and parenteral corticosteroids are administered at a dose equivalent to more than 40 to 60 mg of prednisone per day. Signs of improvement include a decrease in abdominal girth and the return of bowel sounds. Deterioration is marked by the development of rebound tenderness, increasing abdominal girth, and cardiovascular collapse. If the patient does not begin to show signs of clinical improvement during the first 24 to 48 hours of medical therapy, the risk for perforation increases markedly, and surgical intervention colectomy is indicated.

Follow-Up

Colon Cancer, Dysplasia, and Colonoscopic Surveillance

The risk of colorectal cancer is increased beginning after 8 years of disease and continues to increase in subsequent years. Patients with extensive ulcerative colitis have a markedly increased risk for colon cancer, patients with left-sided disease have an intermediate risk, and patients with long-standing ulcerative colitis are at risk for colorectal cancer even if their symptoms have been relatively mild or even quiescent for 10 to 15 years.

Colon cancers are commonly submucosal and may be missed at colonoscopy. Colon cancer in patients with ulcerative colitis is most commonly associated with dysplastic changes in the mucosa, often at multiple sites in the colon. Dysplasia cannot be always be identified by visual inspection, so microscopic examination of biopsy specimens is required.

Current practice guidelines recommend colonoscopy with random biopsies in patients with long-standing ulcerative colitis beginning 8 years after the onset of disease and repeated every 1 to 2 years. If the specimens show dysplasia, colectomy is recommended.

The risk for colon cancer in patients with Crohn's colitis is similar to the risk in patients with a similar extent of ulcerative colitis. Surveillance colonoscopy is also recommended in patients with Crohn's colitis.

Pregnancy

Fertility in women with inflammatory bowel disease usually is normal or only minimally impaired, and the incidence of prematurity, stillbirth, and developmental defects in the offspring of women with inflammatory bowel disease, except fetal complications may be somewhat more likely when the mother's disease is clinically active, regardless of drug therapy. Previous proctocolectomy or the presence of an ileostomy is not an impediment to successful completion of a pregnancy, but women who have had ileal pouch anal anastomosis surgery with a total proctocolectomy have markedly reduced fertility.

If a woman's disease is inactive at the time of conception, it is likely that it will remain inactive during the course of the pregnancy. Ulcerative colitis that is active at the time of conception tends to worsen. In patients with active Crohn's disease at the time of conception, the degree of activity remains the same in two thirds of women; of the other one third, some improve clinically, and others deteriorate.

Sulfasalazine does not harm the fetus, but pregnant women have an increased requirement for folic acid, and sulfasalazine interferes with folate absorption. Therefore, women who are taking sulfasalazine and who are pregnant or considering pregnancy should receive folate supplementation (1 mg twice daily) to ensure that the fetus receives adequate amounts for normal development. The use of corticosteroids by pregnant women with inflammatory bowel disease is associated with an increased rate of premature rupture of the membranes and a higher rate of cleft lip. In general, it appears that the risk to the pregnancy of treatment with sulfasalazine or corticosteroids is less than the risk of allowing disease activity to go untreated.

Most of the data on the teratogenicity of azathioprine and 6-mercaptopurine in pregnancy are derived from the transplant literature and involve higher doses than are commonly used for inflammatory bowel disease. Reported fetal effects in the transplant population include congenital malformations, immunosuppression, prematurity, and growth retardation. The risks of these medications in the inflammatory bowel disease population are not completely known, given that only small a number of such patients have been formally studied.

PROGNOSIS

Ulcerative Colitis

The prognosis of patients with ulcerative colitis is usually characterized by repeated flares and remissions. A rapidly progressive initial attack results in serious complications in about 10% of patients. Complete recovery after a single attack may occur in another 10% of patients, some of whom may actually have had an acute undetected infection rather than true ulcerative colitis. The probability that a patient with clinically inactive disease will remain in remission the following year is 80 to 90%. By comparison, patients with clinically active disease have a 70% probability of relapse during the following year.

Patients who present with ulcerative proctitis have the best overall prognosis, and only about 5% of patients with proctitis will require colectomy over a lifetime. Severe complications are very uncommon, but the disease will spread more proximally in the colon in approximately 10% to 30% of patients. Ulcerative colitis–related mortality has decreased substantially since the introduction of corticosteroids, and recent studies suggest that long-term survival rates for patients with ulcerative colitis are similar to those of the general population.

Crohn's Disease

Crohn's disease classically waxes and wanes. A patient with clinically active Crohn's disease has a 70 to 80% chance of having active disease in the subsequent year, whereas 80% of patients in remission will remain so over the following year. Over the course of a 4-year period, about 25% of patients will have persistently active disease after diagnosis, about 25% will remain in remission, and 50% will have a fluctuating course with years of remission and years with clinically active disease. Approximately 75 to 80% of all patients with luminal and fistulizing Crohn's disease will require surgical intervention for their disease, with approximately 50% of them requiring surgery within 6 months of diagnosis. The rate for a second surgery for luminal Crohn's disease ranges from 25 to 38% within 5 years, and 40 to 70% will need reoperation by 15 years.

Patients with Crohn's disease have an increased mortality rate, about 1.3 to 1.5 times higher than the general population, unrelated to whether they have small intestine or large intestine involvement, or both. This excess mortality, which is most notable in the first few years after diagnosis, is most commonly related to complications of Crohn's disease (e.g., colorectal cancer, shock, volume depletion, protein-calorie malnutrition, and anemia). Whether aggressive use of immunomodulators and biologic therapy will alter the natural course of disease is unknown.

INFLAMMATORY AND ANATOMIC DISEASES OF THE INTESTINE, PERITONEUM, MESENTERY, AND OMENTUM

CHARLENE PRATHER

APPENDICITIS

DEFINITION AND EPIDEMIOLOGY

Acute appendicitis refers to inflammation of the appendix. Appendicitis is the most common acute surgical emergency involving the abdomen. Although appendicitis occurs most commonly in young adults, it can develop at any age. The lifetime prevalence of acute appendicitis is approximately 7%.

PATHOBIOLOGY

Obstruction of the appendix by a fecalith, which is thought to be the usual inciting event, is found in less than 30% of patients. Other causes of obstruction include ulceration of the appendiceal orifice, lymphoid hyperplasia, tumor (e.g., carcinoid; Chapter 240), inspissation of barium, and ascariasis (Chapter 365). Obstruction blocks the ongoing production of mucus by the appendix, thereby resulting in distention and subsequent mucosal ischemia. This process allows invasion by intraluminal bacteria, infection, and inflammation. Continued obstruction and inflammation can result in perforation, peritonitis, diarrhea, and abscess formation.

CLINICAL MANIFESTATIONS

More than 95% of patients with appendicitis have abdominal pain, but only 50 to 60% have the classic symptoms of appendicitis: an acute onset of periumbilical pain, often with nausea and vomiting and later localizing to the right lower quadrant. The position of the appendix has important implications for the location of pain, with pain from appendicitis occurring in the suprapubic region or the right upper quadrant. Anorexia is nearly universal, nausea is frequent, but vomiting is uncommon. Acute appendicitis occurs with nonspecific abdominal symptoms and signs in elderly patients and in patients who are immunosuppressed, as from corticosteroid use, organ transplantation, or diabetes mellitus. In elderly patients, the diagnosis is unsuspected 25% of the time.

Adults older than 50 years have a perforation rate of greater than 50%, with an intra-abdominal abscess in one third. Signs of perforation include the presence of peritoneal irritation, fever, and increasing abdominal pain.

DIAGNOSIS

A broad differential diagnosis (Table 144-1) may be narrowed by diagnostic testing, which usually includes a complete blood count, serum electrolytes, and tests of renal function, with the addition of amylase and lipase levels when pancreatitis (Chapter 146) is suspected and liver enzymes (aminotransferase levels and alkaline phosphatase) and a bilirubin level when gallbladder (Chapter 158) or bile duct conditions are suspected. An elevated white blood cell count, usually in the 12,000 to 18,000/mm^3 range, is common in acute appendicitis but may not be seen early in the course; the presence and degree of elevation are not helpful in identifying complicated appendicitis.

Computed tomography (CT), which is the preferred test to confirm the diagnosis or suggest other causes (Fig. 144-1), has a sensitivity ranging from 88 to 100%, a specificity of 91 to 99%, a positive predictive value of 92 to 98%, and a negative predictive value of 95 to 100%. With a reported overall diagnostic accuracy of 94 to 98% and the ability to detect abscess formation (Fig. 144-2), CT has become the imaging diagnostic modality of choice. A disadvantage, which is more significant in children and young adults, is the need for ionizing radiation. Intravenous contrast may be used, but CT with rectal contrast is an alternative to avoid the risk of nephrotoxicity. Ultrasound is useful when gynecologic causes, especially an ectopic pregnancy, are also in the differential diagnosis. Plain abdominal radiographs are not useful.

TABLE 144-1 DIFFERENTIAL DIAGNOSIS IN SUSPECTED APPENDICITIS

Crohn's ileitis
Mesenteric adenitis
Right-sided colonic diverticulitis
Yersinia, Campylobacter enterocolitis
Meckel's diverticulitis
Tuberculous colitis
Perforated right colon adenocarcinoma
Nephrolithiasis (right sided)
Foreign body perforation (e.g., toothpick bowel perforation)
Right tubo-ovarian abscess
Tubal pregnancy
Ovarian cyst rupture or torsion

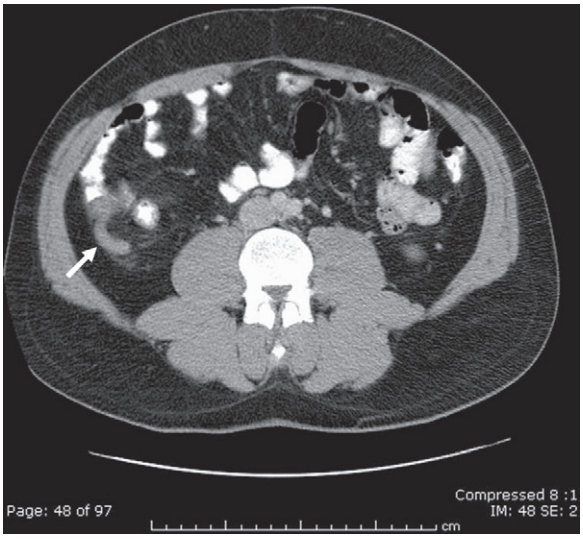

FIGURE 144-1. Appendicitis. A computed tomography scan shows an edematous appendix with a diameter greater than 1 cm *(arrow)*, consistent with acute, uncomplicated appendicitis.

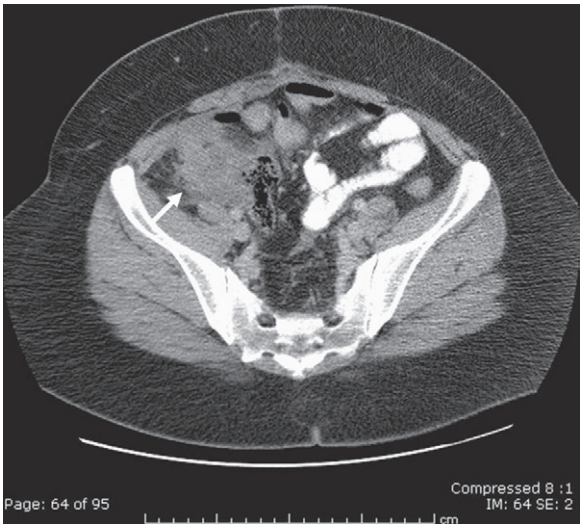

FIGURE 144-2. Appendicitis. A computed tomography scan shows appendicitis complicated by perforation with abscess formation *(arrow)*.

TREATMENT

Rx

When appendicitis is suspected, emergent surgical consultation is indicated. Treatment of appendicitis is appendectomy, which is increasingly being performed laparoscopically. Two days of intravenous antibiotics followed by 10 days of oral antibiotics is a reasonable short-term alternative in the absence of evidence of perforation when surgery cannot be performed safely in the interim, but about one third of patients will require appendectomy. Laparoscopic appendectomy generally takes longer than the open operation but results in faster recovery and a lower rate of wound infection. Preoperative antibiotics (e.g., cefotetan, 2 g intravenously, or cefoxitin, 2 g intravenously, followed by three postoperative doses, or ticarcillin–clavulanic acid) reduce infectious complications in otherwise uncomplicated appendicitis.

In the presence of a perforated appendix with an appendicular abscess, immediate appendectomy yields similar results to a strategy of percutaneous ultrasound- or CT-guided drainage, intravenous antibiotics, and laparoscopic appendectomy about 10 weeks later. In the setting of perforation, once-daily dosing with ceftriaxone and metronidazole for 7 to 10 days is as good as triple-dose therapy.

PROGNOSIS

The frequency of complications associated with perforated appendicitis is greater than 18%, as opposed to a 10% frequency of complications in nonperforated appendicitis. Overall mortality in patients with perforated appendicitis is 3%, but it can be as high as 15% in elderly patients. Most patients who are operated on for suspected appendicitis, but who do not have it, have benign self-limited disease. In adults, however, appendiceal diverticulitis, granulomatous appendicitis, carcinoid tumors (Chapter 240), and occasionally other tumors may be found.

DIVERTICULITIS OF THE COLON

DEFINITION

Colonic diverticulosis refers to uncomplicated herniations of the colonic mucosa and submucosa through the muscular layer of the colon. Technically, these lesions are actually pseudodiverticula because all layers of the colon are not involved. Diverticular disease encompasses a spectrum of problems occurring in the setting of diverticulosis, including diverticulitis, painful diverticular disease, and complicated diverticular disease (Table 144-2).

EPIDEMIOLOGY

Although colonic diverticulosis is quite common and affects up to 10% of middle-aged adults and 50 to 80% of those older than 80 years, few people are aware that they have them. Diverticulosis is uncommon in individuals younger than 40 years of age. Diverticulosis is predominantly a disorder of industrialized or Western populations, where it correlates with low intake of dietary fiber. Obesity appears to be a risk factor for diverticulosis in young males.

TABLE 144-2 TERMINOLOGY IN DIVERTICULAR DISEASE

Diverticular disease	The entire spectrum of diverticulosis and its complications
Diverticulosis	The presence of one or more diverticula
Diverticulitis	Inflammation or infection of one or more colonic diverticula
Complicated diverticulitis	Diverticulitis with abscess, fistula formation, free perforation, or obstruction
Painful diverticular disease	Abdominal pain and altered bowel habit in the setting of diverticulosis without another explanation (may be a manifestation of irritable bowel syndrome)
Diverticular bleeding	Acute lower gastrointestinal bleeding from a colonic diverticulum

PATHOBIOLOGY

Colonic diverticulosis most commonly occurs at the location where the vasa recta (nutrient artery) penetrates through the muscularis propria. In Western populations, diverticulosis occurs more commonly in the left colon, with the sigmoid colon most frequently involved, perhaps because of the relatively higher pressure present in the lumen of the sigmoid colon. However, in Asian populations, a right-sided distribution is more common.

Diverticulitis, which is infection and inflammation of a diverticulum, develops in 10 to 25% of persons with diverticulosis during their lifetimes. Diverticulitis results from inflammation of a colonic diverticulum with subsequent microperforation, which is thought to occur when particulate debris within the diverticular sac compresses or erodes the blood vessel and thereby leads to perforation. Diverticulitis occurs most commonly in the sigmoid colon. Complications of diverticulitis, which include abscess formation, free perforation, colonic obstruction, and fistula formation, are more common in middle-aged and elderly patients but can also occur in young patients.

CLINICAL MANIFESTATIONS

Patients with diverticulitis most commonly have anorexia, left lower quadrant pain, and fever. The pain in diverticulitis may radiate to the flank, back, or suprapubic region. Patients may report loose stools or constipation. Additional associated symptoms include nausea, vomiting, altered bowel pattern, and urinary symptoms. On physical examination, left lower quadrant tenderness can usually be demonstrated. The examination may also identify localized guarding and, occasionally, a tender painful mass. The presence of peritoneal signs (e.g., rebound) suggests a free perforation.

Diverticular bleeding is manifested as painless rectal bleeding, with massive bleeding occurring in 5% of patients with diverticulosis (Chapter 137). Diverticular bleeding is rare in the setting of acute diverticulitis.

DIAGNOSIS

Leukocytosis is present in 70 to 80% of patients. When the diverticulitis is adjacent to the bladder, pyuria may occur. Conditions with findings similar to those of diverticulitis include gastroenteritis, appendicitis, inflammatory bowel disease (Chapter 143), and a perforating colon cancer (Chapter 199).

CT radiography, which reliably identifies the presence and location of inflammation, may show the colonic diverticula, inflammation involving the pericolic fat, and a colonic wall thicker than 4 mm (Fig. 144-3). Barium radiography, which can demonstrate diverticula (Fig. 144-4), will also identify whether the colon connects with the fluid collection in the setting of perforation and abscess formation; it is not recommended in the acute setting because of a higher risk for colonic perforation from contrast or air insufflation. After the acute syndrome has resolved and the patient has become stable, colonoscopy can also show diverticula (Fig. 144-5) and is essential to exclude malignancy, even in younger patients.

TREATMENT

Rx

Uncomplicated diverticulitis may be treated in the outpatient setting with broad-spectrum antibiotics such as ciprofloxacin and metronidazole for 7 to 10 days (Table 144-3). Oral antibiotics are as effective as the intravenous route, and 4 days of treatment are as effective as 7 to 10 days for uncomplicated patients. Patients are started on a clear liquid diet that can be advanced

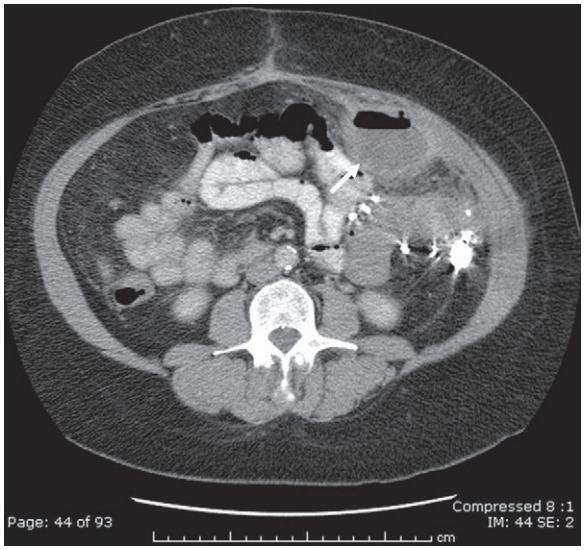

FIGURE 144-3. Diverticulitis. A computed tomography scan shows perforated diverticulitis with abscess formation *(arrow)*. The abscess is identified as the air-filled collection. Residual contrast remains in the diverticulum.

FIGURE 144-4. Colonic diverticula. An abdominal flat plate shows residual barium in diverticula scattered throughout the colon.

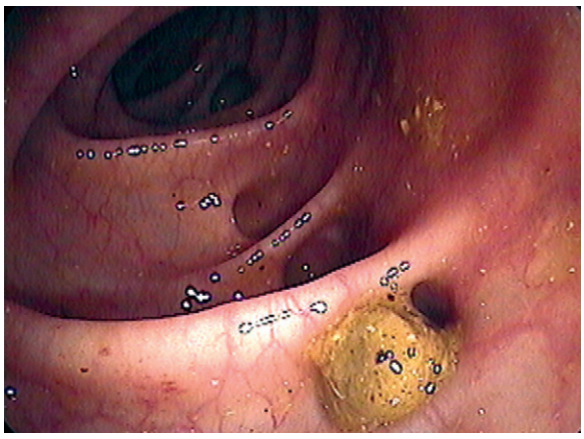

FIGURE 144-5. Sigmoid diverticula. A colonoscopic photograph shows sigmoid diverticula.

TABLE 144-3 ANTIBIOTIC OPTIONS FOR ACUTE DIVERTICULITIS*

Ciprofloxacin, 750 mg bid, and metronidazole, 500 mg q6h
Levofloxacin, 750 mg IV q24h, and metronidazole, 500 mg q6h
Trimethoprim-sulfamethoxazole-DS, bid
Piperacillin-tazobactam, 3.375 g q6h
Ampicillin-sulbactam, 3.0 g q6h
Imipenem–cilastatin sodium, 500 mg q6h (reserved for life-threatening infection)

*Four days in uncomplicated patients; 7 to 10 days in others.

as symptoms resolve. Patients unable to maintain oral intake require hospitalization for hydration and intravenous antibiotics.

Elective resection carries a mortality rate of 1 to 4%, and expectant management rather than operative treatment is probably associated with less mortality and fewer colostomies, and it is also less expensive.

However, patients younger than 40 years may experience a more aggressive form of the disease, so surgical resection is sometimes recommended after the first episode of diverticulitis. Patients with conditions resulting in immune system compromise may benefit from earlier (after a first episode) surgery because of their reduced ability to ward off infection and their increased risk for emergency surgery. For sigmoid diverticulitis, laparoscopic resection is preferred over open resection.

Patients with diverticular abscesses are treated by CT-guided drainage and subsequent surgery, usually 6 weeks after successful abscess drainage. Laparoscopic resection, which is increasingly being performed for diverticular disease, results in shorter hospitalization and an early return to full function. Patients with complicated diverticulitis have a mortality of 6.5% and morbidity of 41%; when perforated diverticulitis is excluded, the mortality is less than 2%. Older age, immunosuppressive medications, preexisting medical problems (especially preexisting cardiac and pulmonary disease), and perforated diverticulitis increase postoperative morbidity.

PREVENTION

Randomized trials show that the combination of fiber and rifaximin (400 mg twice daily for 7 days every month), a poorly absorbable antibiotic, decreases symptoms over a 12-month period. Other medications used to reduce recurrent diverticular symptoms included mesalazine and calcium-channel blockers, although the evidence to support their use is inconclusive. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) increases the risk for diverticular perforation.

PROGNOSIS

Most patients with diverticulitis improve quickly over a period of 2 to 3 days, and the risk for a second attack of diverticulitis is less than 25%. After a second attack of diverticulitis, the risk for subsequent episodes of diverticulitis exceeds 50%, and the risk increases with each subsequent episode. Surgical therapy to remove the segment of colon involved with diverticulosis is often recommended after a second episode of diverticulitis. After elective resection, 25% of patients have persistent symptoms, including altered bowel habits and pain that probably reflect a coexistent irritable bowel syndrome (Chapter 139), and 10% have recurrent diverticulitis.

OTHER INFLAMMATORY CONDITIONS

Neutropenic Enterocolitis

Neutropenic enterocolitis is also referred to as typhlitis. Although originally described in children after induction chemotherapy for acute leukemia, it is an increasingly recognized clinical syndrome in adults as well.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The syndrome occurs in neutropenic patients (absolute neutrophil count <500/μL) and consists of right lower quadrant abdominal pain, distention, fever, nausea, vomiting, and diarrhea, which may be bloody. Symptoms typically occur 10 to 14 days after high-dose chemotherapy. The clinical findings are nonspecific and overlap with symptoms seen in *Clostridium difficile* colitis (Chapter 304), ischemic colitis (Chapter 145), and colonic pseudo-obstruction (Chapter 138). CT findings include a thickened colonic wall (>4 mm), dilated cecum, and pericecal inflammatory changes (Fig. 144-6).

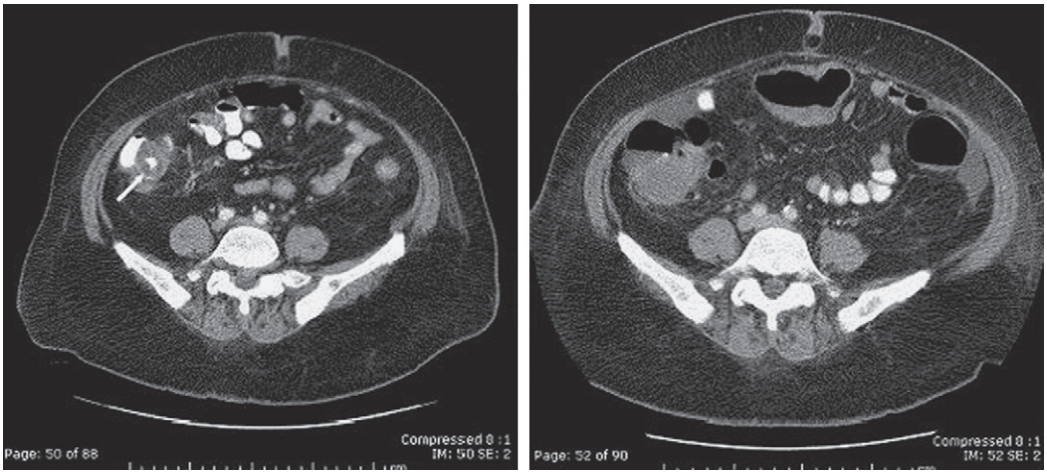

FIGURE 144-6. Computed tomography scans showing neutropenic colitis. The *left scan* shows a thickened cecal wall *(arrow)*. Eight days latter a follow-up scan showed resolution *(right scan)*.

TREATMENT

Rx

Conservative management includes bowel rest, nasogastric suction when bowel dilation is present, and broad-spectrum antibiotics to cover gram-positive and enteric gram-negative organisms, as well as anaerobes. Recombinant granulocyte colony-stimulating factor has been recommended to correct neutropenia. Lower gastrointestinal bleeding resulting from the colitis with a coexisting coagulopathy necessitates correction of the coagulopathy and blood transfusions. Surgery is indicated in the setting of impending or free perforation, when bleeding cannot be stopped, and for otherwise unexplained clinical deterioration. Symptoms improve rapidly as the neutropenia resolves.

Visceral Angioedema

Visceral angioedema is seen with hereditary and acquired C1 esterase inhibitor deficiency (Chapter 260), hypocomplementemia, drugs (especially angiotensin-converting enzyme inhibitors), or foods or may be idiopathic. Acquired C1 esterase inhibitor deficiency may occur as a paraneoplastic syndrome and is occasionally seen in autoimmune disorders. Angioedema of the gastrointestinal tract is commonly manifested as abdominal pain and distention, nausea, vomiting, and diarrhea. The symptoms may be accompanied by swelling of the mucous membrane, hives, wheezing, or dyspnea. CT findings include thickened, fluid-filled loops of small bowel. Ascites may also be present. The symptoms last 1 to 3 days and may recur periodically. The diagnosis is established by identifying suspect drugs, low serum levels of C4, low C1 esterase quantitative levels, or reduced C1 esterase functional activity. Hereditary and acquired C1 esterase inhibitor deficiency can be treated with C1 inhibitor therapy (Chapter 260).

Radiation Enterocolitis

Patients who receive radiation therapy for intra-abdominal and pelvic neoplasms are at risk for radiation-induced injury.

EPIDEMIOLOGY

The risk for injury varies according to the size of the radiation field and the dose received. Chronic radiation enterocolitis occurs approximately a year after completion of radiation therapy but may develop up to 20 years later. Doses greater than 50 Gy increase the risk for chronic changes, such as the development of obliterative arteritis, intestinal wall fibrosis, and serosal thickening. Other risk factors include older age, previous abdominal surgery, and a larger field of radiation. The quantity of small bowel in the radiation field is a strong predictor of subsequent complications.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms of acute radiation enterocolitis commonly include diarrhea, intestinal bleeding, and fecal incontinence. These symptoms are typically self-limited and resolve within a few months after the completion of radiation treatment.

Symptoms of chronic radiation enterocolitis commonly include abdominal pain and diarrhea. Gastrointestinal bleeding results from vascular ectasia. The bleeding is typically chronic and occult, with the development of iron deficiency anemia, but occasionally it is overt. Complete or partial bowel obstruction from adhesions or strictures, fistulas, small bowel bacterial overgrowth, and malabsorption can also occur.

Diagnostic imaging includes CT radiography or colonoscopy. The finding of a stricture necessitates an evaluation to exclude malignancy.

PREVENTION AND TREATMENT

Rx

Prevention of radiation enteritis includes minimizing the volume of small bowel and colon in the radiation field. Treatment is predominantly supportive. Management of bleeding includes endoscopic ablation of telangiectatic lesions and chronic iron therapy. Sucralfate enemas (2 g twice daily) may improve symptoms, but the data are not conclusive.

For acute obstruction, bowel rest and nasogastric suction may allow resolution; surgery is reserved for complete bowel obstruction that does not improve or perforation. Poor wound healing, anastomotic leaks, and fistulas may complicate surgical operations. Patients with diarrhea should be evaluated for small bowel bacterial overgrowth. Cholestyramine, loperamide, and diphenoxylate-atropine provide first-line options for treating diarrhea (Chapter 142), but stronger opiates such as codeine, morphine, or tincture of opium are sometimes required. Caution is necessary when using these agents because of the risk for development of bowel dilation and obstipation.

Nonsteroidal Anti-inflammatory Drugs

Small intestinal ulcerations are increasingly being recognized with the advent of small bowel capsule endoscopy (Chapter 136). The most common cause of small intestinal ulcers is the use of NSAIDs (Chapter 36). Small bowel and colonic erosions and ulcerations occur in 60 to 70% of long-term users of NSAIDs. Diaphragm-type strictures of the small bowel and, less frequently, the colon also result from chronic NSAID use.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most NSAID-related lesions are asymptomatic, but symptoms suggesting NSAID enteropathy include gastrointestinal bleeding, abdominal pain, iron deficiency anemia, diarrhea, hypoalbuminemia, and obstructive symptoms. Ulceration can be detected by small bowel enteroscopy, small bowel capsule endoscopy, and colonoscopy.

TREATMENT

Rx

Treatment consists of discontinuing NSAIDs. When obstruction is present and conservative treatment fails, surgical resection may be required.

Systemic Inflammatory Conditions

Ulcerative jejunitis is an uncommon manifestation of celiac disease (Chapter 142). This diagnosis is suspected in patients with persistent symptoms despite a gluten-free diet.

Mycobacterium tuberculosis (Chapter 332) involvement of the small intestine and occasionally of the colon, especially in the cecum, most commonly

manifests as abdominal pain, vomiting, and diarrhea. The disease may be subacute with waxing and waning symptoms or be marked by more fulminant sepsis. The intestinal lesions include nodularity, ulcerations, skip lesions, and strictures, features similar to those found in small bowel Crohn's disease. The diagnosis is made by biopsy, stains, and culture. When the small bowel is not accessible endoscopically, exploratory laparotomy for full-thickness biopsy may be required to make the diagnosis. Treatment with conventional antituberculous therapy results in symptomatic improvement.

Histoplasma capsulatum (Chapter 340) typically involves the gastrointestinal tract in the setting of disseminated disease in immunocompromised patients, predominately in patients with acquired immunodeficiency syndrome. Gastrointestinal involvement is accompanied by bleeding, obstruction, diarrhea, and malabsorption. Small bowel lesions include ulcerations, polypoid lesions, and masses that simulate carcinoma. The granulomatous changes present on biopsy must be differentiated from Crohn's disease, tuberculosis, and less commonly, sarcoidosis. Treatment is directed at the underlying disseminated infection.

Sarcoidosis (Chapter 95) of the gastrointestinal tract is relatively uncommon. Small bowel and colonic involvement has manifestations similar to those of Crohn's disease, with ulceration and non-necrotizing granulomas. Gastrointestinal involvement typically occurs in the setting of other systemic symptoms of sarcoidosis. Patients have abdominal pain, vomiting, diarrhea, or protein-losing enteropathy, or any combination of these findings. Treatment is aimed at the systemic disease.

Systemic lupus erythematosus (Chapter 274) frequently affects the gastrointestinal tract. Abdominal pain may be due to serositis, mesenteric ischemia, vasculitis, intestinal dysmotility, angioedema, or pancreatitis. Clinical manifestations include abdominal pain, nausea, vomiting, abdominal bloating, distention, diarrhea, and malabsorption. Small bowel bacterial overgrowth also occurs, presumably secondary to the underlying dysmotility. Treatment consists of management of the underlying systemic disease.

Ulceration of any part of the gastrointestinal tract may occur in *Behçet's disease* (Chapter 278). Symptoms include abdominal pain, diarrhea, and gastrointestinal bleeding. Most patients with gastrointestinal involvement have ileocecal involvement with a single or few ulcers. In the absence of obvious systemic symptoms, Behçet's disease can be difficult to differentiate from Crohn's disease.

Patients with *polyarteritis nodosa* (Chapter 278) may have intermittent or persistent abdominal complications. Gastrointestinal involvement occurs in half or more of patients with polyarteritis nodosa. Most have abdominal pain, nausea, vomiting, melena, hematochezia, diarrhea, and occasionally, constipation; however, severe abdominal pain can also develop as a result of mesenteric vasculitis with gastrointestinal infarction and perforation. These gastrointestinal complications of polyarteritis nodosa result in considerable morbidity and mortality, with a mortality rate of 23% to greater than 60% when the symptoms include an acute abdomen. The diagnosis is typically made by CT radiography and magnetic resonance or CT angiography; less frequently, angiography is required. Although colonoscopy can identify ischemia, its role is limited in the acute setting because of the risk for perforation. Treatment is directed at the systemic disease (Chapter 278).

Henoch-Schönlein purpura (Chapter 278) is an immunoglobulin A (IgA)-mediated vasculitis with skin, abdominal, and renal manifestations. Abdominal symptoms include pain, nausea, vomiting, diarrhea, and gastrointestinal bleeding. Small bowel thickening and intussusception can be seen on CT radiography. Upper endoscopy and colonoscopy are not usually necessary diagnostically but can show submucosal hemorrhage, erythema, swelling, and ulcerations. Similar changes are also present in the small intestine as imaged by capsule endoscopy. The disease is often self-limited but may require systemic therapy (Chapter 278).

PERITONEAL DISORDERS

Peritonitis

DEFINITION

The peritoneum is the smooth serous membrane that lines the abdominal and pelvic cavities. The most common clinical disorders of the peritoneum are ascites (Chapter 156) and peritonitis. Peritonitis may be acute or chronic, septic or aseptic, primary or secondary, and localized or diffuse.

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute peritonitis results from acute disruption of the peritoneal cavity with infectious or inflammatory materials. In the setting of perforation of the bowel or an intra-abdominal viscus, the contents themselves may be inflammatory, such as with bile spillage, or may be infectious, such as with contamination from intraluminal contents (e.g., bacteria and fecal material). Aseptic peritonitis results from the introduction of sterile bile, digestive juices, or extrinsic materials (e.g., chemotherapeutic medications) into the peritoneal cavity. Aseptic peritonitis rarely remains that way, with infection typically following in due course. Primary peritonitis refers to spontaneous bacterial peritonitis without an identifiable cause, typically in the setting of chronic liver disease (Chapter 148). Secondary peritonitis results most commonly from a perforated viscus such as the appendix, a diverticulum, peptic ulcer disease, or trauma with secondary spillage of luminal contents into the peritoneum. The most common bacteriology in secondary peritonitis is a mixed flora with *Escherichia coli, Streptococcus faecalis, Pseudomonas aeruginosa, Klebsiella mirabilis, Bacteroides fragilis, Clostridium* species, and anaerobic streptococci.

CLINICAL MANIFESTATIONS

Clinical manifestations of acute diffuse peritonitis typically include the sudden onset of abdominal pain that is usually constant. The pain may be diffuse or referred to the umbilicus or the portion of the abdomen where the inciting event originated. The peritoneal inflammation may subside or localize, thereby resulting in a reduction in pain and improved localization. Additional symptoms include nausea, vomiting, and fever. The development of progressive tachycardia and a falling temperature are grave signs of impending peritoneal shock from bacterial toxemia and septicemia (Chapter 108) (Fig. 144-7).

Additional physical signs (Chapter 134) include a very still patient. Bowel sounds are typically diminished or absent in the setting of peritonitis. Percussion often reveals tympany from the resultant ileus. On palpation, tenderness and rigidity are present. Rebound tenderness, with increasing pain when the examining hand is lifted from the abdomen, is usually present. Increased pain may also be elicited in the affected area on examination of an uninvolved portion of the abdomen. The abdominal muscles may become boardlike with rigidity, although this sign is frequently absent in elderly patients and in immunosuppressed patients.

DIAGNOSIS

Identifying the cause of the peritonitis depends on the age and sex of the patient. In younger patients, appendicitis and a perforated duodenal ulcer (Chapter 141) are most common. In older patients, perforated diverticula and cancer (Chapter 199) are more common. The use of NSAIDs or aspirin increases the likelihood of a perforated ulcer or diverticula. In young females, tubal pregnancy and a ruptured tubo-ovarian abscess must be considered (Chapters 293 and 308). CT imaging identifies the presence of free air and often is the cause of the intra-abdominal calamity (see Fig. 144-3).

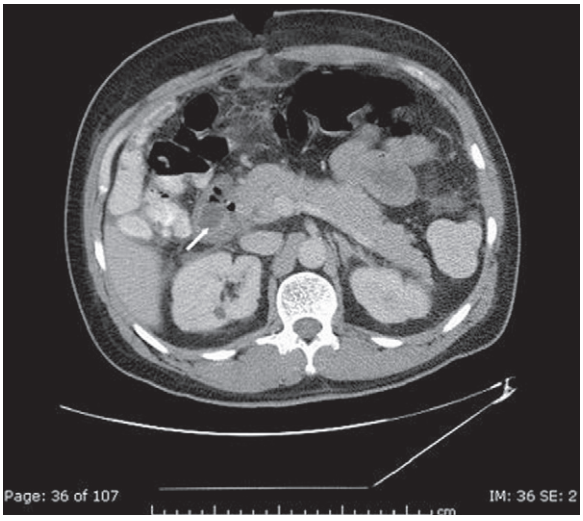

FIGURE 144-7. Computed tomography scan in a patient with peritonitis. Thickening of the duodenal wall *(arrow)* was identified at surgery as a perforated duodenal ulcer.

TREATMENT

Rx

Treatment focuses on resuscitation, control of infection, and laparoscopy. The presence of suspected acute peritonitis necessitates surgical consultation. Correction of volume depletion and electrolyte disturbances with intravenous fluids is the cornerstone of initial management. Blood should be obtained for culture and broad-spectrum antibiotics administered prophylactically to cover gram-negative and anaerobic bacteria (Table 144-4).

PROGNOSIS

Peritonitis is a life-threatening disorder whose outcome depends on its cause as well as the rapidity of treatment. Mortality rates can be as low as 15% in patients who have correctable causes, such as a perforated appendix, and who do not develop multiorgan failure before treatment, but mortality rates can be as high as 50% for postoperative peritonitis.

Peritoneal Carcinomatosis and Malignant Ascites

Less than 10% of cases of ascites are malignant. Peritoneal carcinomatosis results from the metastatic spread of intra-abdominal malignancy (Table 144-5), usually in the setting of endometrial, colonic, gastric, and pancreatic carcinoma. The manifestation is similar to ascites of other causes (Chapter 148), although the ascites typically occurs rather suddenly in the absence of known portal hypertension, tuberculosis, or right heart failure.

DIAGNOSIS

In the setting of new-onset ascites, diagnostic paracentesis should be performed. Aspirated fluid should be sent for cell count and differential, Gram stain and culture, and measurement of albumin with simultaneous serum albumin measurement. A serum minus ascites albumin value of less than 1.1 g/mL (Chapter 156) supports the diagnosis of malignant ascites but is also seen in pancreatitis, nephrotic syndrome, and peritoneal tuberculosis. In the setting of hepatic metastases, the serum-ascites albumin gradient may be greater than 1.1. Ascitic fluid cytology will identify malignant cells 50 to 60% of the time.

Abnormal ultrasound findings can confirm the presence of ascites, but CT is preferred to help identify the underlying cause (Fig. 144-8). Malignant ascites is frequently loculated, sometimes from previous surgically related adhesions.

TABLE 144-4 ANTIBIOTIC OPTIONS FOR INTRA-ABDOMINAL SECONDARY PERITONITIS

TREATMENT

Rx

Treatment of malignant ascites is symptomatic and quite challenging. In general, malignant ascites does not respond to diuretic therapy, except that patients with malignant ascites in the setting of hepatic metastases may respond to spironolactone. Therapeutic paracentesis in the setting of tense ascites improves symptoms, including shortness of breath and abdominal discomfort. Unfortunately, malignant ascites rapidly reaccumulates. The use of intracavitary radioisotopes or chemotherapy has been advocated in some cases for palliation with variable success.

PROGNOSIS

The development of malignant ascites is usually a poor prognostic indicator, with few patients surviving beyond 4 months. An exception is the better prognosis with malignant ascites from ovarian (Chapter 205) or breast cancer (Chapter 204).

Peritoneal Tuberculosis

In the United States, tuberculosis (Chapter 332) is relatively uncommon, although it is increasingly being identified in immigrants. Tuberculous ascites also occurs in cirrhosis and in patients with chronic renal disease who are maintained on peritoneal dialysis.

Peritoneal tuberculosis is accompanied by abdominal swelling, fever, anorexia, and weight loss. The diagnosis should be considered in the setting of refractory ascites. Analysis of ascitic fluid reveals an exudative ascites. The fluid protein is typically greater than 2.5 g/100 mL, with a serum-ascites gradient of less than 1.1 g/mL.

TREATMENT AND PROGNOSIS

Rx

Treatment involves conventional antituberculous therapy (Chapter 332). Prognosis is dependent on whether tuberculosis is systemic or restricted to the peritoneum. It is important to document clearance of the tuberculosis with repeat paracentesis.

Peritonitis Associated with Continuous Ambulatory Peritoneal Dialysis

Patients in whom peritonitis develops while undergoing continuous ambulatory peritoneal dialysis (Chapter 133) have abdominal pain and cloudy peritoneal fluid. Approximately 50% of patients have fever. Nausea and diarrhea may also occur. On physical examination, abdominal pain is usually present.

Diagnosis is based on the peritoneal fluid cell count and differential. Although Gram stain is rarely positive, any organisms that are seen are predictive of subsequent culture results. Peritoneal cultures are positive 90% of

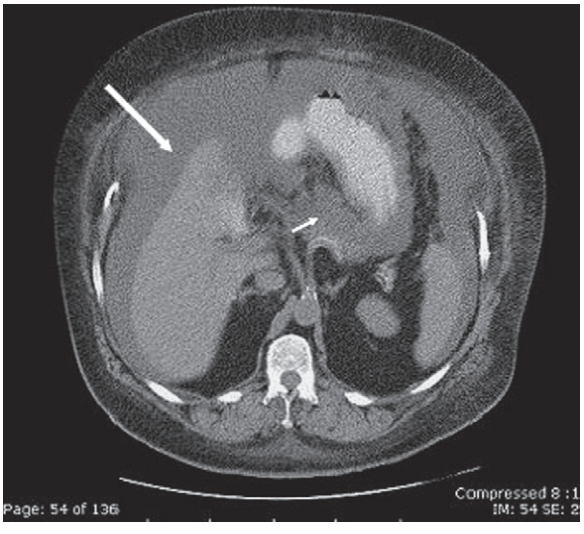

FIGURE 144-8. Malignant ascites. A computed tomography scan shows ascites *(large arrow)* and a gastric mass *(small arrow)*.

the time. Gram-positive organisms predominant, with coagulase-negative staphylococci and *Staphylococcus aureus* most commonly identified. Gram-negative organisms are present about 20% of the time, and 10% of patients have polymicrobial infections. Fungal peritonitis is infrequent and usually due to *Candida* species.

Antibiotic choices for empirical therapy include intraperitoneal cefazolin, cephalothin, and ceftazidime. Aminoglycosides should be used only when residual urine volume is less than 100 mL/day. Once culture results are available, antibiotics are adjusted according to the sensitivity of the organisms.

MISCELLANEOUS DISEASE OF THE MESENTERY AND OMENTUM

Mesenteric disorders are uncommon. Patients with mesenteric cysts complain of abdominal pain, fever, and emesis. Symptomatic cysts are treated surgically.

Mesenteric panniculitis refers to an inflammatory process of the adipose tissue of the mesentery. A variety of other terms are used, including lipodystrophy, sclerosing lipogranulomatosis, lipogranuloma of the mesentery, and mesenteritis. The disease is manifested as thickening or nodularity of the mesentery with fat necrosis. Mesenteric panniculitis is characterized by a variety of nonspecific abdominal symptoms, including fever, abdominal pain, anorexia, weight loss, and altered bowel habits. The diagnosis is made at laparoscopy. Laboratory studies are rarely helpful, although an elevated erythrocyte sedimentation rate may be seen. Surgical resection is required only when obstruction is present.

ANATOMIC AND MECHANICAL DISORDERS

Groin Hernias

In addition to hiatal hernias (Chapter 140), hernias may occur in the groin as inguinal or femoral hernias or as a result of weakness or abnormalities of other abdominal and pelvic muscles.

EPIDEMIOLOGY

About 3 to 4% of men have groin hernias, and the incidence increases with age. Indirect inguinal hernias, caused by a defect in the abdominal wall, account for about two thirds of hernias. Direct inguinal hernias, which protrude through an area bounded by the rectus abdominis muscle, the inferior upper gastric artery, and the inguinal ligament, account for about 30% of hernias in men and about 2% of hernias in women. Femoral hernias, which pass through an opening associated with the femoral artery and vein, represent about 30% of hernias in women and about 2% in men.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Groin hernias may be asymptomatic or be perceived as a mass that enlarges with standing or with increases in intra-abdominal pressure. If a hernia is not readily reducible (i.e., incarcerated), it may be associated with constant discomfort. With strangulation, ischemia or bowel obstruction may occur. The diagnosis is usually readily apparent by palpation of a soft groin mass that becomes larger with standing or with increases in intra-abdominal pressure.

TREATMENT Rx

Although femoral hernias should be repaired when first diagnosed because of the risk for strangulation, watchful waiting is an acceptable option for men with minimally symptomatic inguinal hernias.[1,1] Surgical options for both the initial operation and for recurrent hernias include laparoscopic repair and open mesh repair.[1,2,3]

Other Hernias

Incisional hernias develop after 1 to 4% of laparotomy incisions. These hernias may cause chronic abdominal discomfort, especially with maneuvers that increase intra-abdominal pressure. Repair is usually performed with prosthetic mesh.

Colonic Volvulus

Most cases of colonic volvulus involve the sigmoid colon (>90%), but volvulus can also involve the cecum and transverse colon. Elderly persons are at greatest risk. Volvulus results in colonic obstruction when the colon twists on its mesentery. Patients with volvulus frequently report a history of chronic constipation or laxative use or have previously been noted to have a dilated colon. A history of psychiatric illness or institutionalization is also associated with an increased risk for the development of volvulus.

CLINICAL MANIFESTATIONS

Symptoms of volvulus include the acute development of abdominal distention, nausea, and vomiting, with abdominal pain present initially in about one third of patients. Progressive or severe pain and tenderness suggest developing colonic ischemia and perforation. Much less commonly, patients have an intermittent history of obstructive symptoms and distention suggesting chronic volvulus.

DIAGNOSIS

The diagnosis of volvulus is made by abdominal radiographs, which show a dilated colon that may lack haustral folds and has a "bent inner tube" appearance, with the apex pointing to the right upper quadrant. Cecal volvulus is suspected radiographically when a dilated cecum is located in the epigastrium or left upper quadrant. Small bowel dilation may also be present. Water-soluble contrast enema will also confirm the presence and site of obstruction with the classic finding of a "bird's beak" configuration at the obstructed site.

TREATMENT Rx

Patients who have suspected colonic volvulus and who exhibit peritoneal signs or have complete obstruction on abdominal radiographs require fluid emergency exploratory laparotomy. In the absence of signs of complete obstruction or impending ischemia and when sigmoid volvulus is suspected, endoscopic sigmoidoscopic examination will document the site of obstruction and endoscopic reduction is the emergent treatment of choice for colonic decompression. Endoscopic procedures are generally avoided in patients with suspected cecal volvulus, however, and surgical resection is required emergently when endoscopic treatment is not appropriate or is unsuccessful or later after endoscopic treatment because of the risk of recurrence.

Intussusception

Intussusception results when a segment of intestine is drawn distally into another segment of intestine, thereby resulting in obstruction. Intussusception may occur in the small intestine itself, or the small intestine may intussuscept into the colon. Intussusception occurs most commonly in children, in whom it is seen in the setting of recent viral enteritis (e.g., rotavirus; Chapter 388), cystic fibrosis (Chapter 89), or Meckel's diverticulum. In adults, intussusception is more likely to occur in the setting of small bowel neoplasia (Chapter 199).

CLINICAL MANIFESTATIONS

Most patients have symptoms of partial small bowel obstruction—crampy abdominal pain, nausea, vomiting, and occasionally, diarrhea. An abdominal mass may be palpable on examination, and patients may have evidence of occult or overt gastrointestinal bleeding (the passage of "currant jelly" mucus-like stool is described in infants and children).

DIAGNOSIS AND MANAGEMENT

The diagnosis is most commonly confirmed by CT radiography, which classically shows a "target" lesion of the small bowel that represents the layers of the small bowel and intussuscepted segment. The finding of intussusception in an adult necessitates abdominal exploration and resection of the intussuscepted segment.

Adhesions

Peritoneal adhesions cause most cases of small bowel obstruction. Adhesions can result from previous laparotomy, with an increased risk for adhesions occurring in patients with intra-abdominal infections, ischemia, and foreign bodies. Symptomatic adhesive bowel obstruction will subsequently develop in 5 to 10% of patients undergoing laparotomy. Adhesive disease may also result in reduced fertility in females. After laparotomy, adhesive-related obstruction can occur at any time from the early postoperative period to many years later.

CLINICAL MANIFESTATIONS

Patients have crampy abdominal pain, nausea, vomiting, and increasing abdominal distention. In the setting of complete bowel obstruction, patients no longer pass stool or flatus.

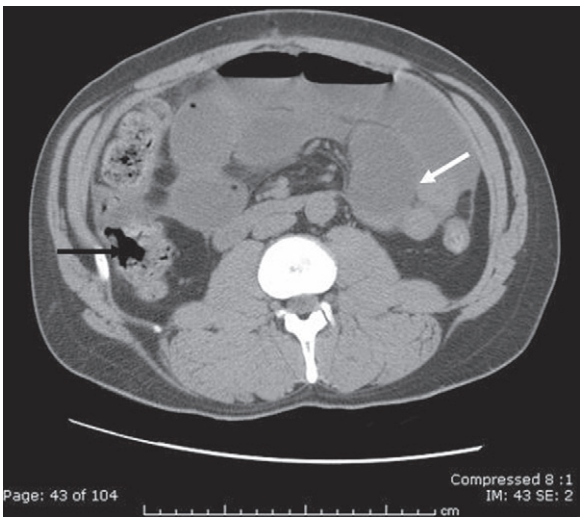

FIGURE 144-9. Adhesion-related small bowel obstruction. A computed tomography scan shows dilated, fluid-filled small bowel *(white arrow)* and a nondilated colon *(black arrow)*. At laparotomy, an obstruction secondary to adhesions was found in the midileum.

DIAGNOSIS AND TREATMENT

Rx

On an upright abdominal radiograph, findings of adhesive-related bowel obstruction include dilated loops of bowel (>6 cm of small bowel) and air-fluid levels, with reduced air distal to the obstruction. Similar findings are present on CT radiography (Fig. 144-9). Limitations of radiographic examination include subtle findings when the obstruction is very proximal in the bowel or the obstruction is only partial. In these settings, small bowel radiographs with water-soluble or barium contrast may be necessary to make the diagnosis.

Treatment of complete small bowel obstruction is fluid resuscitation and urgent laparotomy. Nasogastric tube decompression reduces nausea, vomiting, and distention. Nonoperative management may be tried in the setting of partial small bowel obstruction, with surgery reserved for patients whose obstruction fails to resolve. Patients with recurrent small bowel obstruction may benefit from a low-roughage diet to reduce the risk for obstruction from nondigestible food residue in a narrowed lumen.

The presence of chronic or recurrent abdominal pain in the absence of bowel obstruction has often been blamed on adhesions. Unless a clearly identified obstruction is present radiographically, surgical intervention for adhesiolysis is not warranted and does not reliably reduce abdominal pain symptoms. The search continues for intraoperative techniques or substances to reduce the development of adhesions.

VASCULAR DISEASES OF THE GASTROINTESTINAL TRACT

STEPHEN CRANE HAUSER

INTESTINAL ISCHEMIA

Intestinal ischemia can occur as a result of a variety of conditions that decrease intestinal blood flow. Both diminished arterial blood flow to the gut and compromised venous circulation from the intestine can cause intestinal or mesenteric ischemia. Several conditions, such as adhesions and malignancy (Chapter 199), may predispose to mesenteric ischemia by secondarily diminishing blood flow through extrinsic compression of otherwise normal intestinal arteries or veins (Table 145-1). These disorders and esophageal varices (Chapters 137 and 156) are discussed elsewhere.

EPIDEMIOLOGY

Intestinal ischemia is responsible for about 1 per 1000 hospital admissions. When considering the diagnosis of intestinal ischemia, it is important to distinguish *primary* (occlusive or nonocclusive) from *secondary* (extrinsic to the blood vessel) mesenteric ischemia, *acute* manifestations from *chronic, arterial* versus *venous,* and *small bowel* versus *colonic* ischemia. Risk factors for intestinal ischemia include older age (all the disorders discussed) and conditions that predispose to arterial embolism (e.g., cardiac arrhythmias, heart failure, cardiomegaly, dyskinesia, valvular heart disease, recent myocardial infarction, cardiac catheterization, intracardiac thrombus, atheromatous cholesterol embolism), occlusion of arteries (atherosclerosis, fibromuscular dysplasia, abdominal aortic aneurysm, trauma, vasculitis), low-flow states (sepsis, dialysis, reduced cardiac output, vasoconstrictive drugs), and pathologic thromboses (largely venous; hypercoagulable and hyperviscosity states, trauma, malignancy, inflammation).

PATHOBIOLOGY

Arterial or venous disease of the esophagus, stomach, duodenum, and rectum is very unusual for anatomic reasons. The esophagus receives its main blood supply segmentally through multiple small vessels from the aorta, right intercostal artery, bronchial arteries, inferior thyroid artery, left gastric artery, short gastric artery, and left phrenic artery. Likewise, the stomach, duodenum, and rectum have numerous arterial inputs with rich collateralization. Patients who have undergone extensive surgical resection of the esophagus, stomach, or duodenum are at increased risk for ischemia. Vasculitic disorders, which can involve small or large arteries or veins, may affect the esophagus, stomach, duodenum, or rectum.

The arterial supply of blood to the small and large intestine is from the *celiac artery, superior mesenteric artery* (SMA), and *inferior mesenteric artery* (IMA). Collateral vessels, which vary from person to person, may include the meandering mesenteric artery or arc of Riolan at the base of the mesentery (connecting the SMA and IMA), the marginal artery of Drummond along the mesenteric border (connecting the SMA and IMA), the pancreaticoduodenal arcade (connecting the celiac artery and SMA), the arc of Barkow (connecting the celiac artery and SMA), and the arc of Buhler (connecting the celiac artery and SMA). These collaterals can rapidly enlarge in response to localized mesenteric ischemia. During states of low arterial flow, such as in patients with low systemic arterial blood pressure, "watershed" areas such as the splenic flexure, which is farthest away from arterial flow, are more likely to be involved. In contrast, when a major arterial vessel such as the IMA is suddenly occluded, the splenic flexure is less likely to be involved because of collaterals from the SMA circulation.

Intestinal blood flow, which accounts for approximately 10% of cardiac output, increases to as much as 25% of cardiac output after eating a meal. Blood flow to the intestine is regulated by the sympathetic nervous system and a variety of systemic (angiotensin II, vasopressin) and local (prostaglandins, leukotrienes) humoral factors.

Mesenteric ischemia can occur as a result of decreased *arterial* blood flow, which can be *occlusive* (arterial embolus, arterial thrombus, and vasculitis) or *nonocclusive* (low-flow states). *Venous* obstruction (thrombosis, vasculitis) can also result in mesenteric ischemia.

Whatever the cause of mesenteric ischemia, the gut is able to adapt to as much as a 75% reduction in normal blood flow for as long as 12 hours. Increased flow through available and newly opened collateral vessels and increased oxygen extraction help compensate. However, with a more prolonged and more severe reduction in blood flow, generalized mesenteric arterial vasoconstriction often develops and can become irreversible, even with correction of the original underlying condition (i.e., relief of focal arterial obstruction or resolution of a low-flow state). Hypoxia and reperfusion injury by oxygen radicals, reduced endothelial synthesis of nitric oxide, and an enhanced cellular inflammatory response cause microvascular and end-organ damage. Initially, the end-organ damage is primarily mucosal, but damage can rapidly progress to transmural necrosis (gangrene). Some ischemic segments of bowel will heal with fibrosis (strictures).

CLINICAL MANIFESTATIONS

Symptoms of intestinal ischemia at initial evaluation may be acute (sudden, lasting hours), subacute (days), or chronic (intermittent, occurring over a period of weeks to months). With acute and many subacute manifestations, abdominal pain is often the cardinal symptom. Usually the pain is severe, persistent, and poorly localized. Initially, the pain is typically more severe than the findings on abdominal palpation (i.e., pain out of proportion to tenderness). With or without pain, other initial features may include fever, altered mental status, abdominal distention, difficulty eating, nausea, vomiting, and diarrhea. With small bowel ischemia, overt gastrointestinal bleeding (Chapter 137) is a late and ominous finding that often suggests small bowel infarction.

Findings on physical examination can include hypotension, tachycardia, abdominal distention, initially increased and later decreased bowel sounds, and nonspecific diffuse abdominal tenderness, often mild at first. Over time, peritoneal signs with localized to generalized abdominal tenderness, rebound, and rigidity may become manifest. Occult gastrointestinal bleeding can be an early finding.

DIAGNOSIS

Even as the diagnostic evaluation is begun, appropriate attention must be directed to emergency therapy, including fluid resuscitation, antibiotics, and invasive therapy (Fig. 145-1).

Initial Diagnostic Evaluation

The initial laboratory findings in patients with an acute onset of bowel ischemia can be entirely normal. Nonspecific abnormalities such as leukocytosis with a predominance of neutrophils and hemoconcentration may be observed. Elevated serum levels of amylase, lactate, aminotransferases, lactate dehydrogenase, creatine kinase, and phosphate often portend more advanced (necrotic) small bowel ischemia, but these findings lack sensitivity as well as specificity.

Noninvasive Imaging

The presence or absence of radiographic features suggestive of ischemia in patients with acute-onset mesenteric ischemia varies and depends on the duration and extent of ischemia. Plain abdominal radiographs are useful in helping exclude secondary causes of mesenteric ischemia, as well as other causes of acute abdominal pain, nausea, vomiting, or distention, such as obstruction and perforation. Radiographic findings such as "thumbprinting" (caused by submucosal hemorrhage), an ileus pattern, or formless loops of small bowel, or with more advanced disease, pneumatosis intestinalis or portal venous gas (often a sign of transmural necrosis or gangrene) may on occasion be seen. Contrast-enhanced abdominal-pelvic computed tomography (CT) is also helpful to exclude alternative diagnoses. CT may demonstrate entirely normal findings in acute mesenteric ischemia, or findings such as segmental bowel wall thickening, submucosal hemorrhage, mesenteric stranding, mesenteric venous thrombosis, pneumatosis, and portal venous gas may be present (Fig. 145-2). Multidetector CT angiography (MDCTA) has a greater sensitivity and specificity (each up to 95%) than traditional CT (about 65%). Magnetic resonance angiography (MRA) is less sensitive for more peripheral emboli. Subacute manifestations of bowel ischemia may be due to a wide variety of causes, including mesenteric venous thrombosis, which is best diagnosed by CT scan. However, the time needed to obtain a CT scan should not delay resuscitation or arteriography in very ill patients with suspected acute-onset ischemia.

TREATMENT

Rx

Acutely ill patients require prompt, definitive diagnosis and treatment, which often requires selective mesenteric angiography (Fig. 145-3). If transmural intestinal necrosis (gangrene) is suspected from peritoneal signs, pneumatosis, or portal venous gas on imaging procedures, emergency laparotomy is indicated. The presence of predisposing conditions (e.g., arrhythmias, systemic hypotension) and their extraintestinal manifestations (e.g., heart failure, sepsis, respiratory insufficiency, acute renal failure, anemia) dictate the initial therapy: volume replacement, optimization of cardiac output, management of respiratory function, avoidance of splanchnic vasoconstrictors such as digoxin, and administration of broad-spectrum antibiotics (e.g., meropenem, imipenem/cilastatin, metronidazole and a third-generation cephalosporin, ciprofloxacin and metronidazole, or piperacillin until symptoms resolve to cover aerobic gram-negative and anaerobic organisms and to prevent sepsis secondary to translocation of bacteria across ischemic gut mucosa.

PROGNOSIS

Acute primary arterial mesenteric ischemia involving the small bowel is an urgent condition, which, if unidentified or untreated, can result in death within hours. Mortality rates may be as high as 70% but are much lower with early diagnosis and prompt therapy. Overall, colonic ischemia has a much better prognosis than does small bowel ischemia. Mesenteric venous thrombosis also has a much better prognosis than acute primary arterial mesenteric ischemia of the small intestine.

Specific Ischemic Bowel Syndromes

SUPERIOR MESENTERIC EMBOLISM

Embolization to the intestine through the SMA *(SMA embolus)* accounts for 5% of peripheral emboli and nearly 50% of cases of primary noncolonic mesenteric ischemia. Emboli originate most commonly from the heart, with an aortic origin being less common (Table 145-2), and tend to obstruct beyond the origin of the SMA.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients who are evaluated early in the course of their illness may have entirely normal CT scans, or the CT findings may be consistent with mesenteric

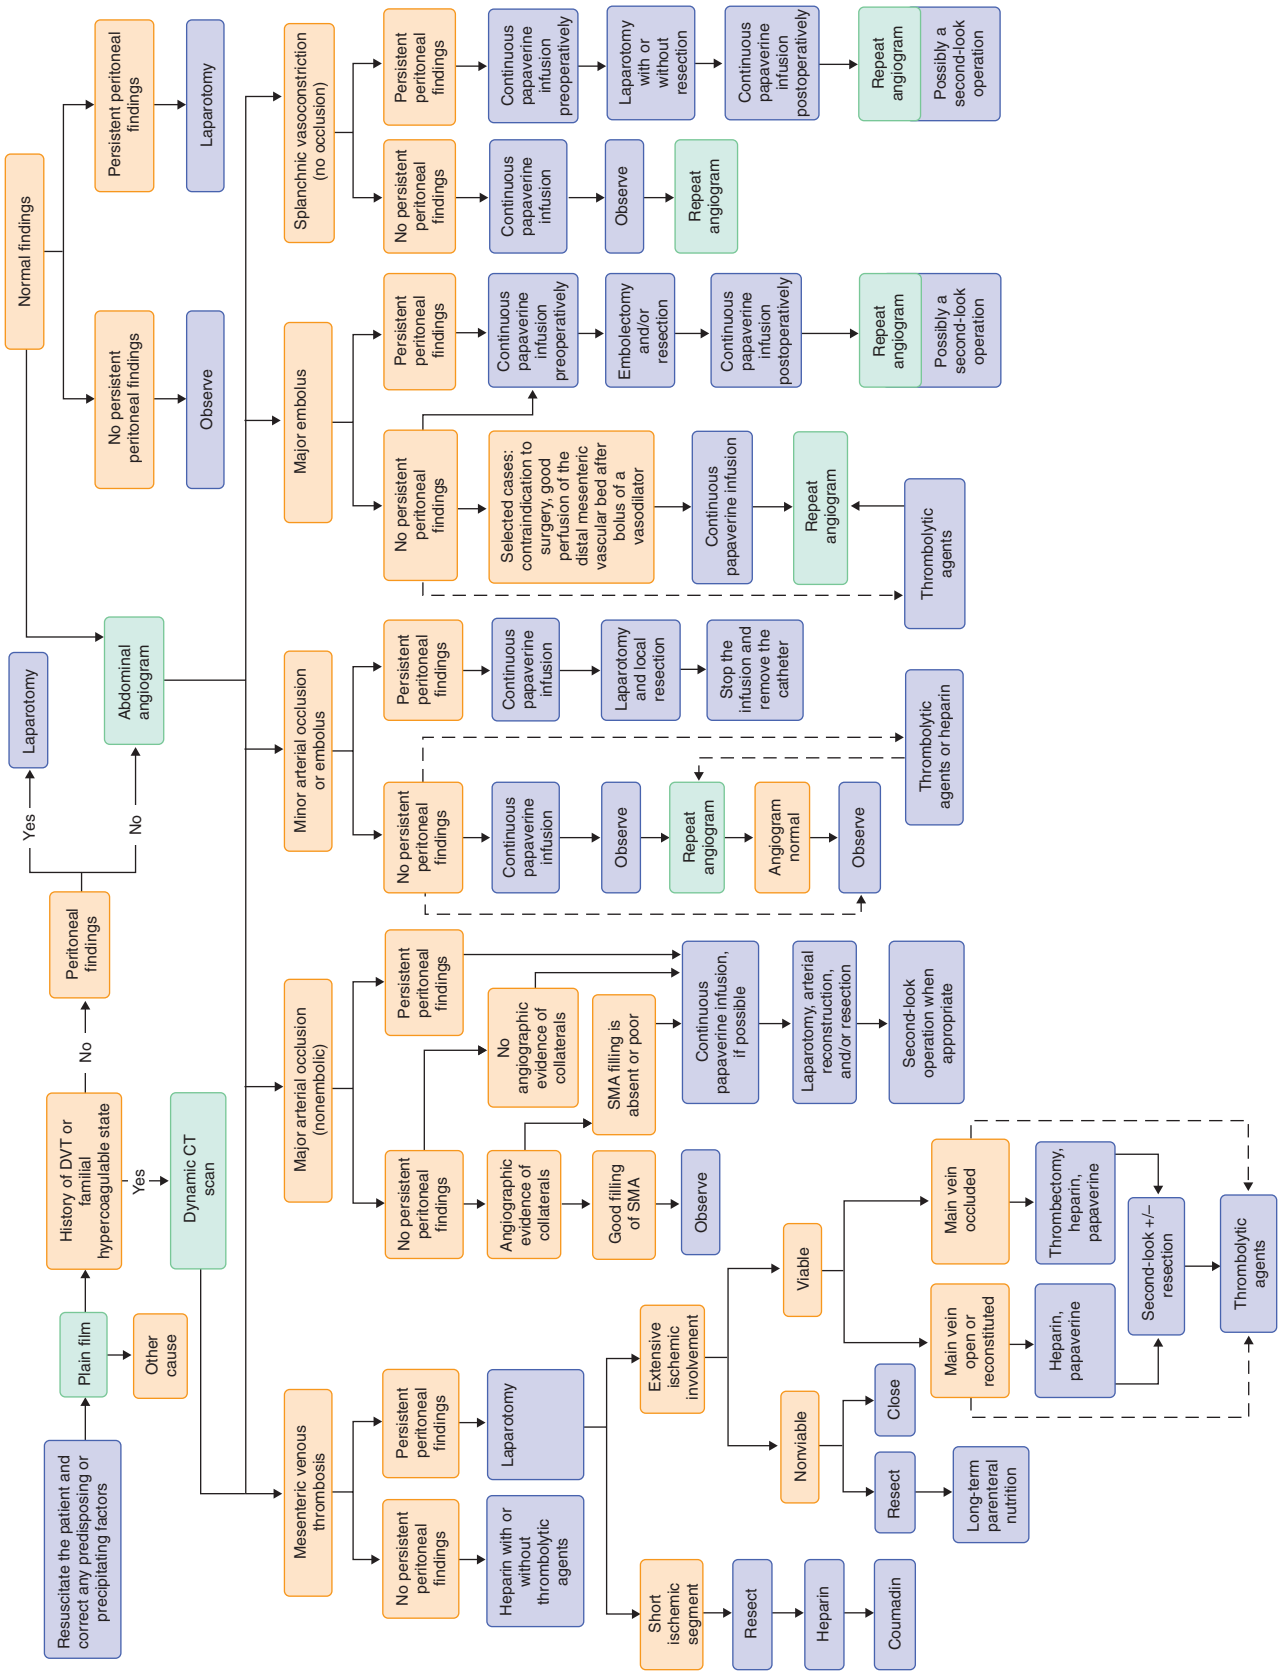

FIGURE 145-1. Algorithm for managing patients with suspected acute mesenteric ischemia: diagnosis and management. *Solid lines* indicate an accepted management plan; *dashed lines* indicate an alternative management plan. CT = computed tomography; DVT = deep venous thrombosis; SMA = superior mesenteric artery. (From American Gastroenterological Association Medical Position Statement: guidelines on intestinal ischemia. *Gastroenterology*. 2000;118:951-953 [corrected algorithm in *Gastroenterology*. 2000;119:2811].)

ischemia without features that would suggest alternative diagnoses (e.g., perforation, obstruction). MDCTA is much more likely than standard CT to diagnose embolic disease reliably in the mesenteric arterial vasculature. Selective mesenteric angiography offers the possibility of therapy as well as diagnosis.

TREATMENT Rx

Select patients with acute onset of a partial or small SMA branch occlusion may be candidates for thrombolytic therapy (e.g., streptokinase, urokinase, tissue plasminogen activator) infused through an arterial catheter directly into the vicinity of the embolus; this therapy can lyse the embolus and resolve symptoms such as abdominal pain. Because segmental arterial embolic occlusion of a small portion of the SMA vascular bed results in widespread splanchnic visceral arterial vasoconstriction, which may persist even after the original inciting event (i.e., an embolus) is rectified, infusion of a vasodilator such as papaverine (often given as a 60-mg bolus, followed by a continuous infusion of 30 to 60 mg/hour for 12 to 48 hours) through an arterial catheter reverses this reflex vasoconstriction and improves the outcome, including mortality rates. The same scenario occurs with other arterial occlusive lesions (SMA thrombi), arterial nonocclusive disease (nonocclusive mesenteric ischemia), and disorders associated with mesenteric venous occlusion.

Patients evaluated in the course of their acute embolic illness with peritoneal signs require laparotomy, with or without resection and with or without embolectomy, which is usually performed during surgical exploration. A "second-look" operation 24 hours after embolectomy to make sure that all necrotic tissue has been resected may be necessary.

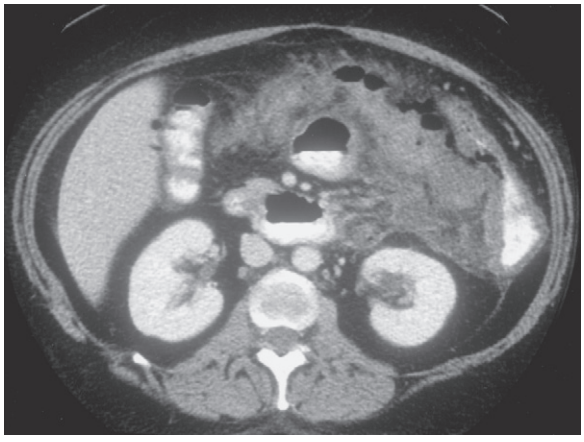

FIGURE 145-2. Computed tomography of the abdomen in a patient with ischemic colitis as a result of superior mesenteric vein thrombosis. A segmental area of the transverse colon demonstrates a thick wall, as well as considerable fluid and soft tissue stranding in the adjacent mesentery. (From Johnson CL, Schmit GD, eds. *Mayo Clinic Gastrointestinal Imaging Review*. Boca Raton, Fla: Mayo Clinic Scientific Press, Taylor and Francis Group; 2005. By permission of the Mayo Foundation for Medical Education and Research. All rights reserved).

Any patient in whom SMA embolization is diagnosed requires preoperative systemic anticoagulation (e.g., intravenous heparin) to prevent propagation of clot around the embolus and to guard against further embolization to the intestine or other organs (i.e., brain, coronary arteries, kidneys, extremities). Anticoagulation is usually discontinued before surgery and is often resumed 24 to 48 hours postoperatively, depending on the operative findings. Mortality can be as high as 70%.

SUPERIOR MESENTERIC THROMBOSIS

Thrombosis of the SMA *(SMA thrombus)* accounts for nearly 15% of cases of primary noncolonic mesenteric ischemia. Risk factors include older age, atherosclerosis (e.g., hypertension, diabetes mellitus, hyperlipidemia, smoking history), low-flow states, hypercoagulable states, and less often, vasculitis and aortic or mesenteric aneurysms.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nearly one third of these patients have a history of symptomatic chronic mesenteric ischemia (see later) antedating their acute manifestation of SMA thrombosis. Proximal mesenteric arterial occlusions are well recognized by MDCTA, MRA, and Doppler ultrasound, but similar abnormalities are common in asymptomatic elderly persons. Similar to acute SMA embolism, the diagnosis is confirmed by selective mesenteric angiography, with intra-arterial infusion of a vasodilator used to reverse reflex-generalized vasoconstriction.

TREATMENT Rx

Although thrombolytic therapy has been helpful in a limited number of case reports, surgical thrombectomy or bypass grafting, with or without bowel resection, is the most common therapeutic approach. Because many thrombi occur near the SMA origin, angioplasty may be therapeutic in very select cases, but the risk for reocclusion is high. Similar to acute SMA embolism, anticoagulation (intravenous heparin) is important preoperatively and at some point postoperatively in the acute state, as is administration of broad-spectrum antibiotics (see earlier).

TABLE 145-2 CONDITIONS ASSOCIATED WITH EMBOLIZATION TO THE GASTROINTESTINAL TRACT

Cardiac arrhythmias
Valvular heart disease
Heart failure

Intracardiac thrombus
Cardiac catheterization
Cardioversion
Atherosclerosis of the aorta

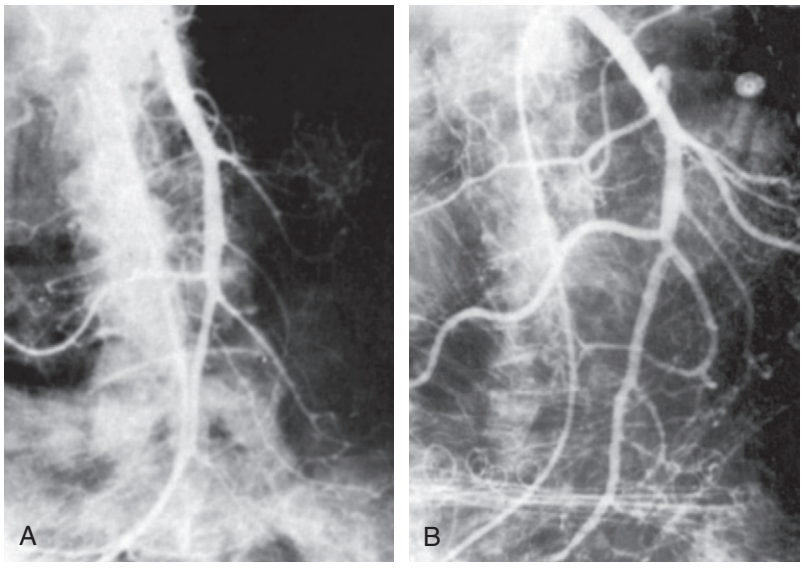

FIGURE 145-3. Selected films from superior mesenteric angiography. **A,** Diffuse vasoconstriction characteristic of nonocclusive mesenteric ischemia. **B,** Intra-arterial infusion of papaverine (30 to 60 mg/hour) resulted in vasodilation.

ACUTE NONOCCLUSIVE, NONCOLONIC PRIMARY ARTERIAL ISCHEMIA

Nonocclusive mesenteric ischemia, which accounts for about 20% of primary noncolonic mesenteric ischemia cases, is caused by low arterial blood flow to the intestine. Risk factors include advanced age, decreased systolic blood pressure (e.g., cardiac arrhythmia, heart failure, myocardial infarction, shock, sepsis, burns, pancreatitis, hemorrhage, multiple organ failure, dialysis, perioperative states), vasospasm (e.g., digoxin, vasopressin, amphetamines, cocaine), and atherosclerotic disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical findings are generally indistinguishable from those of embolic or thrombotic vascular disease, except that symptoms may be less acute. As a result, patients initially may be seen without acute abdominal pain but rather with more nonspecific symptoms such as distention, nausea, fever, altered mental status, and borderline or low systolic blood pressure. Selected mesenteric angiography establishes the diagnosis (lack of embolus or thrombus, alternating areas of vessel spasm and dilation, vascular pruning and spasm).

TREATMENT

Rx

The best specific treatment is prolonged intra-arterial instillation of a vasodilator (e.g., papaverine, often given as a 60-mg bolus, followed by a continuous infusion of 30 to 60 mg/hour) to reverse the vasospasm. Avoidance of vasospastic medications and optimization of cardiac output, blood volume, and blood pressure are crucial. Anticoagulation is generally not necessary, but broad-spectrum antibiotics (similar to those recommended earlier) should be administered to cover aerobic gram-negative and anaerobic organisms. Although many of these patients have serious conditions that predispose them to low-flow states and their ultimate prognosis is dependent on the outcomes of these serious conditions, diagnosis and treatment of acute nonocclusive mesenteric ischemia with therapeutic angiography can be life-saving.

MESENTERIC VENOUS THROMBOSIS

Occlusive disease of the mesenteric venous circulation *(mesenteric venous thrombosis)* usually involves the superior mesenteric vein (SMV) and may be accompanied by symptoms that are acute (hours to days) or subacute (weeks to months) in onset.

EPIDEMIOLOGY AND PATHOBIOLOGY

Thrombosis of the SMV accounts for about 10% of cases of primary noncolonic mesenteric ischemia. Colonic involvement with ischemic colitis is much less common. In contrast to arterial occlusive disease, risk factors and causes for SMV thrombosis are more numerous and diverse. Individuals with a personal or family history of a hypercoagulable state or deep venous thrombosis are at increased risk for SMV thrombosis. Hypercoagulable states, hyperviscosity syndromes, portal hypertension, intra-abdominal infections (e.g., pyelophlebitis, diverticulitis, appendicitis) or inflammation (e.g., Crohn's disease, pancreatitis), malignancy, vasculitis, and trauma may all cause thrombosis of the SMV (Table 145-3).

CLINICAL MANIFESTATIONS

Symptoms in acute-onset cases are similar to those observed in acute occlusive and nonocclusive arterial mesenteric ischemia—abdominal pain, anorexia, nausea, vomiting, abdominal fullness, diarrhea, and constipation—but tend to persist over a longer time period. Some patients may have bacteremia, especially infection with *Bacteroides.* Gastrointestinal hemorrhage, if present, is often indicative of infarction. However, many patients with SMV thrombosis experience more vague symptomatic abdominal pain, nausea, distention, or diarrhea over a period of weeks to months (subacute).

DIAGNOSIS

Abdominal-pelvic contrast-enhanced CT, which is the preferred diagnostic test, usually (>90% sensitivity) demonstrates SMV thrombosis with or without portal vein or splenic vein thrombosis. By definition, chronic mesenteric venous thrombosis is asymptomatic and usually detected as an incidental CT finding in patients with portal hypertension, pancreatitis (acute or chronic), or malignancy. The presence of abundant collateral vessels suggests chronic or sometimes subacute mesenteric venous obstruction.

TABLE 145-3 RISK FACTORS FOR MESENTERIC VENOUS THROMBOSIS

Hypercoagulable and hyperviscosity states
Protein S deficiency
Protein C deficiency
Antithrombin III deficiency
Factor V Leiden mutation
Hyperfibrinogenemia
Antiphospholipid syndrome
Primary myeloproliferative syndrome
Sickle cell disease
Estrogen or progesterone
Intra-abdominal infections and inflammation
Appendicitis
Diverticulitis
Crohn's disease
Abscess
Pancreatitis
Cholecystitis
Pyelophlebitis
Neonatal omphalitis
Portal hypertension
Variceal sclerotherapy
Malignancy
Trauma
Vasculitis

Small bowel radiography may demonstrate segmental bowel wall thickening and separation of bowel loops. Selective mesenteric angiography is not generally necessary.

TREATMENT

Rx

Therapy for acute-onset cases may include laparotomy with or without bowel resection when infarction is suspected, fluid resuscitation, broad-spectrum antibiotics (similar to those recommended earlier to cover aerobic gram-negative and anaerobic organisms), avoidance of vasoconstrictors, and anticoagulation (e.g., intravenous heparin) in the absence of gastrointestinal bleeding. Selected patients may be candidates for thrombolytic therapy (e.g., streptokinase, urokinase, tissue plasminogen activator), followed by anticoagulation. Underlying conditions such as hypercoagulable states, portal hypertension, intra-abdominal infections, intra-abdominal inflammation, and malignancy require concomitant diagnosis and therapy. The indications for anticoagulation in the chronic setting are uncertain, and it is generally avoided in patients who have portal hypertension but do not have symptoms related to their mesenteric venous thrombosis.

CHRONIC MESENTERIC ISCHEMIA

Chronic atherosclerotic stenosis of the visceral arteries is the cause of most cases of chronic mesenteric ischemia, sometimes called *intestinal angina.*

EPIDEMIOLOGY AND PATHOBIOLOGY

Risk factors for chronic mesenteric ischemia are principally older age and the risk factors for atherosclerosis. Rarely, vasculitis or an aortic aneurysm can be manifested as chronic mesenteric ischemia. Atherosclerotic stenoses usually involve the origins of two or all of the three major visceral arteries supplying the intestine. However, many age-matched patients also harbor atherosclerotic lesions and do not have symptoms of chronic mesenteric ischemia.

CLINICAL MANIFESTATIONS

Patients typically complain of episodic ischemic abdominal pain. The pain is usually upper or midabdominal, typically begins 15 to 30 minutes after a meal, lasts 1 to 3 hours, and progresses in severity over time, as well as occurs after smaller meals and more frequently after meals. Patients may lose weight as a result of fear of eating (sitophobia). Nausea, vomiting, bloating, diarrhea, and constipation can also occur. Malabsorption with steatorrhea, otherwise unexplained gastroduodenal ulcerations, and small bowel biopsy findings of villous atrophy, nonspecific surface cell flattening, and chronic inflammation may be seen in some patients. More than one half of patients have a bruit on

abdominal examination. In some patients with episodic symptoms, acute thrombotic mesenteric ischemia develops suddenly.

DIAGNOSIS AND TREATMENT Rx

Atherosclerotic lesions usually can be identified by Doppler ultrasound because they are proximal in these vessels and demonstrate increased flow velocity through areas of marked stenosis. MDCTA and MRA are also useful to screen for arterial stenoses consistent with chronic mesenteric ischemia in symptomatic patients, but neither technique is adequately sensitive to exclude the diagnosis of chronic mesenteric ischemia when the pretest probability is high. Thus, selective mesenteric angiography is important to ensure that the anatomic findings are consistent with the diagnosis. Patients must be evaluated thoroughly to exclude other causes of abdominal pain (i.e., gastric cancer, gastroparesis, gastric volvulus, partial small bowel obstruction, small bowel bacterial overgrowth states, pancreatic cancer, biliary disease, paraesophageal hernias). For symptomatic patients with appropriate findings on angiography and no other causes of symptoms, surgical reconstruction provides better long-term outcomes than angioplasty and stenting.

ISCHEMIC COLITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Ischemic colitis, which is the single most common cause of mesenteric ischemia, accounts for nearly 50% of all cases and for almost 1 in 2000 hospital admissions. Many cases are acute and self-limited and occur in persons older than 60 years without any apparent cause; these cases are probably due to transient nonocclusive hypoperfusion involving a segment of the colon. It is controversial whether subtle hypercoagulable states contribute to the pathogenesis of idiopathic cases. Atherosclerotic or thrombotic occlusion of the IMA or its branches and low-flow states are recognizable causes of ischemic colitis. Less common causes include hypercoagulable states (especially in younger persons), iatrogenic ligation of the IMA (e.g., with aortic surgery), embolism, vasculitis, and any cause of colonic obstruction, including malignancy, stricture, and fecalith, that can produce localized compression of the vasculature with an upstream segment of ischemia. Other unusual associations include long-distance running (dehydration, mechanical trauma to the vasculature, generally involving the cecum), pit viper bite, scuba diving, and intra-abdominal infections or inflammatory disease. A variety of medications, illicit drugs, and chemicals also can result in a chemical picture identical or similar to ischemic colitis (Table 145-4), sometimes probably secondary to vasoconstriction that can affect other parts of the gastrointestinal tract, liver, and other organ systems (e.g., cocaine, amphetamines, pseudoephedrine), sometimes due to constipation (e.g., alosetron), sometimes due to a hypercoagulable effect (e.g., estrogens), and sometimes as a result of a chemical effect (e.g., sodium polystyrene with sorbitol enemas).

CLINICAL MANIFESTATIONS

The clinical presentation of ischemic colitis is acute and, in most patients, includes abdominal pain (mostly left lower quadrant), often with urgency, diarrhea, and passage of bright red blood per rectum. Anorexia, nausea, vomiting, abdominal distention, and passage of maroon material per rectum may also occur. Although the blood loss is not usually enough to require transfusion, some patients may be orthostatic because of loss of blood and fluid. Fever, tachycardia, abdominal tenderness over the affected portion of the colon, and distention may be found on physical examination.

TABLE 145-4 MEDICATIONS AND DRUGS ASSOCIATED WITH ISCHEMIC COLITIS

Alosetron
Psychotropics
Nonsteroidal anti-inflammatory drugs
Various enemas
Tegaserod
Interferon/ribavirin

DIAGNOSIS

Laboratory findings range from normal to nonspecific findings such as leukocytosis and hemoconcentration to those observed in persons with bowel necrosis (see earlier). Evaluation of patients younger than 50 years should include tests for thrombophilic disorders (Chapter 179).

Plain radiographs of the abdomen may reveal "thumbprinting" or may be normal. Similar to small bowel ischemia, CT scanning can be useful to help exclude other disorders, especially in more symptomatic and ill patients; the findings may be consistent with segmental colonic edema and inflammation, with or without adjacent pericolonic inflammatory stranding. These radiographic features are consistent with ischemic colitis in an appropriate clinical setting but are nonspecific and may be seen in patients with other disorders such as acute diverticulitis (Chapter 144), infectious colitis (Chapter 142), and inflammatory bowel disease (Chapter 143). The diagnosis is best made by colonoscopy, which should provide endoscopic and histologic findings consistent with acute ischemic colitis: segmental patchy ulceration, edema, erythema, single stripe sign, and submucosal bluish purple hemorrhagic nodules (Fig. 145-4).

Typically, visceral angiography is not required because most patients with ischemic colitis have self-limited involvement of the left colon or distal transverse colon–splenic flexure with sparing of the rectum, and findings on urgent angiography in these patients are usually normal. However, about 10% of patients with acute ischemic colitis have predominantly right-sided involvement of the cecum, ascending colon, hepatic flexure, and proximal transverse colon. Because the arterial supply to the right colon is through the ileocolic branch of the SMA, there may be concomitant distal ileal ischemia, often owing to low-flow states (especially hemodialysis patients) or embolization. These patients have more pain, less bleeding, and a much worse outcome and are at risk for small bowel necrosis.

Differential Diagnosis

Gastrointestinal infections, such as with *Escherichia coli* O157:H7, *Clostridium difficile, Klebsiella oxytoca*, and cytomegalovirus, can mimic ischemic colitis clinically and even histologically. Acute-onset inflammatory bowel disease involving the colon can also be difficult to distinguish from ischemic colitis. However, patients with subacute or chronic pain, diarrhea, obstructive symptoms, weight loss, or bleeding may be thought to have complicated

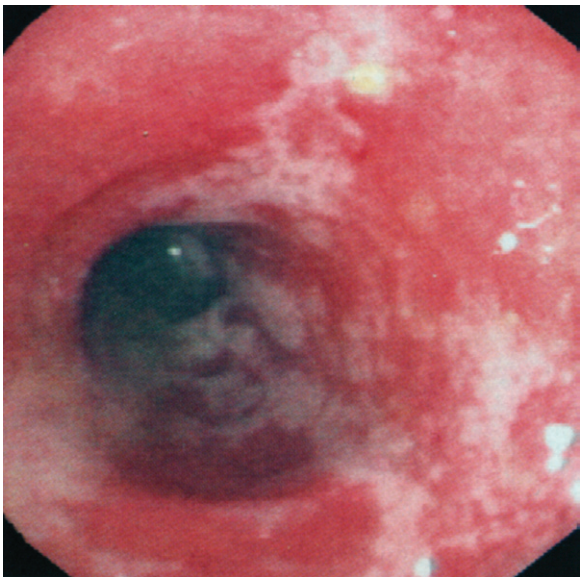

FIGURE 145-4. Endoscopy of the splenic flexure of the colon in a patient with ischemic colitis. Note the shallow, irregular, exudative ulceration with interspersed erythema. (From Emory TS, Carpenter HA, Gostout CJ, et al, eds. *Atlas of Gastrointestinal Endoscopy and Endoscopic Biopsies*. Washington, DC: Armed Forces Institute of Pathology, American Registry of Pathology; 2000.)

diverticular disease, Crohn's disease, or malignancy with stricture, and chronic ischemic stricture of the colon may not be correctly diagnosed until after surgery is performed.

Stool culture can exclude infection, especially with *E. coli* O157:H7, *C. difficile,* and parasites. In immunocompromised patients, colonic biopsy can be performed to diagnose cytomegalovirus infection.

TREATMENT Rx

Patients with right-sided ischemic colitis require visceral angiography not only for diagnosis but also for intra-arterial administration of vasodilators (e.g., papaverine as a 60-mg intravenous bolus followed by an infusion of 30 to 60 mg/hour). Some patients may require urgent surgery. The clinical course in patients with right-sided ischemic colitis may be subacute, with a mortality rate as high as 50% or greater.

By contrast, left-sided acute ischemic colitis, which accounts for most cases, tends to resolve within hours to a few days with supportive therapy, including volume replacement, correction of any low-flow state, broad-spectrum antibiotics (similar to those recommended earlier for patients with small bowel ischemia), avoidance of vasoconstrictive medications, and rarely, blood transfusion; surgery is required only in patients with signs and symptoms of transmural necrosis, perforation, or massive bleeding. Occasional patients with acute-onset left-sided ischemic colitis have persistent or recurrent symptoms of pain, diarrhea, bleeding, sepsis, or stricture formation that develop over a period of weeks to months and may require segmental surgical resection.

VASCULITIS

Many vasculitic syndromes can involve the gastrointestinal tract. Usually, but not always, other organ systems are also involved.

Large and Medium Vessel Vasculitis

Takayasu's arteritis (Chapters 78 and 278) and *giant cell arteritis* (Chapter 279), which affect large to medium-sized muscular arteries, rarely involve the gastrointestinal tract. Takayasu's arteritis has been associated rarely with inflammatory bowel disease.

Medium to Small Vessel Vasculitis

Polyarteritis nodosa (Chapter 278) is characterized by segmental microaneurysms typically involving small and medium-sized arteries. The small bowel is involved more commonly than the large bowel. Many patients will have abdominal pain, fever, hypertension, and multiple organ involvement. Gastrointestinal bleeding or perforation will develop in some patients. The gallbladder, spleen, pancreas, and liver may also be involved. Nearly half of patients with polyarteritis nodosa are infected with hepatitis B virus.

Both *Wegener's granulomatosis* (Chapter 278) and *Churg-Strauss syndrome* (Chapter 278) affect small and medium-sized arteries. Although gastrointestinal involvement is not common in Wegener's granulomatosis with granulomatous inflammation, in up to one third of patients with Churg-Strauss syndrome, abdominal pain or gastrointestinal bleeding may develop as a result of ischemia. Mesenteric venous involvement can also occur with Churg-Strauss syndrome.

Thromboangiitis obliterans (Buerger's disease; Chapter 80) involves small and medium-sized arteries and can cause multiple distal occlusions of the mesenteric arterial circulation. Patients with *Behçet's disease* (Chapter 278) often have lymphocytic inflammation of small and medium-sized arteries, as well as veins. Like Crohn's disease, the ileocecal region is frequently involved with ulceration. Abdominal pain, diarrhea, gastrointestinal bleeding, and perforation may occur.

Small Vessel Vasculitis

Small vessel involvement with immunoglobulin A immune complex deposition in blood vessel walls is typical in *Henoch-Schönlein purpura* (Chapter 278). These patients usually have palpable purpura, arthritis, and abdominal pain, as well as gastrointestinal bleeding. *Hypersensitivity vasculitis* (Chapter 278), which affects small arterioles, venules, and capillaries, is related to a variety of drugs, infections, and chemicals; on occasion there may be gastrointestinal involvement. *Cryoglobulinemia* (Chapter 193) with immune complex involvement of small blood vessels can sometimes involve the gastrointestinal tract. These patients are often infected with hepatitis C virus.

HEMORRHAGIC VASCULAR DISORDERS

Angiodysplasia

DEFINITION AND EPIDEMIOLOGY

Angiodysplasia or vascular ectasia is a thin-walled, dilated, punctate red vascular structure in the mucosa or submucosa of the bowel; it typically involves adjacent venules, capillaries, and arterioles. Angiodysplasia is found in the colon, especially the right colon, in up to 1% of persons and is found also in the stomach and small bowel but rarely in the esophagus. Angiodysplastic lesions may be single or multiple, and they increase in frequency with age. Some data suggest associations with chronic renal failure (Chapter 132), von Willebrand's disease (Chapter 176), and aortic stenosis (Chapter 75); whether correction of these associated disorders diminishes future gastrointestinal hemorrhage (Chapter 137) from angiodysplasia is uncertain.

CLINICAL MANIFESTATIONS

Clinically, these lesions can produce painless bleeding, which may be occult and manifest only by guaiac-positive stools or iron deficiency anemia, or the bleeding may be overt, with hematochezia, maroon stools, melena, and hematemesis.

DIAGNOSIS

Endoscopic procedures most often make the diagnosis of bleeding secondary to angiodysplasia (Fig. 145-5). In some patients, endoscopic procedures may need to be repeated, especially in volume-depleted patients and after the administration of narcotics. Small bowel angiodysplasia, beyond the reach of both a colonoscope from below and an extended-length endoscope from above, may be the cause of major bleeding (Chapter 137) and require video capsule endoscopy (Chapter 136) or small bowel enteroscopy for diagnosis.

TREATMENT Rx

Electrocoagulation laser therapy or argon plasma coagulation can be accomplished during endoscopy. When very active bleeding makes urgent colonoscopy technically difficult, visceral angiography can be diagnostic and also permit embolization of bleeding lesions or intra-arterial infusion of a vasoconstrictor. Rarely, bowel resection is required.

PROGNOSIS

More than 90% of gastrointestinal angiodysplasias never bleed. If found incidentally in patients without a history of bleeding, they should not be treated.

FIGURE 145-5. Endoscopy of the sigmoid colon in a patient with angiectasia. The lesion is discrete and contains a tight, radiating cluster of ectatic mucosal vessels. (From Emory TS, Carpenter HA, Gostout CJ, et al, eds. *Atlas of Gastrointestinal Endoscopy and Endoscopic Biopsies*. Washington, DC: Armed Forces Institute of Pathology, American Registry of Pathology; 2000.)

Dieulafoy's Lesion

Dieulafoy's lesion is an unusually large submucosal artery typically found in the proximal portion of the stomach within 6 cm of the gastroesophageal junction. Similar lesions may also occur in the rectum, colon, small bowel, and far less often, the esophagus. Dieulafoy's lesion is manifested clinically as sudden, massive bleeding, which may be recurrent.

DIAGNOSIS AND TREATMENT

Rx

Urgent endoscopy is required to identify what is usually a very small vascular protuberance (Fig. 145-6) but can rapidly become inapparent once the acute bleeding stops. Ulceration is not seen, and repeat endoscopic procedures during active bleeding may be required to make the diagnosis. Sometimes the diagnosis requires angiography during a bleeding episode. Endoscopic injection and electrocoagulation therapy are generally effective, but endoscopic band therapy and hemoclips may also be used, and surgery is sometimes required.

PROGNOSIS

Endoscopic therapy is successful long-term in nearly 90% of patients.

Other Ectasias

Telangiectases are similar to angiodysplasias but occur in all the layers of the bowel wall, are usually congenital, and often occur in other organ systems. *Hereditary hemorrhagic telangiectasia* (Osler-Weber-Rendu disease; Chapter 176) is an autosomal dominant disorder with telangiectases involving the lips; mucous membranes, especially in the mouth and nose; gastrointestinal tract, especially the stomach and small bowel; liver; lung; retina; and central nervous system. Patients with *Turner's syndrome* (Chapter 243), *scleroderma* (Chapter 275), and the *CREST syndrome* (Chapter 275) (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasia) may also have gastrointestinal tract telangiectases.

Vascular ectasias involving venules and capillaries can also be seen in the small bowel *(congestive enteropathy),* in the colon *(congestive colopathy),* and more commonly, in the stomach *(congestive gastropathy)* in patients with portal hypertension (Chapter 156). In contrast to angiodysplasias, these lesions tend to be more diffuse, appear as multiple, fine punctate red spots or as a mosaic pattern similar to the gastritis of *Helicobacter pylori,* and are more often found in the proximal than the distal part of the stomach. Therapies that decrease portal hypertension can reduce or eliminate these lesions and bleeding from them.

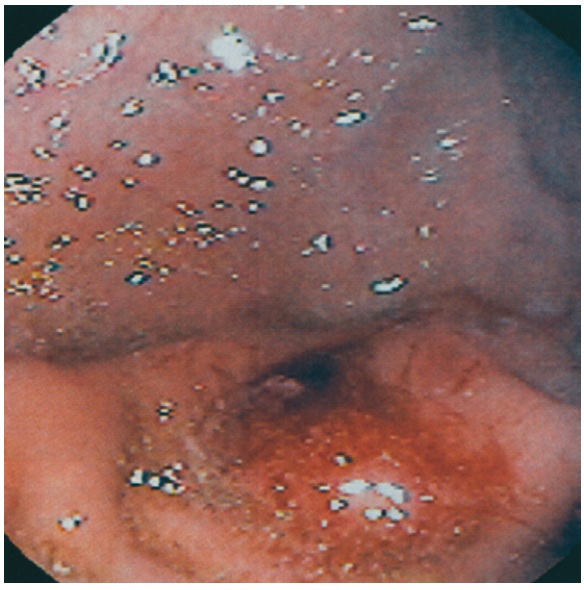

FIGURE 145-6. Endoscopy of the stomach in a patient with Dieulafoy's lesion. Note the visible vessel manifested as a pale protuberance surrounded by a clot with adjacent normal-appearing mucosa. (From Emory TS, Carpenter HA, Gostout CJ, et al, eds. *Atlas of Gastrointestinal Endoscopy and Endoscopic Biopsies*. Washington, DC: Armed Forces Institute of Pathology, American Registry of Pathology; 2000.)

Gastric antral vascular ectasia (GAVE), or watermelon stomach, also involves venules and capillaries with thrombosis as well as ectasia. Erythematous streaks similar to the stripes on a watermelon are typically seen in the antrum radiating toward the pylorus. Patients usually have occult bleeding and less often melena. GAVE is associated with connective tissue diseases (e.g., systemic lupus erythematosus [Chapter 274], mixed connective tissue disease [Chapter 275], scleroderma [Chapter 275]), pernicious anemia (Chapter 167), and portal hypertension (Chapter 156). However, unlike congestive gastropathy, treatment of portal hypertension does not eliminate GAVE or bleeding from it. Argon plasma coagulation is the usual therapy if iron replacement alone is not effective. Antrectomy is rarely needed.

Neoplastic Vascular Lesions

Hemangiomas are uncommon, usually benign vascular tumors that can be found throughout the gastrointestinal tract, often in the rectum or colon. They may be single or multiple, bluish purple, and sessile or polypoid. In some persons, these lesions are multiple and associated with skin lesions, such as the *blue rubber bleb nevus syndrome* with purple-blue cutaneous hemangiomas or the *Klippel-Trenaunay* syndrome with port-wine-colored cutaneous hemangiomas, hemihypertrophy, and varicose veins. Rare vascular malignant neoplasms of the gastrointestinal tract include *angiosarcomas* and *hemangioendotheliomas.*

Miscellaneous Vascular Disorders

Aortoenteric fistulas, which most commonly occur after surgery for an aortic aneurysm (Chapter 78), may be related to infection of the graft and can result in torrential gastrointestinal bleeding. Many of these fistulas communicate with the duodenum. Evaluation of bleeding in persons who have previously undergone abdominal aortic surgery should include urgent extended-length upper endoscopy to document a fistula or diagnose another definitive source of the bleeding. Angiography and radiographic tests (CT, magnetic resonance imaging [MRI]) are helpful only if the findings are abnormal (i.e., there is evidence of a fistula) because of their poor sensitivity for the presence of aortoenteric fistulas. If no clear alternative source for the bleeding can readily be found, explorative surgery is indicated.

Celiac artery compression syndrome (median arcuate ligament syndrome) is a very rare pseudo-ischemic syndrome. Patients are often young and healthy and have postprandial upper abdominal pain, most likely caused by extrinsic compression of the celiac axis by the median arcuate ligament of the diaphragm. Sitophobia can result in considerable weight loss, and there may be a loud systolic bruit in the epigastric region on physical examination. Visceral angiography supports the diagnosis, but bruits and celiac axis compression may occur without symptoms. Surgical therapy is indicated after other possible causes of the patient's symptoms have been excluded.

Bowel as well as large vessel rupture can occur as a complication of *Ehlers-Danlos syndrome type IV* (Chapter 268). Similar vascular catastrophes with gastrointestinal or intraperitoneal hemorrhage can occur in patients with *pseudoxanthoma elasticum type I* (Chapter 268) or with *visceral artery aneurysms* (secondary to atherosclerosis, fibrodysplasia, portal hypertension, pregnancy, pancreatitis, vasculitis, or trauma).

HEPATIC AND SPLENIC VASCULAR DISEASE

Budd-Chiari Syndrome

Budd-Chiari syndrome can occur as a result of any process that interferes with the normal flow of blood out of the liver, including constrictive pericarditis (Chapter 77) and veno-occlusive disease (Chapter 152). Hepatic vein thrombosis, which is the main cause of Budd-Chiari syndrome, may involve one, two, or all three of the major hepatic veins, with or without partial or complete occlusion of the inferior vena cava. Often, Budd-Chiari syndrome is due to a hypercoagulable state (Chapter 179), such as a chronic myeloproliferative disorder (e.g., polycythemia vera [Chapter 169], essential thrombocythemia [Chapter 169], myeloid metaplasia [Chapter 169]), paroxysmal nocturnal hemoglobinuria, or other hypercoagulable conditions (Chapter 179), such as factor V (Leiden) gene mutation, antiphospholipid antibody syndrome, protein C deficiency, protein S deficiency, or antithrombin III deficiency. A high percentage of these patients harbor *JAK2* V617F mutations. Nearly 50% of patients with Budd-Chiari syndrome have more than one risk factor. Malignancies (direct compression or invasion of hepatic veins, hypercoagulable state), infections (liver abscess), pregnancy, inflammatory disorders (e.g., Behçet's syndrome, inflammatory bowel disease, connective tissue disease, sarcoidosis), and membranous

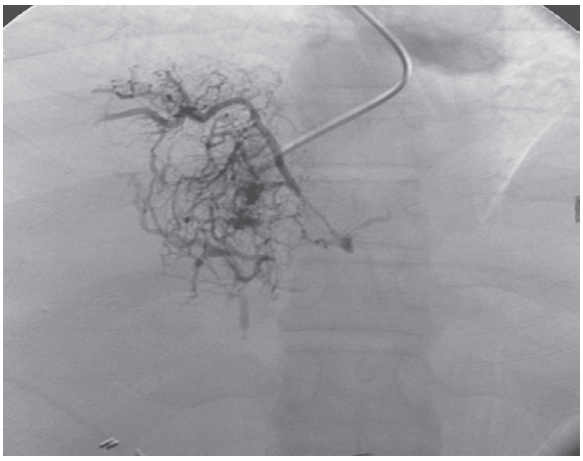

FIGURE 145-7. Budd-Chiari syndrome. A hepatic vein contrast study depicts the "spider web" pattern of venovenous collaterals attempting to bypass a thrombosed hepatic vein. (Courtesy of Patrick Kamath.)

obstruction (webs) of the inferior vena cava are also associated with Budd-Chiari syndrome.

CLINICAL MANIFESTATIONS

The syndrome is usually subacute or chronic, occurs over a period of weeks to months, and is characterized by the insidious onset of upper abdominal pain, hepatomegaly, and ascites. Fulminant or acute presentations, including encephalopathy, jaundice, ascites, and liver failure, are rare.

DIAGNOSIS

Liver function testing usually reveals normal or mild to moderate nonspecific elevations in serum aspartate and alanine aminotransferase levels. Doppler ultrasound of the liver is the initial diagnostic test of choice, but the absence of hepatic venous flow or venous thrombosis (or both) is also readily apparent with contrast-enhanced CT scanning or MRA. Hepatic venography can confirm the diagnosis (Fig. 145-7) and, with imaging of the inferior vena cava, as well as selective venous pressure measurements, can help guide therapy.

TREATMENT Rx

Therapy includes diagnosis and treatment of underlying conditions, anticoagulation (intravenous heparin; see Table 81-4 in Chapter 81) to prevent the propagation of thrombi, and treatment of the ascites (e.g., diuretics; Chapter 156). To decompress the congested liver, most patients require interventional radiologic procedures, such as angioplasty, stenting, or transjugular intrahepatic portosystemic shunts, to restore hepatic venous flow. Surgical procedures such as surgical shunts to drain the portal or mesenteric venous system into the inferior vena cava can also decompress the liver. Liver transplantation (Chapter 157) should be considered for patients with fulminant liver failure or cirrhosis, or both. Most patients with Budd-Chiari syndrome require lifelong warfarin anticoagulation (Chapter 37), even after liver transplantation. Selective JAK2 inhibitors (Chapter 169) are being tested in preclinical and clinical studies.

PROGNOSIS

Overall, the 5-year survival rate of patients with the Budd-Chiari syndrome is more than 80%. Indices such as levels of serum albumin and bilirubin, the international normalized ratio, ascites, and encephalopathy, as well as the Child-Pugh score (see Table 156-2 in Chapter 156), can be useful in determining prognosis.

Portal Vein Thrombosis

In adults, cirrhosis, hypercoagulable states, intra-abdominal malignancy, inflammatory disorders (e.g., pancreatitis, Crohn's disease), and medical procedures (e.g., splenectomy, cholecystectomy, gastrectomy, liver transplantation, transjugular intrahepatic portosystemic shunt) are most often the cause of acute portal vein thrombosis. Similar to Budd-Chiari syndrome, a substantial number of these patients harbor JAK2 V617F mutations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations include portal hypertension with variceal bleeding and ascites. Abdominal pain and diarrhea may indicate extension of the thrombus into the SMV with intestinal ischemia. The diagnosis of acute portal vein thrombosis is confirmed by Doppler ultrasound, MDCTA, or MRA. CT imaging may reveal multiple small liver abscesses.

TREATMENT Rx

Anticoagulation (see Table 81-4 in Chapter 81) therapy for at least 3 months is recommended for patients with acute portal vein thrombosis and should be continued long term in those persons with permanent thrombotic risk factors not otherwise correctable, as well as in patients with extension of thrombus into the mesenteric veins.

High fever, chills, a tender liver, and sepsis suggest pylephlebitis, which usually requires treatment with parenteral antibiotics such as piperacillin/tazobactam, ticarcillin/clavulanate, carbapenem, or a third-generation cephalosporin plus metronidazole for at least 6 weeks. Blood cultures can help to guide the choice and course of antibiotics, which should be administered intravenously for at least 2 weeks.

Treatment is less clear in cirrhotic patients with acute or chronic portal vein thrombosis. Endoscopy for the diagnosis and treatment of varices (Chapter 136), with or without pharmacologic treatment of the portal hypertension (e.g., β-blockade with propranolol; Chapter 156), is often beneficial, and surgical shunts are rarely necessary. Antibiotics, such as those recommended previously for pylephlebitis, should be administered in patients with any sign of infection.

Chronic portal vein thrombosis is defined as an obstructed portal vein replaced by collateral veins. Doppler ultrasound, MDCTA, or MRA will confirm the diagnosis. Patients may be asymptomatic but often have hypersplenism and portal hypertension (e.g., subclinical encephalopathy, rare ascites). Some patients may develop jaundice owing to biliary cholangiopathy and will require endoscopic placement of biliary stents. Endoscopic screening and treatment of varices (Chapter 136), with or without pharmacologic treatment of portal hypertension (Chapter 156), is recommended. After treatment of the varices, long-term anticoagulation therapy (see Table 81-4 in Chapter 81) should be considered in noncirrhotic patients whose permanent thrombotic risk factors are not otherwise correctable, unless there is a contraindication.

PROGNOSIS

Mortality rates after treatment of acute portal vein thrombosis are less than 10%, and the prognosis for patients with chronic portal vein thrombosis over 5 years is similar.

Splenic Vein Thrombosis

Splenic vein thrombosis is usually secondary to malignancy (e.g., pancreatic cancer), pancreatitis, or trauma. In many of these patients, isolated gastric varices develop and are difficult to treat by therapeutic endoscopy. Liver function and portal pressure are normal. Most patients with splenic vein thrombosis have splenomegaly (Chapter 171). Doppler ultrasound, MRI, and CT assist in making the diagnosis. Patients with symptomatic isolated splenic vein thrombosis (e.g., gastric variceal bleeding, hypersplenism) are best treated by splenectomy.

Hepatic and Splenic Arterial Disease

Hepatic arterial disease may be nonocclusive or occlusive. Nonocclusive disease, termed *ischemic hepatitis,* occurs when arterial blood flow to the liver is insufficient, usually because of cardiogenic hypotension, volume depletion, or sepsis. Typically, serum aminotransferase rises acutely to levels greater than 1000 U/L. With restoration of adequate hepatic arterial blood flow, serum aminotransferase levels eventually fall back to their baseline by about 40 to 60% per day. Hepatic artery thrombosis is extremely rare except in a post–liver transplantation (Chapter 157) patient, in whom it may be manifested as mild abnormalities in liver function test results, bile duct injury (e.g., biliary stricture, cholangitis, liver abscess), or liver failure. Doppler ultrasound and angiography will confirm the diagnosis, and these patients often require biliary stents, drainage of abscesses, surgical reconstruction of the hepatic artery, or retransplantation of the liver.

The splenic artery or hepatic artery may be predisposed to the development of aneurysmal dilation, usually secondary to atherosclerosis, trauma, portal hypertension, pancreatitis, pregnancy, infection, or vasculitis. Common clinical manifestations include abdominal pain and intra-abdominal hemorrhage. Hemobilia may occur with hepatic artery aneurysms.

Angiography is usually required to make the diagnosis. Symptomatic as well as sizable (variably defined, usually 1 cm or greater for a hepatic aneurysm and 2 cm or greater for a splenic artery aneurysm) aneurysms require surgery. Splenic artery aneurysms discovered during pregnancy are more likely to bleed and should be treated, usually by interventional radiology.

Fistulas from the hepatic artery to the portal vein can occur as a result of trauma, malignancy, or the inherited disorder hereditary hemorrhagic telangiectasia. The resultant portal hypertension may cause abdominal pain, ascites, and gastrointestinal bleeding, and involvement of the hepatic artery may result in biliary strictures and hepatobiliary infection. Radiographic embolization of these fistulas, surgery, or liver transplantation may be required.

ACUTE PANCREATITIS

DEFINITION

Acute pancreatitis is defined as a discrete episode of cellular injury and inflammation in the pancreas, usually with symptoms of abdominal pain, nausea, and vomiting, and typically accompanied by elevations in serum levels of amylase or lipase and by radiographic evidence of pancreatic inflammation, edema, or necrosis. Although pancreatic morphology and function may appear to recover promptly after the attack, recovery may not be complete if the damage is substantial. With repeated episodes, there is a shift from acute inflammation, necrosis, and apoptosis to the chronic inflammation and fibrosis that is characteristic of chronic pancreatitis. In some patients, it may be difficult to distinguish acute pancreatitis from a flare of chronic pancreatitis.

EPIDEMIOLOGY

The incidence of acute pancreatitis in the United States is estimated to be between 5 and 30 cases per 100,000 population, thereby resulting in about 250,000 hospital admissions annually and making acute pancreatitis the second most common gastrointestinal discharge diagnosis in U.S. hospitals. The cost of caring for these patients is about $4 to $6 billion annually. The incidence of acute pancreatitis is increasing in the United States and many other developed countries, perhaps because of better diagnostic tests but also perhaps owing to an increasing prevalence of gallstones (Chapter 158) in the setting of the obesity epidemic.

PATHOBIOLOGY

Acute pancreatitis is characterized by premature activation of digestive enzymes within the pancreas. In particular, the activation of trypsinogen to trypsin appears to be a critical initial step, with trypsin then activating other proteases within the gland. These activated enzymes produce cellular injury and death, which is a mixture of necrosis, apoptosis, and autophagy. Necrosis may involve not only the pancreas but also the surrounding fat and structures, thereby leading to fluid extravasation into the retroperitoneal spaces ("third space" losses). Although necrosis may be present in many cases, necrosis visible on a contrast-enhanced computed tomography (CT) scan is usually termed *acute necrotizing pancreatitis* and distinguished from the milder interstitial pancreatitis, in which necrosis is not visible on a CT scan. In addition to the local damage, the release of proinflammatory cytokines and activated digestive enzymes into the systemic circulation can produce a systemic inflammatory response syndrome (SIRS; Chapter 108) with hypotension, renal failure, and respiratory failure. Gallstones and alcohol account for about 70 to 80% of all cases of acute pancreatitis, but the cause is unknown in about 10% (Table 146-1).

Gallstones

Passage of a gallstone (Chapter 158) through the ampulla of Vater with transient obstruction of the pancreatic duct is the initiating event for gallstone pancreatitis. Only about 5% of all patients with gallstones develop pancreatitis, and patients with smaller gallstones (≤5 mm), which can pass the cystic duct and reach the ampulla, are at highest risk. Patients with microlithiasis, defined as tiny gallstones or biliary sludge, may account for up to 75% of patients initially labeled as having acute idiopathic pancreatitis.

Alcohol

More than 5 years of alcohol intake averaging more than 5 to 8 drinks daily is usually required before pancreatitis develops, but most people with this level of intake do not develop pancreatitis. A variety of cofactors have been proposed, including a high-fat diet, genetic variability in detoxifying enzymes, and cigarette smoking. By the time patients present with a first episode of acute pancreatitis, most already have evidence of underlying chronic pancreatitis. The mechanism of alcoholic pancreatic injury likely involves a mixture of direct toxicity, oxidative stress, and alterations in pancreatic enzyme secretion.

Drugs, Toxins, and Metabolic Factors

Drug-induced pancreatitis is a rare and generally idiosyncratic event. Implicated drugs include 6-mercaptopurine and azathioprine (up to a 4% attack rate), didanosine, pentamidine, valproic acid, furosemide, sulfonamides, and aminosalicylates. Toxins that may cause acute pancreatitis include methyl alcohol, organophosphate insecticides, and venom from certain scorpions.

Levels of serum triglycerides above 500 mg/dL, and usually more than 1000 mg/dL, can cause acute pancreatitis, but the mechanism is not known. Hyperlipidemic pancreatitis can be caused by the administration of estrogens, which can worsen underlying hypertriglyceridemia. Hypercalcemia is an exceedingly rare cause of acute pancreatitis.

Trauma

Iatrogenic trauma to the pancreas and pancreatic duct during performance of an endoscopic retrograde cholangiopancreatography (ERCP; Chapter 136) is a common cause of pancreatitis, with the risk ranging from less than 5% for those with simple common bile duct stones or malignancy, to as high as 20% for those with suspected sphincter of Oddi dysfunction. The risk of post-ERCP pancreatitis is markedly reduced with the placement of small-caliber temporary pancreatic duct stents.

Penetrating and blunt trauma ranging from a contusion to severe crush injury and even transection of the gland can cause pancreatitis. Acute presentation is the rule, but some patients with milder injury may present in a subacute or chronic fashion. Ischemic injury to the gland can occur after surgical procedures, especially cardiopulmonary bypass, and can be quite severe.

Obstruction of the Pancreatic Duct

In addition to gallstones and microlithiasis, obstruction of the pancreatic duct by a pancreatic ductal adenocarcinoma, ampullary adenoma or carcinoma, or an intraductal papillary mucinous neoplasm can cause acute pancreatitis. The diagnosis is usually established with endoscopic ultrasound (EUS). Benign strictures of the pancreatic duct or ampulla of Vater may be caused by celiac disease and periampullary diverticula. Sphincter of Oddi dysfunction, which is defined by abnormal manometry of the sphincter at the time of ERCP, and pancreas divisum, in which the larger dorsal pancreas drains through the smaller minor papilla, may also cause pancreatitis by obstruction of the pancreatic duct and should be considered in patients with repeated episodes of otherwise unexplained acute pancreatitis.

Infections and Autoimmune Pancreatitis

Ascaris lumbricoides (Chapter 365) may cause pancreatitis by obstructing the pancreatic duct as the worms migrate through the ampulla. Viruses that may infect the pancreatic acinar cells directly include cytomegalovirus (Chapter 384), Coxsackie B virus (Chapter 387), and mumps virus (Chapter 377). Fungal infections of the pancreas are exceedingly rare but may be seen in the setting of immunosuppression. Autoimmune pancreatitis, which can be systemic, affects the salivary glands, retroperitoneum, biliary ducts, and kidneys.

Genetics

Mutations in the cationic trypsinogen gene (*PRSS1*), which have been identified in families with hereditary pancreatitis, are more commonly seen in association with chronic pancreatitis but can be observed rarely in acute pancreatitis. Mutations in the cystic fibrosis conductance regulator (*CFTR*; Chapter 89) and the serine protease inhibitor Kazal type 1 (*SPINK1*) predispose to pancreatitis but do not cause pancreatitis in the absence of other provocations.

Idiopathic Acute Pancreatitis

Of the 25% of patients who do not have an identified cause after a basic initial evaluation, surreptitious alcohol use and microlithiasis are probably the most common underlying explanations. With additional evaluation and testing, only about 10% of patients are ultimately labeled as having idiopathic pancreatitis.

CLINICAL MANIFESTATIONS

Abdominal pain, nausea, and vomiting are the hallmark symptoms of acute pancreatitis. The abdominal pain is usually maximum in the epigastric region and often radiates to the back. The pain is steady, reaches its maximal intensity over 30 to 60 minutes, and persists for days. These characteristic symptoms may be masked in patients who present with delirium, multiple-organ system failure, or coma.

The physical examination usually reveals tachycardia. Hypotension, tachypnea, dyspnea, and fever are seen in more severe cases. Confusion, delirium, and even coma may be present. The abdomen is often distended with diminished bowel sounds. Tenderness to palpation of the abdomen, which may be epigastric or more diffuse, is typical, and rebound and guarding are seen in more severe cases. Dullness to percussion in the lower lung fields may be noted owing to a pleural effusion. Rare physical findings include ecchymoses of the flank (Grey-Turner sign) or umbilicus (Cullen sign), which occur when fluid and blood tracks into these spaces from the retroperitoneum. Jaundice may be present if there is biliary obstruction by a stone.

The presence of tachycardia, dyspnea, tachypnea, orthostatic hypotension, pleural effusion, oxygen desaturation, or shock signal more substantial third space losses, a higher likelihood of a variety of complications (Table 146-2), and a worse prognosis. More severe pancreatitis is characterized by more substantial pancreatic and peripancreatic necrosis, more peripancreatic fluid collections, and more dysfunction of extrapancreatic organs.

TABLE 146-2 SCORING SYSTEMS TO ASSESS SEVERITY OF ACUTE PANCREATITIS

SYSTEM	CRITERIA	DEFINITION OF SEVERE PANCREATITIS
Ranson	At admission Age > 55 years WBC > 16,000/μL Glucose > 200 mg/dL LDH > 350 IU/L AST > 250 IU/L Within next 48 hours Decrease in hematocrit by > 10% Estimated fluid sequestration of > 6 L Serum calcium < 8.0 mg/dL Pa_{O_2} < 60 mm Hg BUN increase > 5 mg/dL after hydration Base deficit > 4 mmol/L	Total score ≥ 3
APACHE-II	Multiple clinical and laboratory factors. Calculator available at *www.mdcalc.com/apache-ii-score-for-icu-mortality*	Total score ≥ 8
BISAP	BUN > 25 mg/dL Impaired mental status Presence of SIRS Age > 60 years Pleural effusion	Total score > 2
CT	A: Normal pancreas B: Focal or diffuse enlargement of pancreas C: Grade B plus pancreatic and/or peripancreatic inflammation D: Grade C plus a single fluid collection E: Grade C plus two or more fluid collections or gas in pancreas	Grade > C
CT severity index	CT grade A = 0 B = 1 C = 2 D = 3 E = 4 Plus necrosis grade No necrosis = 0 <30% necrosis = 2 30-50% necrosis = 4 >50% necrosis = 6	Score > 5

AST = aspartate aminotransferase; BUN = blood urea nitrogen; CT = computed tomography; LDH = lactate dehydrogenase; SIRS = systemic inflammatory response syndrome; WBC = white blood count.

DIAGNOSIS

The diagnosis of acute pancreatitis is suggested by the clinical features and confirmed by laboratory and imaging studies that exclude other serious intra-abdominal conditions, establish the presence of acute pancreatitis, and, hopefully, define the severity and most likely cause of the pancreatitis.

Laboratory Tests

Amylase and Lipase

Most patients with acute pancreatitis have elevations in serum levels of amylase or lipase within a few hours of the onset of symptoms. Lipase tends to remain elevated for longer than amylase, but both decline gradually over several days. Elevations more than three times the upper limit of normal are

most specific for acute pancreatitis. Amylase and lipase levels may be normal in patients with acute pancreatitis, particularly if the measurement is delayed for several days after the onset of symptoms. Marked hypertriglyceridemia also can interfere with their accurate measurement. Both enzymes are cleared by the kidney, and renal failure can falsely raise the level of these enzymes up to five times the upper limit of normal in the absence of pancreatitis. Amylase and lipase also can be elevated in a variety of other conditions that may mimic acute pancreatitis, including intestinal ischemia and infarction (Chapter 145), bowel obstruction (Chapter 144), cholecystitis (Chapter 158), and choledocholithiasis (Chapter 158). In addition, amylase may be elevated from ectopic pregnancy, acute salpingitis, and a variety of extra-abdominal conditions such as parotitis, lung cancer, and head trauma. In some patients, only amylase or lipase may be elevated. Given its improved specificity, equal cost, and equal sensitivity, lipase is preferred over amylase as a single diagnostic test. Serial measurements of amylase or lipase in patients with established acute pancreatitis are not helpful in clinical decision making.

Other Laboratory Tests

In severe pancreatitis, leukocytosis and hemoconcentration may be seen. Failure of the blood urea nitrogen (BUN) level or hematocrit to normalize with fluid resuscitation is associated with a worse prognosis. Hyperglycemia, hypocalcemia, and mild hypertriglyceridemia can develop in more severe cases. Elevations in alanine aminotransferase levels more than three times the upper limit of normal are most suggestive of gallstones, although any significant elevation in liver chemistries should raise the possibility of gallstones (Chapter 158).

Imaging Studies

Imaging studies are used not only in establishing the diagnosis but also in determining etiology and prognosis. In most patients, both ultrasound and CT are used in a complementary fashion.

Abdominal ultrasound can confirm the presence of acute pancreatitis by documenting pancreatic enlargement, edema, or associated peripancreatic fluid collections. Visualization of the pancreas may be limited owing to body habitus or overlying intestinal gas. Importantly, ultrasound is most accurate in identifying gallstones in the gallbladder or a dilated common bile duct.

CT is more accurate than ultrasound in confirming the diagnosis of acute pancreatitis and in documenting the presence of pancreatic necrosis and peripancreatic fluid collections, but it is less accurate in identifying gallstones. CT is also particularly helpful in excluding intra-abdominal conditions that can mimic acute pancreatitis. On contrast-enhanced CT, pancreatic parenchyma that opacifies with intravenous contrast is considered still viable, whereas parenchyma that does not opacify is necrotic (Fig. 146-1). The extent of pancreatic necrosis, which is best seen about 3 days after presentation and may be missed in an early CT, has prognostic importance. CT scans are not routinely required in patients with acute pancreatitis but should be performed in patients with a first attack, with severe disease, with systemic complications, or when disease is slow to improve or the diagnosis is not clear.

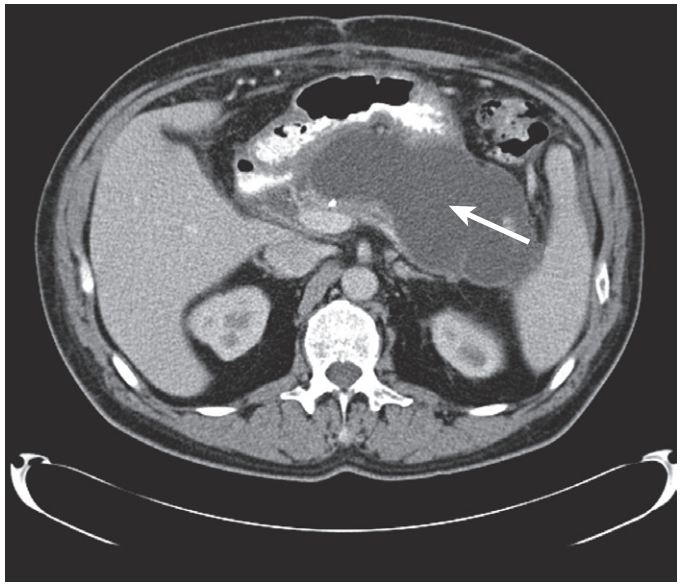

FIGURE 146-1. A computed tomographic scan demonstrating a large area of pancreas that does not enhance with intravenous contrast *(arrow)*, consistent with pancreatic necrosis.

Magnetic resonance imaging (MRI) is equivalent to CT in its ability to document acute pancreatitis, identify necrosis, and diagnose or exclude other diseases that could mimic acute pancreatitis. In addition, MRI with *magnetic resonance cholangiopancreatography* (MRCP) is much better than CT in identifying gallstones. MRI is more difficult than CT to perform in critically ill patients.

ERCP and EUS are important in both diagnosis and therapy of acute pancreatitis. EUS, which is primarily used to establish the cause when the initial evaluation is unrevealing, is particularly accurate in identifying underlying malignancy, premalignant lesions such as ampullary adenoma, and small gallstones or microlithiasis. ERCP is used primarily for therapeutic reasons, but it also may diagnose rare causes of pancreatitis such as pancreas divisum or sphincter of Oddi dysfunction.

Determining Etiology

To identify the cause of acute pancreatitis, the history should focus on alcohol and tobacco use, previous biliary colic, drug history, family history, and recent trauma. Alcohol use may need to be corroborated with family members. Gallstone pancreatitis should be suspected if stones are seen on imaging studies or if liver chemistries are abnormal and then improve over a few days. If these initial studies are unrevealing, EUS can detect small gallstones, microlithiasis, or underlying malignancy, particularly in patients older than 40 years. More specialized investigations like ERCP, sphincter of Oddi manometry, or genetic testing are usually reserved for patients seen in referral centers after multiple attacks of pancreatitis.

Determining Severity

Severe pancreatitis is characterized by organ system failure and by local pancreatic complications such as necrosis, fluid collections, or pseudocysts. Organ failure can be single or multiple, early or late onset, and progressive and persistent or transient. In severe acute pancreatitis, renal failure, pulmonary failure, and circulatory failure most commonly occur as part of the SIRS response. Severe pancreatitis also can be defined by local pancreatic and peripancreatic complications. Necrotizing pancreatitis as defined by CT is associated with a worse outcome, and the degree or amount of necrosis generally correlates with outcome, particularly if infection develops in the devitalized necrotic tissue.

During the acute attack, poorly demarcated fluid collections around the pancreas track into various retroperitoneal and peritoneal spaces. Much of this inflammatory fluid will resolve, but some will form into a more rounded and circumscribed fluid collection, called a *pseudocyst*. This process, which takes weeks, should be distinguished from early areas of pancreatic necrosis that may appear on CT as fluid collections and may be termed *pseudocysts* but in reality are collections of both liquid and solid necrotic material and are better described as *walled-off pancreatic necrosis*. Necrosis on CT, which can be seen in up to 25% of patients with acute pancreatitis and portends a worse outcome and particularly more substantial necrosis, is associated with higher rates of serious pancreatic infections. Organ system failure is quite rare in the absence of pancreatic necrosis.

Clinical features may help identify patients at higher risk, including patients who are older, are obese, or have more serious or more numerous comorbid conditions. In addition, a number of scoring systems can help guide clinicians in gauging prognosis.

The best known multiple-factor scoring systems are the Ranson criteria and Acute Physiology and Chronic Health Evaluation (APACHE) II score (see Table 146-2). Practice guidelines suggest a cutoff of more than 8 APACHE II points or more than 3 Ranson points as the definition of severe disease. Each approach has a high false-positive rate, in that many patients with high scores do not develop organ failure or die. An elevated admission BUN that does not return to normal with fluid therapy is associated with increased mortality, and a C-reactive protein level higher than 150 mg/L at 48 hours may be as accurate as multiple-factor scoring systems at predicting poor outcome. A simpler system is the "BISAP" score (*B*UN > 25 mg/dL, *I*mpaired mental status, *S*IRS, *A*ge > 60, and *P*leural effusion), in which mortality ranges from <1% for patients with none or only one of those risk factors (BISAP score of 0 or 1) to 27% for a BISAP score of 5. Each scoring system should be considered as a guide but not a replacement for clinical judgment.

TREATMENT

General Supportive Care

Most patients recover within several days, but it is usually not possible to identify these patients at the time of admission. All patients should be made NPO. Pain control usually requires parenteral narcotics, and hydromorphone (in divided doses of 1 to 2 mg given intravenously every 4 to 6 hours initially, with titration as needed, or more commonly as patient-controlled analgesia) is generally preferred. Patients with significant third space loss, often augmented by fluid losses through vomiting, will have evidence of intravascular fluid depletion. Even in mild pancreatitis, fluid losses may be substantial. Appropriate fluid resuscitation, which is one of the few medical interventions that appears to affect outcome, should be accomplished within the first 24 hours of admission to correct the blood pressure and pulse, to reduce the hematocrit and blood urea nitrogen levels to normal, and to ensure a urine output of at least 0.5 mL/kg/hour. Crystalloid, either normal or half-normal saline or lactated Ringer's solution, is preferred. If nausea and vomiting require treatment, promethazine (12.5 to 25 mg intravenously three times daily) is usually successful, although some patients may be more effectively treated with 5-HT3 antagonists (e.g., ondansetron, 8 mg orally or 4 or 8 mg intravenously up to every 8 hours). Nasogastric suction is needed for those with intractable nausea and vomiting. Patients can be fed, preferably with a full solid diet,[1] when bowel sounds and appetite have returned, nausea has resolved, enzyme levels are normalized, and pain is controlled.

In patients with more severe pancreatitis, based on the severity of their comorbid conditions, early organ system failure, or substantial third space fluid losses, admission to an intensive care unit (ICU) is appropriate. Vigorous fluid replacement, as outlined previously, which may reach 5 to 10 L/day, is required. Appropriate fluid resuscitation can be gauged by serial measurements of BUN and hematocrit as well as by urine output. Careful monitoring for progressive organ system failure and metabolic complications is critical in these patients.

Patients who appear to have sufficiently severe disease that they might not be able to eat for 5 to 7 days should be started on nutritional therapy. Trials suggest that enteral nutrition, using an elemental or semi-elemental formula, is associated with fewer complications, including hyperglycemia and line infections, compared with total parenteral nutrition.[2] Nasogastric feeding is easier and may be as good as nasojejunal feeding.[3]

Treatment of Complications

Most patients who develop acute gallstone pancreatitis have already passed the offending stone into the duodenum, but patients with a persistent stone or multiple stones are at higher risk of developing cholangitis and more severe pancreatitis. Data support current practice guidelines that recommend early ERCP in patients who have gallstone pancreatitis and evidence of concomitant cholangitis (e.g., fever, jaundice, right upper quadrant pain) or of a persistent bile duct stone (e.g., visible persistent stone on imaging study, jaundice, persistently dilated bile duct, worsening liver chemistries at 48 hours after admission).[4] Early ERCP is occasionally considered for patients who have severe pancreatitis, as evidenced by early and progressive organ system failure, but who do not have cholangitis or strong evidence of a stone; however, data do not support benefit from this intervention.[5] There is no other role for early endoscopic intervention in patients with acute pancreatitis.

The systemic complications (Table 146-3) that develop from multiple-organ system failure in patients with severe acute pancreatitis include some that are similar to those commonly encountered in other ICU patients as well as specific metabolic complications of severe pancreatitis. Hyperglycemia is commonly a result of the pancreatitis and may be seen with enteral nutrition; hyperglycemia may contribute to higher rates of infections. In severe acute pancreatitis, ionized calcium levels are usually normal, but hypocalcemia is common owing to a diminished serum albumin level; treatment (Chapter 253) is not needed in the absence of signs of hypocalcemia, such as tetany or a Chvostek's sign. Mild hypertriglyceridemia is common, but underlying hypertriglyceridemia is often the cause of acute pancreatitis when levels of triglycerides surpass 1000 mg/dL; triglyceride levels usually drop promptly when the patient is made NPO, but plasmapheresis may be required.

Any hospital-acquired infection dramatically worsens prognosis. Infections in patients with acute pancreatitis include urinary tract infections, pulmonary infections, line infections, and *Clostridium difficile* infection. High-quality nursing care, antibiotic stewardship, and careful attention to catheters and lines can minimize these infections.

For necrotizing pancreatitis, a step-up approach of percutaneous drainage followed, if necessary, by minimally invasive retroperitoneal necrosectomy reduces the risk of multiple-organ failure by more than two thirds and new diabetes by more than 50% with no change in in-hospital mortality compared with routine open necrosectomy.[6] Patients with necrotizing pancreatitis may develop infected pancreatic necrosis, which increases mortality to nearly 30%. Infection of preexisting necrosis typically occurs 2 to 3 weeks into the illness and is heralded by fever, leukocytosis, and worsening abdominal pain. The responsible organisms are usually gram-negative rods and other gut flora, but *Staphylococcus aureus* (Chapter 296) is an important agent as well. If infected necrosis is suspected, a CT scan should be obtained, followed by CT-directed fine-needle aspiration of the necrotic area for culture and Gram stain. If infection is documented, antibiotics tailored to the organism should be promptly initiated. Conservative therapy is continued, often for weeks, to allow the necrotic material to demarcate, begin to liquefy, and become encapsulated. When this walled-off necrosis is sufficiently liquefied to allow less invasive approaches, therapy can include percutaneous, endoscopic, or minimally invasive surgical therapy. Open surgical drainage is reserved for patients with progressive clinical deterioration and sepsis.

Given that infected necrosis has such substantial impact on prognosis, numerous studies have assessed the ability of prophylactic antibiotics to prevent infection in patients with preexisting sterile pancreatic necrosis. Data are unconvincing,[7] and current practice guidelines do not endorse prophylactic antibiotics in sterile pancreatic necrosis.

Fluid collections around the pancreas are common in acute pancreatitis and do not require any specific therapy. Most will resolve spontaneously, whereas some will mature into an encapsulated pseudocyst. It is important to distinguish a pseudocyst (usually outside the confines of the pancreas and filled with fluid) from an area of necrosis (usually inside the confines of the pancreas and a mixture of solid and liquid material). Therapy is not needed for asymptomatic pseudocysts, even if they are large, but therapy is indicated for pseudocysts that cause abdominal pain, obstruct a surrounding hollow viscus, or are associated with infection or bleeding. Bleeding may be limited to within the pseudocyst itself or may reach the intestine through the pancreatic duct if the pseudocyst is in communication with the duct. In some patients, bleeding into the pseudocyst may be caused by a pseudoaneurysm of a nearby visceral artery; this type of bleeding may be massive. Unexplained gastrointestinal bleeding or a sudden, unexplained drop in the hematocrit in a patient with pancreatitis or a pseudocyst should prompt an emergent CT scan, followed by embolization if a pseudoaneurysm is identified. A pseudocyst can be treated successfully using endoscopic, percutaneous or surgical techniques, and the choice among these approaches can be determined by local expertise.

Prevention of Relapse

Preventing relapse requires a clear knowledge of the precipitating causes. Abstinence from alcohol (Chapter 32) and tobacco (Chapter 31) should be strongly encouraged, including referral to appropriate resources. Cholecystectomy (Chapter 158) prevents subsequent attacks of gallstone pancreatitis and should be accomplished within a few weeks of discharge, if not sooner, if gallstones are the cause. In patients who have gallstone pancreatitis but who are not surgical candidates, endoscopic sphincterotomy provides reasonable protection from subsequent attacks. Control of serum lipids (Chapter 213) prevents subsequent attacks of hyperlipidemic pancreatitis. Therapy of lesions that obstruct the pancreatic duct, such as strictures, ampullary adenomas, and possibly sphincter of Oddi dysfunction and pancreas divisum, may also prevent relapse.

TABLE 146-3 COMPLICATIONS OF ACUTE PANCREATITIS

COMPLICATION	EXAMPLES
Systemic complications	Hypotension and shock Adult respiratory distress syndrome Acute renal failure Disseminated intravascular coagulation Hypocalcemia Hypertriglyceridemia Hyperglycemia Encephalopathy and coma
Gastrointestinal bleeding	Stress ulceration Pseudoaneurysm
Local (pancreatic) complications	Acute fluid collection Pseudocyst Pancreatic necrosis (infected and sterile) Duodenal and biliary obstruction

PROGNOSIS

More than 80% of all patients with acute pancreatitis recover promptly without developing severe pancreatitis. Mortality is usually from progressive multiple-organ system failure, either from the acute pancreatitis itself or from hospital-acquired infections, including infection of pancreatic fluid collections and pancreatic necrosis. The presence of early organ failure (within 24 hours of admission), multiple-organ system failure, and persistent

or progressive (present beyond 48 hours after admission) organ failure are associated with prolonged hospitalization, ICU admission, need for surgery, and death. Overall mortality is about 2% but can be as high as 20% in patients referred to tertiary hospitals. Mortality can approach 30% in patients with more severe comorbid conditions and in patients who develop pancreatic necrosis, infection, or organ system failure. Although high-quality ICU care minimizes mortality, no specific therapy is currently available to affect these risks.

CHRONIC PANCREATITIS

DEFINITION

Chronic pancreatitis, which is a complex process rather than an isolated event, implies the presence of irreversible and permanent fibrosis, often with chronic mononuclear cell inflammation, damage to nerves, and loss of ducts, acini, and islets. Chronic pancreatitis evolves after episodes of acute pancreatitis, which may be subclinical, but the transition between acute and chronic pancreatitis may be difficult to identify.

EPIDEMIOLOGY

The prevalence of symptomatic chronic pancreatitis in Western countries is about 25 to 30 per 100,000 population, with an estimated incidence of 3 to 9 cases per 100,000. In the United States, chronic pancreatitis accounts for about 125,000 outpatient visits and 25,000 hospitalizations yearly. Interestingly, the prevalence of histologic evidence of chronic pancreatitis in autopsy studies approaches 5%, indicating that many people apparently develop chronic pancreatic damage as a consequence of normal aging, other diseases, or exposure to toxins, such as consumption of alcohol, but do not develop any symptoms or signs of chronic pancreatitis during life.

PATHOBIOLOGY

Multiple episodes of acute inflammation, whether clinical or subclinical, eventually change the inflammatory milieu of the pancreas, with a shift to chronic inflammation, the activation of pancreatic stellate cells, and the production of fibrosis. This process is self-sustaining and produces the characteristic histologic damage noted previously. Genetic mutations predispose to chronic pancreatitis, but the genetic predisposition is superimposed on exposure to various toxins, which precipitate acute pancreatitis, with cellular necrosis or apoptosis, that progresses in some individuals, particularly those with multiple episodes, to a chronic and fibrotic process. In Western countries, alcohol and tobacco abuse are the dominant causes of chronic pancreatitis.

One important contributor to the pain in chronic pancreatitis is damage to pancreatic nociceptive nerves and the complex neuroimmune interaction driven by the chronic inflammatory state. Chronic pain produces visceral, spinal cord, and central hyperalgesia, and the pain may become self-perpetuating even if therapy on the pancreas is successful. In addition to this neural mechanism, increased pressure within the gland, associated ischemia, obstruction of the pancreatic duct, and a pseudocyst can cause pain.

Alcohol and Tobacco

Alcohol (Chapter 32) causes about 70 to 80% of all cases of chronic pancreatitis in the United States and other major industrial countries. Substantial and prolonged ingestion of alcohol is usually required, on the order of 5 to 8 drinks daily over more than 5 years. Most people who consume this much alcohol do not develop chronic pancreatitis, pointing to important cofactors such as genetic background and cigarette smoking. There is evidence that tobacco alone (Chapter 31) can cause chronic pancreatitis, and the combination of alcohol and tobacco may be synergistic. Most patients will present initially with an episode of acute pancreatitis but will shortly thereafter develop evidence of chronic pancreatitis, but others will have obvious chronic pancreatitis at their first presentation.

Genetic

Hereditary pancreatitis is an autosomal dominant disease characterized by early onset of acute and chronic pancreatitis, the development of exocrine and endocrine pancreatic insufficiency, and a high risk of pancreatic adenocarcinoma. Mutations in the trypsinogen (*PRSS1*) gene in these families appear to cause a gain in function in which the mutant trypsinogen, once activated to trypsin, is difficult to inactivate. This trypsin, if present in an amount that overwhelms normal protective mechanisms, can activate other pancreatic enzymes and lead to pancreatic damage and eventually to chronic pancreatitis. One of the protective mechanisms is a trypsin inhibitor called *SPINK1*. Loss of function mutations in *SPINK1* may predispose to chronic pancreatitis, but unlike *PRSS1* mutations, are not sufficient to cause chronic pancreatitis. Major mutations in *CFTR* lead to cystic fibrosis (Chapter 89), which is associated with chronic pancreatitis and pancreatic atrophy. Milder mutations in *CFTR*, which predispose to chronic pancreatitis without causing the sinopulmonary features of cystic fibrosis, are encountered in patients with idiopathic chronic pancreatitis.

Other Causes

Autoimmune pancreatitis is a disease that most often presents as a masslike lesion with obstructive jaundice, mimicking cancer, but it also may present as chronic pancreatitis and rarely as acute pancreatitis. Characteristic features of the disease include a diffuse swelling of the pancreas, elevations in serum immunoglobulin G4 (IgG4), and involvement of other organs, especially biliary strictures, salivary gland inflammation, retroperitoneal fibrosis, and renal lesions. Histologically, these organs are infiltrated by chronic inflammatory cells, especially plasma cells bearing IgG4 on their surface.

Tropical pancreatitis is seen primarily in southern India. Characteristic features include childhood onset, exocrine insufficiency, diffuse pancreatic calcifications, and inevitable diabetes. There may be a genetic component (*SPINK1*), but cofactors such as malnutrition and dietary toxins have been suggested. In southern India, this disease is becoming uncommon and is being replaced by alcohol as the most common cause of idiopathic chronic pancreatitis.

Although most chronic pancreatitis evolves from multiple episodes of acute pancreatitis, a single severe acute attack that causes substantial pancreatic necrosis can destroy enough gland to produce exocrine and endocrine insufficiency. In addition, diseases that cause repeated attacks of pancreatitis can lead to chronic pancreatitis. For example, *hypertriglyceridemia* causes acute pancreatitis but commonly leads to chronic pancreatitis.

In about 20% of patients, no clear cause of chronic pancreatitis is found. Some patients may have underlying genetic mutations, and others may be surreptitiously using alcohol or tobacco. Two general forms of idiopathic chronic pancreatitis are seen. In the first, pain is the predominant feature, and the onset of disease is in young adulthood. In the second, the onset is in middle age, and exocrine and endocrine insufficiency, rather than abdominal pain, are the major clinical manifestations.

CLINICAL MANIFESTATIONS

The most common symptom of chronic pancreatitis is abdominal pain. The pain may be episodic or constant, and it is generally felt in the epigastrium with radiation to the back. If pain is episodic, the patient may be labeled as having acute pancreatitis or an acute flare of chronic pancreatitis. When pain is severe, nausea and vomiting may occur. Pain may worsen, improve, or remain stable over time. Up to 5% of patients do not have pain and instead present with exocrine (steatorrhea, weight loss) or endocrine (diabetes) pancreatic insufficiency. The disease tends to be progressive over time, even if the original cause (e.g., alcohol) is removed. The pathophysiology of pain is complex.

DIAGNOSIS

The diagnosis may be suspected based on the clinical features but should be confirmed by tests that identify structural damage to the pancreas or derangements in pancreatic function (Table 146-4). Chronic pancreatitis is a slowly

TABLE 146-4 DIAGNOSTIC TESTS FOR CHRONIC PANCREATITIS

STRUCTURAL	FUNCTIONAL
Biopsy	Hormonal (secretin) test
Endoscopic ultrasound	Fecal elastase
Endoscopic retrograde cholangiopancreatography	Serum trypsin
Magnetic resonance imaging with magnetic resonance cholangiopancreatography	Fecal fat
Computed tomography	Blood glucose
Ultrasonography	
Plain x-ray	

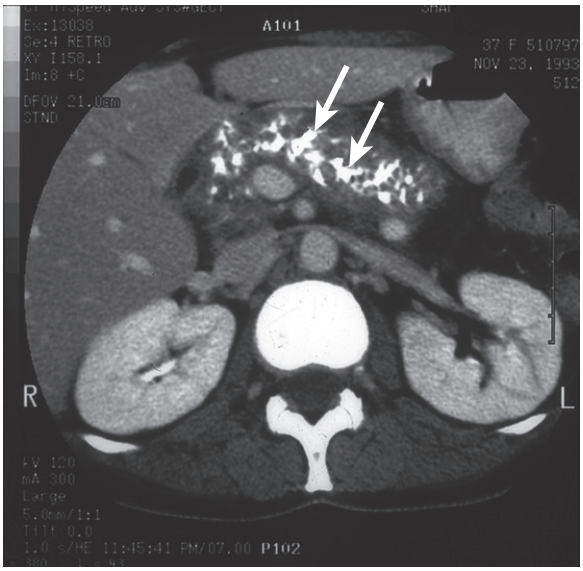

FIGURE 146-2. A computed tomography scan demonstrating diffuse pancreatic calcification in a patient with long-standing chronic pancreatitis *(arrows)*.

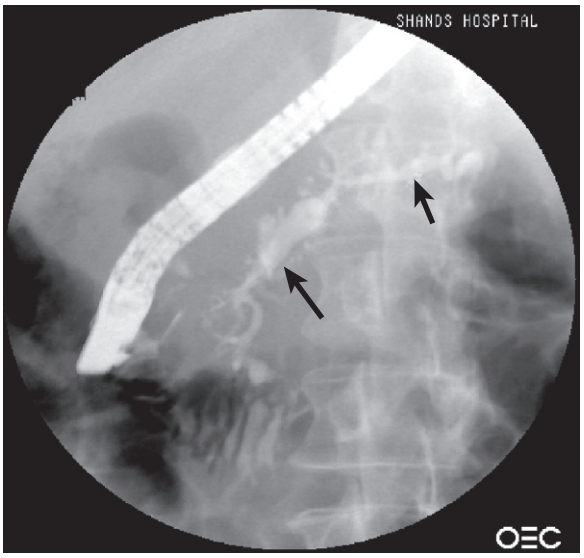

FIGURE 146-3. Endoscopic retrograde cholangiopancreatography demonstrating a very irregular pancreatic duct with areas of dilation and structuring in a patient with chronic pancreatitis *(arrows)*.

progressive disease in which visible damage to the gland (e.g., on a CT scan) and functional failure (e.g., steatorrhea or diabetes) may not be apparent for years. All diagnostic tests are most accurate when the disease is far advanced, and all are far less accurate in the early stages of disease.

Tests of Pancreatic Structure

Plain abdominal radiographs may demonstrate diffuse or focal pancreatic calcification in patients with advanced chronic pancreatitis. Although specific for chronic pancreatitis, these findings are quite insensitive.

Abdominal ultrasound is of limited utility because overlying gas often limits the ability to visualize the pancreas. An abnormal pancreatic duct, pancreatic calcifications, gland atrophy, or changes in echotexture are seen in about 60% of patients.

CT is the most widely used diagnostic test for chronic pancreatitis, and high-quality images can be obtained of the pancreas and pancreatic duct. Characteristic findings include a dilated pancreatic duct, ductal or parenchymal calcifications, and atrophy (Fig. 146-2). These structural changes take years to develop, so CT is not as accurate in early or less advanced disease. Like CT, MRI allows detailed images of the pancreas, and the addition of MRCP allows even better assessment of pancreatic duct morphology. At some centers, secretin is administered at the time of MRCP to allow better visualization of the pancreatic duct.

ERCP provides the most detailed images of the pancreatic duct. Changes in the duct, including dilation, irregularity, ductal stones, and strictures, can be appreciated (Fig. 146-3). These findings are not completely specific for chronic pancreatitis and can be seen in other situations, including with pancreatic cancer and in very elderly individuals. ERCP carries risk but has the advantage of providing both diagnostic and therapeutic impact.

EUS allows very detailed images of pancreatic parenchyma and duct (Fig. 146-4). A normal EUS essentially excludes chronic pancreatitis, whereas a very abnormal EUS is highly consistent with chronic pancreatitis.

Tests of Pancreatic Function

Serum trypsinogen (also called *trypsin*) is abnormally low in patients with far advanced chronic pancreatitis but is often normal in patients with less advanced disease. Levels lower than 20 ng/mL are seen in patients with chronic pancreatitis that is sufficient to cause functional failure (e.g., steatorrhea). Serum levels of amylase or lipase are not useful for chronic pancreatitis. Serum glucose levels will be elevated in those with endocrine insufficiency.

Quantification of fat in stool during a 72-hour collection while on a high-fat diet can be used to document steatorrhea (Chapter 142) but is rarely performed. Qualitative analysis of fat with Sudan staining of a stool specimen has poor sensitivity and specificity. Fecal levels of pancreatic elastase are diminished to less than 100 µg/g in patients with advanced chronic pancreatitis and steatorrhea. The test can be performed while patients are taking pancreatic enzyme therapy.

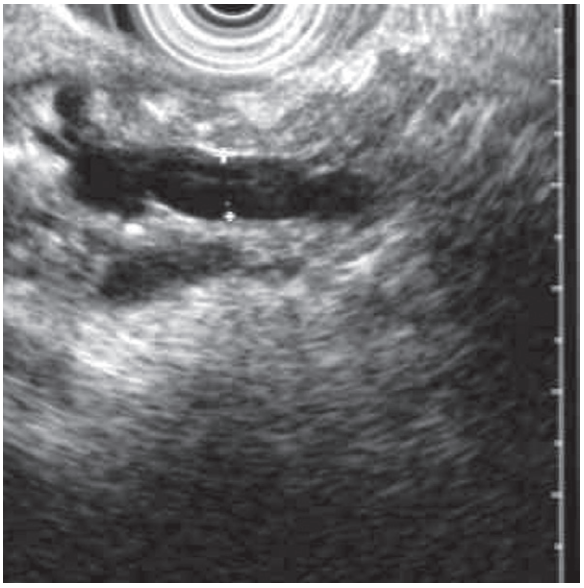

FIGURE 146-4. Endoscopic ultrasound in a patient with chronic pancreatitis, demonstrating a dilated pancreatic duct (*marks* on margin of main duct).

For a pancreatic function test, a tube is passed into the duodenum, where pancreatic secretions are collected over the course of 1 hour in 15-minute aliquots and analyzed for bicarbonate concentration after a supraphysiologic dose of secretin is administered. A normal study is defined by at least one of the samples having a bicarbonate concentration of more than 80 mEq/L. The test becomes abnormal earlier in the disease process than any other test, so it is well suited to diagnose chronic pancreatitis earlier in its clinical course; however, it is not widely available. An alternative, using endoscopy instead of a tube, is possible but somewhat less sensitive.

Diagnostic Approach

As the disease advances over years, structural and functional damage accumulate to the point that essentially all diagnostic tests are positive. In most patients, the diagnosis is established by routine tests such as CT or MRI; EUS and ERCP are rarely needed for diagnostic purposes in patients with long-standing chronic pancreatitis. The diagnostic challenge lies with patients who present with a severe pain syndrome suggestive of chronic pancreatitis but who have a normal CT or MRI. In these patients, EUS is the best choice

unless the physician has access to a secretin-based pancreatic function test. ERCP should not be used for purely diagnostic purposes because patients with a normal-appearing pancreas are particularly prone to complications, especially post-ERCP pancreatitis.

TREATMENT

Abdominal Pain

A search for specifically treatable complications should be undertaken before initiating therapy for pain. Causes include a pseudocyst, obstruction of a surrounding hollow organ (e.g., duodenum or bile duct), or superimposed carcinoma. A good-quality CT or MRI image is usually sufficient to exclude these possibilities. These imaging tests also help in choosing appropriate therapy. Patients with a dilated pancreatic duct (generally >5 mm) are candidates for endoscopic and surgical therapy, which involves decompression of the dilated duct. Patients without duct dilation are generally not appropriate for endoscopic and surgical therapy and must rely instead on medical therapy (Table 146-5).

Medical therapy starts with vigorous attempts to assist patients in stopping alcohol and tobacco, if applicable. Most patients will require analgesics. It is appropriate to start with the less potent agents first, such as tramadol (50 mg, usually starting at one dose given every 6 hours). In patients who require more potent narcotics, it may be helpful to add an adjunctive antidepressant (e.g., amitriptyline, starting at 50 mg at night), selective serotonin reuptake inhibitors (see Table 404-5 in Chapter 404), gabapentin (starting at 100 mg at night), or pregabalin (starting at 50 mg three times daily). Antioxidants (mixtures of selenium, vitamins E and C, β-carotene, and methionine) may also have some beneficial effect on pain.[8] Finally, pancreatic enzyme therapy may have some beneficial effect on pain. Non-enteric-coated (tablet) pancreatic enzymes can reduce pancreatic stimulation and reduce pain by digesting a releasing factor present in the duodenum and providing negative feedback on the pancreas; conversely enteric-coated preparations, which are not active in the duodenum, have no proven effect on pain. These nonenteric preparations are not currently approved for clinical use but must be given with an agent to reduce gastric acid because acid will denature the proteases in these tablets. Autoimmune pancreatitis responds promptly to steroid therapy (usually 40 mg of prednisone daily for 4 weeks, with a taper of 5 mg/week over the next 7 weeks), but relapse may occur, particularly in the biliary tree.

Nerve Block and Neurolysis

EUS-guided celiac plexus block, using a local anesthetic and a steroid, or neurolysis, using absolute alcohol, can be performed relatively easily and safely, but substantial relief of pain is achieved for only weeks or months.[9] This therapy generally is considered only as a temporizing measure to provide relief from debilitating pain.

TABLE 146-5 TREATMENT FOR PAIN

TREATMENT	EXAMPLES
Medical therapy	Alcohol and tobacco cessation Analgesics and adjunctive agents Tramadol, 50 mg, one to three times daily Amitriptyline, starting at 50 mg at night Selective serotonin reuptake inhibitors (citalopram, fluoxetine, sertraline, paroxetine, and others) at recommended starting dose (see Table 404-5 in Chapter 404) Gabapentin, starting at 100 mg at night Pregabalin, starting at 50 mg three times daily Antioxidants Typical mixture containing vitamin C (1000 mg), vitamin E (300 IU), selenium (500 µg, methionine 2 g, and β-carotene 10,000 IU) total daily dose Non-enteric-coated enzymes (see Table 146-6)
Neurolysis	Endoscopic ultrasound–guided celiac plexus block or neurolysis Thoracoscopic splanchnicectomy
Endoscopic therapy	Stent Stone removal, lithotripsy
Surgical therapy	Pancreaticojejunostomy (modified Puestow operation) Partial pancreatic resection (Whipple operation, duodenum-preserving pancreatic head resection, others) Total pancreatectomy with islet cell autotransplantation

Endoscopic Therapy and Lithotripsy

At the time of ERCP, strictures can be dilated, and stents can be placed across the stricture. Ductal stones, if they are not too large and are not affected, may also be removed. Lithotripsy of larger stones is usually required to reduce the stone to fragments that are manageable. Only a subset of patients with chronic pancreatitis has ductal anatomy that is amenable to this type of therapy. In large case series from expert centers, therapy is technically successful in more than 80% of carefully selected patients, and pain relief may be seen in 70 to 80% of patients who undergo therapy. In patients with large stones, intraductal or extracorporeal lithotripsy is needed.

Surgical Therapy

Surgery for chronic pancreatitis is more effective and more durable than endoscopic therapy.[10,11] Surgery can involve decompression of the pancreatic duct, resection of the pancreas, or a combination of the two. The most commonly performed procedure, the modified Puestow procedure, involves a longitudinal incision of the pancreatic duct from the body of the pancreas to as close to the duodenum as possible, and this filleted duct is overlaid with a defunctionalized Roux limb. At the time of surgery, ductal strictures can be incised, and ductal stones can be removed. The procedure is relatively simple in patients with a dilated pancreatic duct (>5 mm). Pain relief in the short term is good (>80%), with about 50% obtaining long-term relief of pain. Alternative surgical procedures for pain include some resection of the pancreas, typically the head of the gland, in patients who have an inflammatory mass that causes biliary or duodenal obstruction. These operations, which include the classic pancreaticoduodenectomy (Whipple operation), provide equal short-term pain relief and better long-term pain relief than a modified Puestow, but with a higher morbidity. Total pancreatectomy, usually coupled with autotransplantation of harvested islet cells, is performed at a small number of centers but is generally considered a therapy of last resort, given the fact that diabetes mellitus is common after the procedure and pain relief is inconsistent.

Exocrine Insufficiency

Steatorrhea and maldigestion do not occur until approximately 90% of pancreatic enzyme secretion is lost, usually after 5 to 10 years of disease or even longer. Patients may note weight loss and oily stools, but often do not complain of diarrhea. Patients with chronic pancreatitis and exocrine insufficiency maldigest fat, protein, and carbohydrates, but fat maldigestion is usually most severe. In addition to weight loss, malabsorption of fat-soluble vitamins, particularly vitamin D, may occur. The diagnosis of exocrine insufficiency is usually suggested by symptoms of oily or floating stools and weight loss. A formal 72 stool fat analysis (Chapter 142) is the most accurate method to document steatorrhea and to gauge effectiveness of therapy but is rarely done. Instead, the clinical features and a fecal elastase of less than 100 µg/g stool, coupled with an appropriate response to enzyme replacement therapy, is the best substitute for 72-hour fecal fat testing.

Enzyme therapy (Table 146-6), which significantly reduces fecal fat levels and may reduce weight loss,[12] is divided into enteric-coated capsules and non-enteric-coated tablets. Non-enteric-coated preparations, as noted previously, are not clinically available but theoretically are the agents of choice if the goal is to treat pain. However, the enteric-coated preparations are used more frequently for exocrine insufficiency because they are more potent and require fewer pills. Enzymes are identified by the lipase content of the pill or capsule, although they all contain proteases and amylase as well. The goal of enzyme therapy, which is to administer at least 10% of normal pancreatic output with each meal, translates to approximately 30,000 IU of lipase with each meal. Most current products are measured in U.S. Pharmacopeia (USP) units, which are one third the amount of an international unit (IU) (e.g., up to 90,000 USP units of lipase with each meal). Because most patients are still producing some enzymes (including gastric lipase), it is usually not necessary to use the full dosage of 90,000 USP units with each meal.

Enzymes should be split during the meal (e.g., equally split before, during, and immediately after the meal). Supplementation with vitamin D (400 to 1000 IU daily) and calcium (1.0 to 1.5 g daily) is appropriate because osteoporosis (Chapter 251) and osteopenia are common. Success of enzyme therapy is generally defined as weight gain and reduction or absence of visible oil in the stool. Failure of enzyme therapy is most often due to inadequate dose. Increasing the dose up to the full 90,000 USP units with meals and encouraging compliance are appropriate as a first step. Some enteric-coated preparations may not release sufficient enzymes in the small bowel unless they are used with an agent to reduce gastric acid. Some patients may not respond owing to the presence of a second disease that also causes malabsorption, such as small intestinal bacterial overgrowth.

Endocrine Insufficiency

Like exocrine insufficiency, diabetes mellitus (Chapter 236) is a very late complication of chronic pancreatitis, occurring years or decades after disease onset. Unlike type 1 diabetes mellitus, there is destruction of the entire islet, which reduces secretion of both insulin and glucagon. As a result, overly aggressive therapy may lead to hypoglycemia, which cannot be reversed by

TABLE 146-6 ENZYME THERAPY FOR EXOCRINE INSUFFICIENCY*

AGENT†	DOSAGE
Creon 6000	10-15 with meals
Creon 12,000	5-8 with meals
Creon 24,000	3-4 with meals
Zenpep 5,000	12-18 with meals
Zenpep 10,000	6-10 with meals
Zenpep 15,000	4-6 with meals
Zenpep 20,000	3-5 with meals

the usual natural glucagon surge. In most patients, therefore, insulin treatment is not aimed at exceedingly tight glucose control. Unfortunately, these patients are at similar risk for microvascular complications, as are all other patients with diabetes.

Complications

Pancreatic Pseudocyst

Pseudocysts, when they are discovered in patients with chronic pancreatitis, are generally mature and have a visible capsule surrounding them. As in acute pancreatitis, benign pseudocysts in chronic pancreatitis do not require therapy if they are not producing symptoms and are not rapidly enlarging. However, some cystic structures in and around the pancreas are cystic neoplasms, not pseudocysts. Symptomatic pseudocysts require drainage, whereas neoplasms require resection. Features that suggest a cystic neoplasm include a cyst with a thick or nodular wall, a cyst with multiple internal septations, or a cyst occurring in a patient who does not have a history of pancreatitis. Any combination of these features should lead to further investigation, generally with EUS and cyst aspiration.

Symptomatic pseudocysts can be treated with endoscopic, percutaneous, or surgical therapy with equal efficacy. In many centers, EUS-guided drainage is becoming first-line therapy. Both short-term and long-term results are excellent. Complications of pseudocysts include infection, bleeding, and rupture. A visceral artery pseudoaneurysm, which may develop as a consequence of a pseudocyst, can bleed torrentially, sometimes preceded by a brief self-limited bleed that stops when the blood is tamponaded within the pseudocyst. If the pseudocyst is in continuity with the pancreatic duct, blood may traverse the duct and enter the duodenum to cause melena; this release of pressure can produce exsanguinating bleeding. Any evidence of gastrointestinal bleeding or unexplained anemia in a patient with known pseudocyst or pancreatitis should raise the possibility of pseudoaneurysm. Embolization of the pseudoaneurysm is highly effective.

Pseudocysts may leak into the peritoneal compartment (pancreatic ascites) or track into the chest (pancreatic pleural effusion). Patients usually present with abdominal distention or dyspnea, rather than abdominal pain. Amylase level in the fluid is usually higher than 4000 U/L. Endoscopic therapy with stent placement across the connection between pseudocyst and pancreatic duct is highly effective in this situation (Fig. 146-5).

Malignancy

Chronic pancreatitis is a strong risk factor for pancreatic ductal adenocarcinoma (Chapter 200), with a lifetime risk of about 4%. The risk of cancer is much greater in patients with hereditary pancreatitis, in whom the risk may range as high as 40 to 70%. Equally importantly, it may be difficult to distinguish cancer from benign disease, particularly in patients with autoimmune pancreatitis.

PREVENTION

Currently, there are no reliable methods to prevent chronic pancreatitis. Patients at risk for chronic pancreatitis, such as members of families with hereditary pancreatitis and patients with established chronic pancreatitis, should avoid alcohol and tobacco and should probably be placed on a low-fat diet.

PROGNOSIS

With prolonged follow-up of 10 to 20 years, most patients will develop exocrine or endocrine insufficiency. The overall mortality is increased 3.6-fold compared with age-matched controls. Patients who are older, smoke, or have alcohol as the cause are at highest risk of mortality. Overall, 10-year survival approximates 70%, and 20-year survival is about 45%. Death is usually not due to pancreatitis itself, but rather to malignancy, postoperative complications, and complications of alcohol or tobacco.

147 DISEASES OF THE RECTUM AND ANUS

ROBERT D. MADOFF

DEFINITIONS

The rectum is best defined anatomically as the level of the large intestine where the taeniae coli splay to form a continuous longitudinal muscle layer. As a practical matter, the rectum begins about 15 cm proximal to the anal margin or verge, where the anus meets the perianal skin. The junction of the colon and rectum bears a variable relationship to the peritoneal reflection, which lies obliquely and at a variable distance from the anal margin.

The anus can be defined both anatomically and histologically. As a practical matter, it is best defined as the distal-most segment of the large bowel that extends from the pelvic floor muscles (levator ani) to the skin. The anorectal junction can be recognized as the point where the rectum angulates posteriorly from the axis of the anal canal. This junction, easily appreciated on digital rectal examination, is caused by the anterior pull of the puborectalis, a U-shaped muscle that loops behind the anorectal junction and pulls it forward. The puborectalis plays an important role in continence, and it is in continuity with the proximal external anal sphincter.

The dentate line lies about 2 cm proximal to the anal margin and roughly corresponds to the level where the distal squamous mucosa meets the more proximal columnar mucosa. Approximately 6 to 12 anal glands located around the perimeter of the dentate line can become infected and become the source of perianal abscesses and fistulas. The anal transition zone, which extends 1 to 2 cm proximal to the dentate line, is the site where many anal cancers develop and marks the proximal boundary for anal cancer surveillance. Hemorrhoids are classified based on their relationship to the dentate line: those proximal are deemed internal, and those distal are external. Anal papillae, the small triangular points of the dentate line, can become hypertrophied and may be mistaken for polyps. Finally, somatic sensation ceases 1 to 2 cm above the dentate line, which explains why hemorrhoid ligation can be performed without anesthesia.

The anal sphincter complex has three major components: the puborectalis, the external anal sphincter, and the internal anal sphincter. The external anal sphincter is composed of skeletal muscle and is under voluntary control. The internal anal sphincter is composed of smooth muscle and represents a continuous though thickened extension of the circular muscle coat of the rectum. The internal anal sphincter is responsible for about 70% of resting anal tone; augmentation of anal sphincter pressure occurs when the individual contracts the external anal sphincter.

SPECIFIC ANORECTAL CONDITIONS

Hemorrhoids

EPIDEMIOLOGY AND PATHOBIOLOGY

The prevalence of hemorrhoids in the United States has been estimated to be 4.4%. However, because many "hemorrhoidal" symptoms are in fact due to other causes, the true incidence and prevalence are unknown.

Despite the commonly held notion that hemorrhoids are always pathologic, hemorrhoids are normal structures, identifiable even in the fetus. Hemorrhoids are vascular cushions that consist of both arterioles and veins. The arteriolar component explains why hemorrhoidal bleeding is typically bright red in color and can be copious in quantity. Hemorrhoids are *not* rectal varices, which are a distinct entity caused by portal hypertension. Many causative factors have been proposed, including constipation, diarrhea, pregnancy, and prolonged straining at stool. Although none of these precipitating factors has been rigorously proved, each can cause either increased abdominal pressure or obstruction of venous return, leading to engorgement and enlargement of the vascular cushions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptom of internal hemorrhoids is bright red rectal bleeding. This bleeding is typically painless and is most often seen on the toilet tissue or in the toilet bowel. The quantity of blood is variable, but some patients complain of blood dripping or squirting into the toilet bowl. Passage of dark blood or blood mixed in the stool suggests a more proximal source. Internal hemorrhoids are classified based on the symptoms they cause. As internal hemorrhoids enlarge, they become associated with redundant rectal mucosa that protrudes from the anus with defecation. Grade 1 hemorrhoids bleed but do not prolapse. Early protrusion reduces spontaneously (grade 2); more advanced protrusion requires digital reduction (grade 3) and, at its most advanced, becomes irreducible (grade 4). Internal hemorrhoids are insensate and are not itchy themselves, but they can cause itching due to associated perianal soiling or mucus deposition caused by mucosal prolapse.

Individuals with anorectal symptoms frequently present complaining of "hemorrhoids." It is always incorrect—and sometimes dangerous—for the physician to apply this diagnosis without completing an adequate evaluation. Fortunately, the initial evaluation is simple, and the correct diagnosis is often suspected based on history alone and confirmed by a limited endoscopic examination. For example, rectal bleeding should never be attributed to hemorrhoids alone, even if hemorrhoids are visible; at a minimum, sigmoidoscopy is required to exclude more proximal pathology. Internal hemorrhoids are best visualized with a slotted anoscope.

External hemorrhoids are usually asymptomatic and should be differentiated from perianal skin tags, which occasionally cause difficulties with hygiene. External hemorrhoids become symptomatic when they thrombose to cause acute-onset pain and swelling (Fig. 147-1). Thrombosed external hemorrhoids are diagnosed by simple inspection.

TREATMENT

Rx

Grade 1 hemorrhoids often respond to dietary manipulation: increased dietary fiber, addition of a fiber supplement, and increased water intake (Table 147-1). The goal, which may not be readily achievable, is approximately 25 g of fiber and 8 glasses of water daily. More advanced hemorrhoids require specific therapy, which is almost always office based. The most popular and simplest technique is rubber band ligation, whereby a tiny rubber band (internal diameter approximately 1 mm) is placed around a quantity of redundant rectal mucosa above the prolapsing hemorrhoid. The banded tissue sloughs in 7 to 14 days, an event sometimes heralded by rectal bleeding. Banding can be repeated at 3- to 4-week intervals until bleeding and protrusion are controlled. Bands placed too close to the dentate line cause immediate severe pain and must be removed promptly. Alternative therapies for moderate internal hemorrhoids include injection sclerotherapy and infrared coagulation, which can be performed in the office.

Operative hemorrhoidectomy is needed in only a small minority of patients. Indications for hemorrhoidectomy include irreducible prolapse, a substantial external component, and failure of more conservative therapies. The most common approach is an excisional hemorrhoidectomy, which is generally performed on an outpatient basis. A more recent approach is the stapled hemorrhoidopexy, which entails resecting a ring of rectal mucosa proximal to the internal hemorrhoids using a circular stapling device. This technique is quicker than conventional hemorrhoidectomy and is associated with less postoperative pain and a shorter period of disability; its drawbacks include a higher recurrence rate than conventional surgery and a small but worrisome risk of significant complications. Another alternative approach is Doppler-guided transanal devascularization of internal hemorrhoids, which is directed at obliterating the feeding arterioles. Although early results are promising, the experience to date is limited, and follow-up is short.

External hemorrhoids are usually treated by excision in the office under local anesthesia. However, because the pain associated with thrombosis generally abates within 7 to 10 days, patients who present with resolving symptoms are often best managed conservatively with standard doses of over-the-counter analgesics, sitz baths, and 25 g/day fiber supplementation.

Perianal Abscess

EPIDEMIOLOGY AND PATHOBIOLOGY

Although perianal abscess is a common condition, its exact incidence is not well documented. Most perianal abscesses are caused by infection of the anal glands that track toward the skin. Other causes include simple skin infections, trauma, anorectal surgery, and malignancy.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients most commonly present with complaints of perianal pain and swelling. In most cases, a local area of erythema, tenderness, and fluctuance can be appreciated. However, local swelling, erythema, and fluctuance are often absent in an intersphincteric abscess, which is a small abscess in the plane

FIGURE 147-1. Thrombosed external hemorrhoids.

TABLE 147-1 INTERNAL HEMORRHOIDS: GRADING AND MANAGEMENT

GRADE	SYMPTOMS AND SIGNS	MANAGEMENT
1	Bleeding No prolapse	Dietary modifications* Rubber band ligation Infrared coagulation Injection sclerotherapy
2	Prolapse with spontaneous reduction Bleeding, seepage	Rubber band ligation Infrared coagulation Dietary modifications Injection sclerotherapy
3	Prolapse requiring digital reduction Bleeding, seepage	Surgical hemorrhoidectomy Rubber band ligation Dietary modifications
4	Prolapsed, cannot be reduced Strangulated	Surgical hemorrhoidectomy Urgent hemorrhoidectomy

*Dietary modifications include increasing the consumption of fiber, bran, or psyllium and water. Dietary modifications are always appropriate for the management of hemorrhoids and to prevent recurrence after banding or surgery (or both).
Adapted from Nelson H, Dozois RR. Anus. In: Townsend CM, ed. *Sabiston Textbook of Surgery*, 16th ed. Philadelphia: Saunders; 2001:979.

between the internal and external sphincter muscles; these abscesses are suspected based on the history of increasing pain and the physical finding of focal perianal tenderness.

As with all acutely painful anal conditions, digital examination should be avoided. Likewise, office instrumentation with an anoscope or proctoscope is contraindicated because these examinations cause substantial pain and yield little if any diagnostic information. When the cause of the acute pain cannot be determined in the office, prompt examination under anesthesia should be performed.

TREATMENT Rx

Treatment for perianal abscess is prompt incision and drainage, which can usually be performed in the office. Antibiotics do not adequately penetrate abscess cavities, and extension of a local infection can lead to severe local sepsis and complex long-term problems. Therefore, antibiotic therapy is inadequate and should never be given in an attempt to avoid or delay incision and drainage. Antibiotics usually are not indicated after incision and drainage; exceptions include immunocompromised patients (those with AIDS, transplant recipients, patients undergoing chemotherapy, diabetics) and those at high risk for endovascular infection (e.g., patients with cardiac shunts, prosthetic valves).

Anal Fistula

EPIDEMIOLOGY

An anal fistula represents the chronic form of a perianal abscess. The incidence of anal fistula is about 8.6 per 100,000. Fistulas are two to three times more common in men than in women.

PATHOBIOLOGY

After a perianal abscess is drained, there is about a 50% chance that the internal opening—the site at the dentate line where the infected gland originated—will remain patent, thereby leaving a source for recurrent infection. Multiple or atypical anal fistulas should always raise the diagnostic suspicion of Crohn's disease, which is isolated to the perianal area in approximately 10% of cases.

Anal fistulas are characterized by their relationship to the sphincter complex. The simplest fistula is intersphincteric—located in the plane between the internal and external sphincter muscles. Transsphincteric fistulas, which traverse both the internal and external sphincter muscles, are classified as low fistulas, which traverse only the distal external sphincter, or high fistulas, which traverse the more proximal portions of the external sphincter. Suprasphincteric fistulas loop over the entire sphincter complex. Extrasphincteric fistulas have internal openings remote from the dentate line; most originate from a pelvic abscess caused by a ruptured appendix (Chapter 144), diverticulitis (Chapter 144), or Crohn's disease (Chapter 143). A horseshoe fistula is one with external openings on both sides of the midsagittal plane; these most commonly have a single internal opening in the posterior midline.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Anal fistulas sometimes present as recurrent abscesses in the same location as the original one, and they sometimes present as persistent purulent drainage from an abscess site that has failed to heal completely. In either case, a persistent track between the external and internal openings remains.

The diagnosis of an anal fistula is established by history and by visualization of an external opening in the perianal skin. A fibrous fistula track can sometimes be palpated along the course of the fistula from the skin toward the anal canal. An internal opening is occasionally visible on anoscopy, but it is not necessary to identify one to make a presumptive diagnosis.

TREATMENT Rx

Treatment of anal fistulas is surgical. Most fistulas are cured by being laid open to eliminate the original source of infection at the internal opening. The fistula track heals by secondary intention. However, this approach divides sphincter muscle and puts the patient at risk for impaired fecal continence in proportion to the quantity of muscle involved. In general, intersphincteric and low transsphincteric fistulas can be safely laid open if the patient has normal baseline continence and no underlying predisposing factors for diarrhea (e.g., colitis) or recurrent fistulas (e.g., Crohn's disease). Because the anterior sphincter mechanism is relatively short and because the anterior sphincter is subject to injury following vaginal delivery, fistulotomy for anterior fistulas in women must be undertaken only after careful consideration.

Treatment of high fistulas is a challenge. When a high fistula is identified, the first step is often placement of a seton, a suture, or other material (now commonly a Silastic vessel loop) that is passed though the fistula track, out the anus, and secured to itself. The seton guarantees that the external fistula opening will not heal over, so a recurrent abscess cannot supervene. Once the track has "matured"—scarred around the seton and become fibrotic—treatment options to eliminate the internal opening include endorectal advancement flap repair and obliteration of the track using fibrin glue or a collagen fistula plug. For individuals with known or suspected Crohn's disease, fistulotomy is avoided, except for the most superficial fistulas. In general, patients with Crohn's disease are best served by placement of long-term draining setons and medical therapy for their underlying disease.

Anal Fissure

EPIDEMIOLOGY

Anal fissures can occur at any age but most frequently affect young adults. Men and women are equally affected.

PATHOBIOLOGY

An anal fissure is a longitudinal tear in the anoderm that occurs just inside the anal margin (Fig. 147-2). The underlying pathophysiology of anal fissures is hypertonia of the internal anal sphincter. Typical anal fissures occur at the midline; most commonly they occur posteriorly, but about 15% are found anteriorly or both anteriorly and posteriorly. "Off-the-midline" fissures should raise the question of other pathology such as anal cancer, Crohn's disease (Chapter 143), syphilis (Chapter 327), HIV, leukemia (Chapter 190), or tuberculosis (Chapter 332). Fissures may occur acutely owing to trauma but are more commonly a subacute condition.

FIGURE 147-2. Anal fissure.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with anal fissures generally have a typical presentation, and in most cases the correct diagnosis is suspected based on history alone. Following bowel movements, patients describe severe anal pain that may persist for hours or even continue until exacerbation by the next bowel movement. There is sometimes an association with minor red rectal bleeding, most commonly seen in small quantities on the toilet tissue. Anal fissures are frequently associated with a diagnostic triad: the fissure itself, a "sentinel" skin tag (so called because its presence should suggest the presence of an underlying fissure), and a hypertrophied anal papilla located just proximal to the fissure at the dentate line. Well-established fissures may have fibrotic margins and visible internal anal sphincter fibers at their base.

Most fissures can be readily seen on physical examination by applying opposing traction to the buttocks. Once a fissure is identified, no further examination is performed. Digital and endoscopic examination should generally be delayed until the patient has healed to avoid causing pain. However, patients should be advised that they will require subsequent sigmoidoscopy to exclude proximal pathology.

TREATMENT Rx

All therapies are directed at the underlying hypertonia of the internal anal sphincter. Approximately 40% of fissures heal with fiber supplementation and increased fluid intake. Patients are also advised to take warm sitz baths for symptomatic relief, especially following bowel movements.

Two pharmacologic approaches can augment diet and sitz baths: topical sphincter relaxants and botulinum toxin injection. Topical nitroglycerine ointment (0.2 to 0.5%) or diltiazem gel (2%) applied to the anal orifice two to three times daily reduces sphincter tone and usually leads to healing.[1] Both drugs have similar efficacy, but nitroglycerine has the significant disadvantage of causing headaches, lightheadedness, or syncope owing to systemic vasodilation in a substantial minority of patients; commercial 2% nitroglycerine ointment for cardiac use is too potent for perianal use. Botulinum toxin injection is another treatment option, but its usefulness is variable, and the risk of fissure relapse is significant.

For patients who fail medical therapy or who are simply too miserable to pursue it, lateral internal sphincterotomy is an appropriate and generally safe approach.[2] This simple operation is easily performed under monitored local anesthesia in an outpatient setting; recovery is rapid, and fissure healing is expected in more than 90% of cases. Sphincterotomy as first-line therapy provides higher healing rates, fewer relapses, and fewer side effects than topical nitroglycerine,[3] with fewer symptoms, greater satisfaction, and no difference in continence at long-term follow-up.[4] However, a small percentage of patients who undergo sphincterotomy develop minor seepage or actual incontinence, so sphincterotomy should be avoided in individuals who have underlying impaired continence, known sphincter injuries, or diarrheal disorders. When such patients have refractory fissures, a trial of botulinum toxin injection is often a good alternative.

Pruritus Ani

Pruritus ani, or perianal itching, is a very common complaint. It is a symptom and not a disease. The most common cause is inadequate perianal hygiene, often exacerbated by scratching, which leads to excoriation of the skin and further inflammation. Other causes include prolapsing hemorrhoids, anal fistulas, anal incontinence, and specific dermatologic conditions such as contact dermatitis (Chapter 446), psoriasis (Chapter 446), lichen sclerosus (Chapter 448), squamous intra-epithelial neoplasia (Bowen's disease), and perianal Paget's disease (intra-epidermal adenocarcinoma).

TREATMENT Rx

Most cases respond to treatment of the underlying pathology, improved hygiene, avoidance of potential contact allergens, and use of either talc to absorb excess moisture or a barrier cream such as zinc oxide. Some patients benefit from the avoidance of certain foods, including caffeinated beverages, alcohol, milk, chocolate, and tomatoes. Mild topical steroids such as 1% hydrocortisone are sometimes helpful, but stronger steroid preparations are frequently counterproductive and should be avoided when they are not indicated for a specific dermatologic diagnosis. Skin biopsies should be obtained when a primary dermatologic condition is suspected or when the perianal irritation fails to heal with conservative therapy.

Fecal Incontinence

EPIDEMIOLOGY AND PATHOBIOLOGY

Involuntary loss of stool or flatus is a relatively common problem that, when severe, can be socially isolating and debilitating. About 2% of individuals in the United States report incontinence symptoms, but the prevalence is substantially higher in patients visiting primary care providers and gastroenterologists. Almost half of U.S. nursing home patients suffer from fecal incontinence.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Fecal incontinence can be caused by many disorders. Sphincter disruption related to vaginal delivery is a common cause that often affects young women; many incontinent women who present later in life have an underlying sphincter injury for which they can no longer compensate. Other causes of incontinence include fecal impaction, surgical or traumatic sphincter injury, rectal prolapse, neurologic disorders (e.g., diabetic neuropathy, stroke, multiple sclerosis, brain or spinal cord injury), chronic diarrheal states, dementia, and impaired mobility.

Because incontinence is a symptom and not a disease, the diagnosis is based on history alone. Specific evaluation of the incontinent patient can include anal manometry, anal ultrasound, pudendal nerve testing, and defecography. Anal ultrasound, which is generally the most helpful test, accurately depicts sphincter anatomy and reliably identifies sphincter defects.

TREATMENT Rx

Mild incontinence is often treated successfully with dietary management, addition of a fiber supplement, and use of an antimotility agent such as loperamide 2 to 4 mg up to four times daily (Fig. 147-3). Biofeedback is successful in many patients. For individuals with sphincter disruption, surgical repair leads to substantial improvement in most patients. Sacral nerve stimulation is highly effective for fecal incontinence, although the implantable device has not yet been approved for this indication in the United States. In a randomized trial, transanal submucosal injections of dextranomer in stabilized hyaluronic acid reduced fecal incontinence by at least 50% with minimal adverse effects.[5] For patients with severe refractory incontinence, creation of a colostomy should be strongly considered. Initial reluctance notwithstanding, most patients regain control of their bowel function and report a substantially improved quality of life.

Rectal Prolapse

EPIDEMIOLOGY AND PATHOBIOLOGY

Rectal prolapse is a full-thickness protrusion of the rectum beyond the anal sphincter. The disorder can occur at any age, but prolapse is most frequently seen in older patients, and approximately 90% of adult patients are women. Prolapse is caused by an internal rectal intussusception that, as it becomes more severe, protrudes externally. Uncorrected prolapse frequently leads to

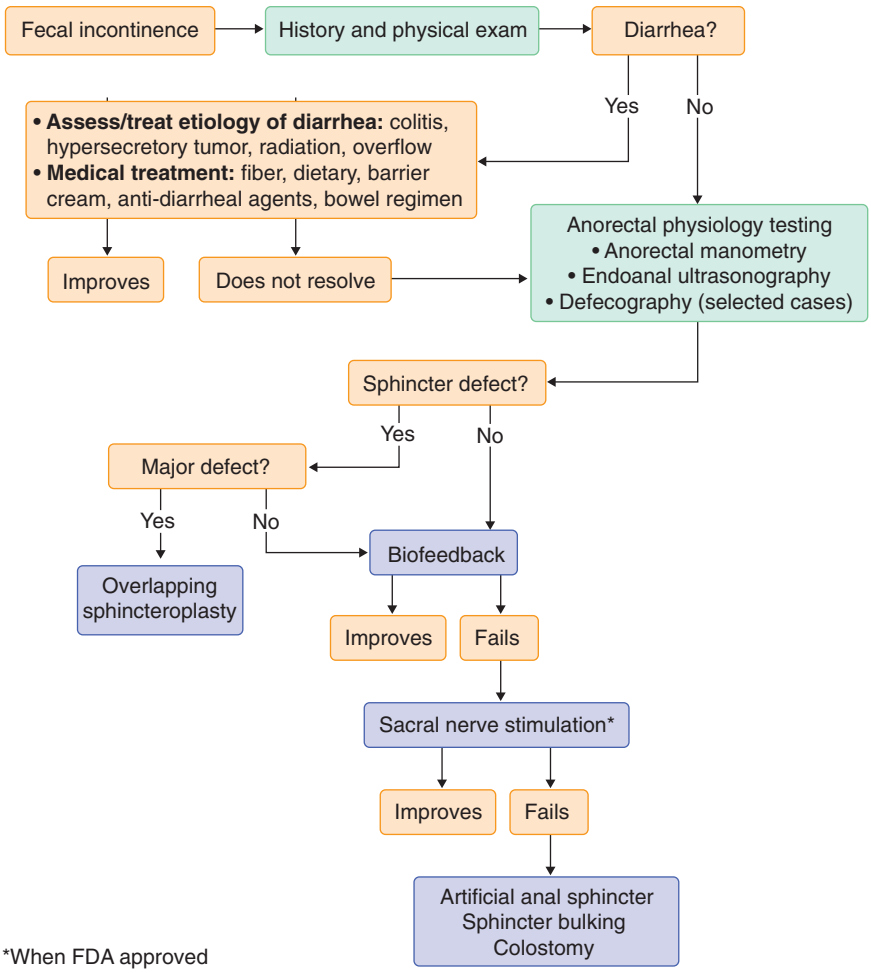

FIGURE 147-3. Algorithm for fecal incontinence. FDA = Food and Drug Administration. (Adapted from Madoff RD, Parker SC, Varma MG, Lowry AC. Faecal incontinence in adults. Lancet. 2004;364:621-632.)

fecal incontinence by mechanically stretching the sphincter complex and causing a stretch injury to the pudendal nerves.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The main clinical manifestation of rectal prolapse is the protruding rectal mass (Fig. 147-4). Most commonly the protrusion occurs with bowel movements, but with time it may occur with coughing or sneezing, and eventually it can occur spontaneously. Some patients present with complaints of fecal incontinence, and many also complain of "constipation," which may be caused by unsuccessful attempts to evacuate the intussuscepting rectum. The protruded rectum may cause minor bleeding and mucus discharge. Occasional patients present with an incarcerated or strangulated prolapse.

The diagnosis of rectal prolapse is confirmed on physical examination. Full-thickness prolapse, which is characterized by concentric mucosal folds, must be differentiated from circumferential mucosal prolapse, which is characterized by radial folds. The prolapse is often best demonstrated by having the patient strain on a commode. Defecography is sometimes helpful to diagnose internal rectal intussusception and associated pelvic floor abnormalities, such as rectocele and enterocele.

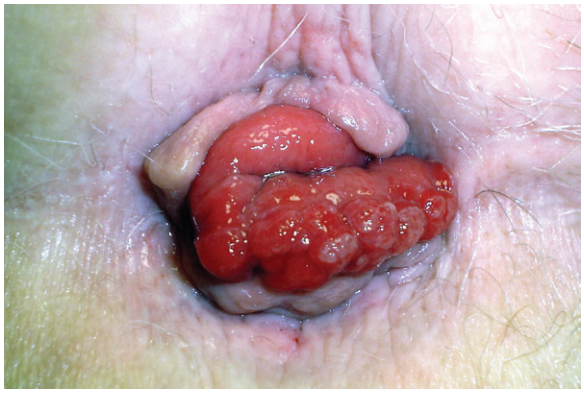

FIGURE 147-4. Rectal mucosal prolapse.

TREATMENT

Rx

Rectal prolapse is treated by surgical correction. Both transabdominal and transperineal approaches are commonly used.

Human Papillomavirus

EPIDEMIOLOGY AND PATHOBIOLOGY

Human papillomavirus (HPV, Chapter 381), which is the most common sexually transmitted infection, is a cause of anal dysplasia and cancer. The approximately 40 HPV subtypes that can cause anogenital infections are divided into low-risk types (e.g., types 6 and 11) that cause anal warts (condyloma acuminata) and high-risk types (e.g., types 16, 18, and 33) that can cause anal dysplasia and cancer. HPV infection is associated with cervical, vulvar, vaginal, and penile cancers, and some patients have HPV-related dysplasia or cancer in multiple sites. Approximately 90% of anal cancers are attributable to HPV infection.

The incidence of anal cancer has been steadily increasing, from 0.6 per 100,000 in 1973 to 1.0 per 100,000 in 2001; the female-male ratio decreased from 1.6 : 1 to 1.2 : 1 over the same period. These epidemiologic trends have been attributed to a particularly rapid increase in anal cancers among men who have sex with men, especially men infected with HIV. Anal HPV, including the high-risk types, is highly prevalent in at-risk populations (sex workers, intravenous drug users, transplant recipients, men who have sex with men, and HIV-positive men and women). Furthermore, anal dysplasia is common in at-risk populations; indeed, the prevalence rates of high-grade anal dysplasia are reportedly 40 to 60% among HIV-positive men who have sex with men seen in specialty clinics in New York and San Francisco.

FIGURE 147-5. Perianal condylomata resulting from human papillomavirus infection.

ANAL WARTS

CLINICAL MANIFESTATION AND DIAGNOSIS

Anal warts can occur in the perianal skin and within the anal canal. The lesions are raised, epithelialized (when external), and narrow based. They can appear as scattered individual warts or as a confluent mass (Fig. 147-5).

TREATMENT Rx

External warts can be treated with topical podophyllin or imiquimod, but extensive warts usually require surgical excision or fulguration. Untreated warts can rarely progress to form Bushke-Löwenstein tumors—giant, locally invasive condyloma acuminata that frequently contain in situ or invasive cancer.

ANAL CANCER

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptoms of anal cancer are bleeding, pain, and a palpable mass. The cancer may be seen externally as an ulcerated mass or may be palpated within the anal canal. Anal dysplastic lesions may appear as anal warts or as flat, pigmented lesions, or they may be invisible to the naked eye. They are best visualized using anal microscopy after topical application of 3 to 5% acetic acid (see later). Biopsy is necessary to make the diagnosis.

The terminology of anal cancer is complex, but the great majority of tumors (including epidermoid, cloacogenic, and basaloid carcinomas) are variants of squamous cell carcinoma. The terminology of preinvasive squamous anal lesions is even more confusing because several terms exist for histologically identical pathology. The terms *anal dysplasia, anal intra-epithelial neoplasia* (AIN), and *squamous intra-epithelial lesion* (SIL) are used interchangeably. SILs are divided into low-grade and high-grade groups; AIN is similarly divided into AIN 1, 2, and 3, with AIN 2 and 3 being classified as high-grade lesions. Squamous cell carcinoma in situ corresponds to high-grade SIL and AIN 3; these terms are preferable to *Bowen's disease*, which has historically been applied to this lesion. Other significant but less common anal cancers include adenocarcinoma, melanoma, and Paget's disease.

Squamous cell carcinoma of the anus is divided into two groups based on tumor location: cancers of the anal margin (extending from the anal orifice for a distance up to 5 cm) and cancers of the anal canal. Tumors visible externally but extending into the anal canal are considered anal canal lesions.

TREATMENT Rx

Management of the patient with anal dysplasia is controversial. Many authorities advocate a screening and treatment approach based on that used for cervical cancer, another HPV-associated disease. High-risk individuals are screened with anal Papanicolaou smears, and high-definition anal microscopy (analogous to colposcopy of the cervix) is performed when abnormal cytology is detected. Using this technique, dysplastic lesions can be identified and focally ablated or treated with topical imiquimod. More extensive dysplasia requires microscopy-directed targeted ablation in the operating room. Although this overall approach is rational and provides good control of most dysplasia, it is also time-consuming and requires multiple follow-up visits. Cost, recurrence, compliance, and provider manpower all remain significant issues. However, even advocates of less aggressive surveillance report significant rates of anal cancer among patients with dysplasia, especially those who are immunocompromised.

Chemoradiotherapy is now standard first-line treatment for squamous cell cancer of the anal canal. Current radiation protocols most frequently use 45-Gy external beam radiation therapy in 25 fractions, with a boost to the primary tumor and involved inguinal nodes to a total dose of 54 to 59 Gy. Standard chemotherapy utilizes 5-fluorouracil (1000 mg/m^2 per 24 hours continuous infusion for 96 hours, starting on days 1 and 29) in combination with mitomycin C (most commonly 10 mg/m^2 intravenous bolus on days 1 and 29). Abdominoperineal resection with permanent colostomy is reserved for tumors that fail to respond to chemoradiation and those that recur. Similarly, groin dissection is performed only when involved inguinal nodes fail chemoradiation.

Early squamous cell cancers of the anal margin can be locally excised if a satisfactory margin can be obtained without injuring the anal sphincter and if there is no evidence of nodal spread. More advanced anal margin tumors are treated with chemoradiotherapy as described for anal canal tumors.

Other Sexually Transmitted Anorectal Diseases

A number of sexually transmitted diseases (Chapter 293) of the anorectum occur most frequently in individuals who practice anoreceptive intercourse. Common causative agents include *Treponema pallidum* (Chapter 327), *Neisseria gonorrhoeae* (Chapter 307), *Chlamydia trachomatis* (Chapter 326), herpes simplex (Chapter 382), and HIV (Chapter 392). Other sexually transmitted pathogens are *Shigella* (Chapter 317), *Campylobacter jejuni* (Chapter 311), *Haemophilus ducreyi* (Chapter 309), *Calymmatobacterium granulomatis* (Chapter 324), *Entamoeba histolytica* (Chapter 360), *Giardia lamblia* (Chapter 359), and *Isospora belli* (Chapter 361).

The widely variable presentations range from asymptomatic to anal pain, pruritus, discharge, fever, cramps, and bloody diarrhea. Clinical suspicion followed by appropriate and specific testing is necessary to make the correct diagnosis, and clinicians should consider the possibility of simultaneous infections. Treatment addresses the specific infection.

APPROACH TO THE PATIENT WITH LIVER DISEASE

PAUL MARTIN

The liver has a variety of key functions, including metabolism of the products of ingested food, production of amino acids to form proteins, detoxification of ingested drugs, conversion of nitrogenous substances from the gut into urea for subsequent renal excretion, formation of clotting factors, metabolism of bilirubin, processing of lipids absorbed from the intestine, and excretion of its products as bile. The liver also stores glycogen, which is a source of glucose, and it has a role in containing bacterial infections by removing bacteria from the blood stream. These various functions are achieved by several types of liver cells, including hepatocytes, bile duct cells, and Kupffer cells.

The liver has a dual blood supply: 70% of its blood is delivered by the portal vein, which drains the intestine, and the remainder is from the hepatic artery. After delivery to the liver by the portal vein, nutrient-rich blood passes along the hepatic sinusoids in close contact with the hepatocytes that line them before draining into the hepatic vein. The hepatocytes detoxify, metabolize, and synthesize the products of digestion delivered to them. Bilirubin, the product of the breakdown of red cells and other hemoproteins, is produced by reticuloendothelial cells predominantly in the liver and spleen. Bilirubin is transported to the hepatocytes while bound to albumin; it is then solubilized by the hepatocytes for excretion into the bile ducts.

Clinical consequences of liver disease may reflect the loss of hepatocellular activity, with diminished detoxification, excretory, and synthetic functions. Interruption of bile flow may be caused by ineffective biliary excretion by diseased hepatocytes or by portal hypertension owing to disruption of portal blood flow through a diseased liver. Hepatocyte dysfunction results in diminished production of clotting factors, albumin, and other proteins, as well as the reduced endogenous formation of lipids. Hepatocyte injury from a variety of causes, including viruses, alcohol, autoimmune disorders, and drug hepatotoxicity, is accompanied by leakage of cellular enzymes into the systemic circulation (Chapter 149). Coagulopathy, decreased serum albumin, and hyperbilirubinemia are typical in more profound hepatocellular injury. Portal hypertension occurs because of disruption of the low-pressure intrahepatic blood flow from the portal to the systemic venous circulation, typically owing to fibrosis within the hepatic parenchyma. Consequences of portal hypertension include the accumulation of abdominal ascites and the development of portal-systemic venous collaterals with portal-systemic shunting, thereby resulting in the formation of varices and ultimately in hepatic encephalopathy. Vascular disorders, including portal vein thrombosis, can also result in portal hypertension.

Because of the diverse functions of the liver, its complicated blood supply, and its intimate relationship with the biliary tree, liver disease can present in a variety of ways. The presenting complaint often reflects whether the cause is diffuse, such as when acute viral hepatitis with widespread hepatocyte injury presents as malaise or fatigue, or discrete, such as when biliary obstruction from a gallstone in the common bile duct presents as severe abdominal pain. Patients with liver disease may present with multiple complaints, such as nausea and anorexia owing to hepatocellular disease accompanied by right upper quadrant discomfort due to stretching of the hepatic capsule by parenchymal cell edema and inflammation. Patients with more advanced liver disease, such as decompensated cirrhosis (Chapter 156), may have marked hepatocellular dysfunction with jaundice and coagulopathy in addition to portal hypertension with ascites and bleeding esophageal varices. Many patients who present with hepatic symptoms or signs may have extrahepatic disease; for example, a tender, swollen liver may be caused by a systemic disorder, such as heart failure with hepatic congestion, rather than a primary hepatic disorder. In cirrhotic patients, the initial presentation of previously undiagnosed liver disease may be a major complication such as variceal hemorrhage, which in turn can precipitate hepatic encephalopathy and other features of frank hepatic decompensation.

HISTORY

Patients with liver disorders come to medical attention for a number of reasons, ranging from the incidental discovery of abnormal liver chemistries to advanced cirrhosis. For patients with possible liver disease, however, a thorough history guides the appropriate diagnostic evaluation. Many complaints related to liver disease, such as fatigue, are nonspecific; unless liver disease is considered in the differential diagnosis, recognition of the hepatic origin of these complaints may be delayed.

In clinical practice, a frequent presentation of liver disease is an asymptomatic patient who is found to have abnormal liver biochemistries (Chapter 149) during a life insurance application, yearly physical examination, or attempt to donate blood. Such patients often have no prior history of liver disease, but it is important to inquire about past occasions when liver biochemistries may have been obtained to determine whether hepatic dysfunction is long-standing or more recent. In a patient with hepatic dysfunction, specific inquiries should be made about the presence of malaise, anorexia, fatigue, and weight change. Jaundice (Chapter 149) is the most typical manifestation of liver disease but is not specific. A patient may first notice lighter-colored stools or dark urine rather than scleral icterus. The absence of these changes suggests that unconjugated hyperbilirubinemia due to hemolysis may be the cause of jaundice rather than intrinsic liver disease. Not infrequently, a patient may be unaware of jaundice until it is noted by a family member or colleague.

Abdominal pain (Chapter 134) related to liver disease can have a variety of causes. Symptomatic gallstones (Chapter 158) can present with the abrupt onset of severe epigastric or right upper quadrant discomfort, often after a large meal and frequently associated with nausea and vomiting. The pain is often steady rather than colicky, and it can radiate widely, including to the chest and back. Patients may not be able to achieve a position that lessens the pain, which may last several hours. More persistent pain, particularly if associated with weight loss and jaundice, raises concern about malignant bile duct obstruction. Pain is also common in parenchymal liver disease in the absence of biliary tract disease. Many patients with chronic hepatocellular disorders, such as chronic hepatitis C (Chapter 151) or nonalcoholic fatty liver disease (Chapter 155), complain of vague right upper quadrant discomfort that has no particular relieving or aggravating factors. Abdominal pain, which can be severe, is also frequent in acute viral hepatitis (Chapter 150), as well as with the hepatic congestion that results from back pressure in heart failure or hepatic vein occlusion, as seen in Budd-Chiari syndrome (Chapter 145).

Fatigue, anorexia, and malaise can be present in both acute and chronic liver disease. In acute liver disorders such as acute viral hepatitis (Chapter 150), drug-induced liver disease (Chapter 152), or an acute presentation of autoimmune hepatitis (Chapter 151), patients may report profound fatigue, nausea, and malaise with decreased appetite and substantial associated weight loss. Distaste for cigarettes is said to be characteristic of acute viral hepatitis. Fatigue is also prominent in chronic liver disease such as chronic hepatitis C (Chapter 151). Pruritus is a prominent feature of cholestatic disorders, such as primary biliary cirrhosis, sclerosing cholangitis, or cholestatic drug reactions, particularly when patients are frankly icteric; however, pruritus also occurs in chronic parenchymal liver disease, most notably chronic hepatitis C, and in acute viral hepatitis. Easy bruisability in those with liver disease reflects coagulopathy and thrombocytopenia.

Fever in a patient with hepatic dysfunction is seen in the prodrome of acute hepatitis A, as well as in alcoholic hepatitis and drug-induced liver disease. In a patient with suspected biliary obstruction, fever suggests complicating bacterial cholangitis or acute cholecystitis.

Ascites is most frequently evidence of cirrhosis and portal hypertension in a patient with liver disease. Patients report increasing abdominal girth, which may be preceded by ankle edema. Weight gain owing to fluid retention may be masked by concomitant loss of muscle mass, and vice versa. The onset of ascites in the absence of a history of liver disease suggests a vascular event, such as hepatic vein occlusion (Chapter 145), or a nonhepatic cause of ascites, such as nephrotic syndrome or heart failure. Accumulation of ascites in a patient with liver disease may be subtle, with a slowly increasing waist circumference, or it may be more rapid, such as in a cirrhotic patient who receives fluid resuscitation following gastrointestinal bleeding. Although ascites in a patient with liver disease implies the presence of cirrhosis, ascites can also complicate severe acute liver disease, including alcoholic hepatitis and viral hepatitis, in which it suggests a poor prognosis.

Hepatic encephalopathy (Chapter 157), which is a neuropsychiatric disorder in patients with liver disease, can range from subtle cognitive

impairment to deep coma. Early symptoms include a disturbed sleep pattern with nocturnal insomnia and daytime somnolence. More advanced encephalopathy can result in impairment of memory, confusion, and difficulty completing routine tasks. However, new-onset confusion or coma in a patient with liver disease should not be presumed to reflect hepatic encephalopathy unless other explanations, such as sedative overdose or subdural hematoma, have been ruled out. Important precipitants of hepatic encephalopathy in a cirrhotic patient include gastrointestinal bleeding, bacterial infection, and electrolyte imbalance, all of which need to be excluded during the initial clinical evaluation. In a patient with acute liver failure, coma owing to cerebral edema may be impossible to distinguish from advanced hepatic encephalopathy unless the increased intracranial pressure results in papilledema.

Gastrointestinal hemorrhage due to bleeding varices is usually profuse and often abrupt in onset. It classically presents with hematemesis or melena (Chapter 137), and coexisting postural hypotension and presyncope can reflect profound blood loss. The increased protein load in the gut can cause hepatic encephalopathy. Nonvariceal causes of gastrointestinal bleeding in a patient with liver disease include portal gastropathy (Chapter 137).

RISK FACTORS FOR LIVER DISEASE

An important aspect of the history is the identification of possible risk factors for liver disease. The history should include directed questioning about alcohol consumption, including frequency and pattern (Chapter 32). The age of initial alcohol use and whether its consumption has increased with age should be ascertained. Family members, if present, should also be asked about their perception of the patient's alcohol use and whether it has resulted in difficulties in personal relationships or work performance. Other clues to alcohol abuse are a history of convictions for driving under the influence of alcohol, motor vehicle accidents, and physical symptoms of alcohol dependence (Chapter 32). More circumspect questioning may be required to elicit a history of recreational drug use, especially given societal disapproval of this activity. Not infrequently, a patient with suspected viral hepatitis admits to smoking marijuana or snorting cocaine but does not acknowledge intravenous drug use. With the increasing frequency of nonalcoholic fatty liver disease as a cause of hepatic dysfunction (Chapter 155), the history should assess comorbid conditions such as diabetes mellitus, hyperlipidemia, or weight gain. Ingestion of medications, whether obtained by prescription or over the counter, must be assessed because drug-induced liver disease is an important cause of apparently cryptogenic hepatic dysfunction and is not limited to therapeutic drugs (Chapter 152). Increasingly, herbal and "natural" products (Chapter 38) are ingested for a variety of maladies, and patients may fail to disclose their use because they do not perceive these agents to have side effects or may sense that the physician does not endorse their use. As with alcohol, it is important to quantify the amount of medication ingested and over what period. The social history should also include details about recent travel and contact with individuals with viral hepatitis through intimate, household, or occupational contact. It is also important to ask about vigorous physical activity that can result in elevated aminotransferase levels of nonhepatic origin.

ASSESSING DURATION OF LIVER DISEASE

The differential diagnosis in a patient with liver disease is determined to a large extent by the presenting symptoms, such jaundice or ascites. In many patients, however, the timing of more subtle findings such as elevated aminotransferases is more difficult to determine. Prior blood test results should be retrieved to determine whether hepatic dysfunction is long-standing or more recent. Hepatic dysfunction of less than 6 months' duration is regarded as acute and is frequently self-limited, whereas abnormalities that persist for more than 6 months are chronic and unlikely to resolve spontaneously. If the patient has had a cholecystectomy, it is important to determine the indication; incidental gallstones are sometimes assumed to be the cause of hepatic abnormality in a patient with parenchymal liver disease, leading to unnecessary removal of the gallbladder. Thrombocytopenia owing to portal hypertension in a patient with unrecognized cirrhosis may have been investigated in the past without a firm conclusion being reached.

REVIEW OF OTHER ORGAN SYSTEMS

Despite the appropriate focus on liver-related symptoms, it is important not to overlook other clues, associated disorders, and complications. Sicca symptoms, including dry eyes and mouth, are common in primary biliary cirrhosis (Chapter 158); florid features of scleroderma and the CREST syndrome (Chapter 275) are also seen in association with this liver disease. Dyspnea in a patient with hepatic dysfunction may reflect cardiac failure with hepatic congestion (Chapter 58). Other explanations include the hepatopulmonary syndrome (Chapter 156), with the characteristic complaint of platypnea–dyspnea (often with chest tightness) that is worse in the upright position owing to aggravation of the ventilation-perfusion mismatch because of intrapulmonary shunting. The hepatopulmonary syndrome can also occur in association with cirrhosis (Chapter 156). A hydrothorax in decompensated cirrhosis can cause dyspnea, as can emphysema in patients with liver disease caused by α_1-antitrypsin deficiency (Chapter 153). A history of premature menopause is common in middle-aged women with cirrhosis, as is decreased libido and sexual potency in male cirrhotic patients. Arthralgias are often reported in viral hepatitis, and hemochromatosis (Chapter 219) may present with involvement of the proximal interphalangeal joints or chondrocalcinosis of the knees; increased skin pigmentation and diabetes mellitus are among other features of this disorder. Accelerated osteopenia occurs in many liver diseases, including primary cirrhosis, primary sclerosing cholangitis, and alcoholic cirrhosis; osteopenia may be aggravated by corticosteroid use in autoimmune chronic active hepatitis. Alcoholic peripheral neuropathy (Chapter 428) can present with pain as well as paresthesia. Tremor and inattentiveness in a younger patient with hepatic dysfunction suggests Wilson disease (Chapter 218). Diarrhea and rectal bleeding in a patient with cholestatic liver disease suggests associated inflammatory bowel disease (Chapter 143).

FAMILY HISTORY

The family history should inquire not only about relatives with liver disease but also about extrahepatic conditions associated with liver disease. Hereditary hepatic conditions, such as Wilson disease and hemochromatosis, may occur in several members of a sibship (Chapter 153). In α_1-antitrypsin deficiency, some family members may experience predominantly emphysema or cirrhosis of unclear cause (Chapter 153). Similarly, renal failure in a family member of a patient with hepatic cysts suggests adult polycystic disease (Chapter 129). A family history of inflammatory bowel disease may be a clue to primary sclerosing cholangitis in a patient with cholestatic liver chemistries. The family history in patients with suspected alcoholic liver disease may reveal other family members with alcoholism.

PHYSICAL EXAMINATION

General Condition

In a patient with suspected liver disease, it is crucial to resist the temptation to palpate the abdomen immediately and ignore other important clues to liver disease as a result. Apart from noting icterus, the initial observation should determine whether muscle wasting, cutaneous stigmata of liver disease, abdominal distention, and peripheral edema are present. The vital signs may reflect the hyperdynamic circulation characteristic of cirrhosis, with a resting tachycardia, wide pulse pressure, and low blood pressure due to peripheral vasodilation. Fetor hepaticus, which is described as a musty smell, may be detected when a cirrhotic patient exhales and must be distinguished from the more frequent halitosis due to poor dental hygiene.

Mucocutaneous Findings

Icterus (Fig. 148-1) is best confirmed by examination of the sclera or, if necessary, under the tongue, where elastin tissue retains bilirubin. Grayish skin discoloration in hemochromatosis may be most evident in the skin folds in

FIGURE 148-1. Scleral icterus.

FIGURE 148-2. Palmar erythema.

FIGURE 148-3. Prurigo nodularis.

the groin or axilla. A Kayser-Fleischer ring (see Fig. 218-1 in Chapter 218), caused by the deposition of copper in Descemet's membrane, is a brownish circle around the periphery of the iris and may require slit lamp examination to detect; it should always be sought in a patient with suspected Wilson disease (Chapter 218). Poor dentition is characteristic in alcoholic or drug-abusing individuals, and excessive dental caries may result from decreased saliva production in the sicca syndrome. Parotid gland swelling is occasionally observed in alcoholic patients. Central cyanosis and clubbing are found in the hepatopulmonary syndrome. Temporal muscle wasting and "paper money" facial skin, owing to atrophy with telangiectasia, are signs of advanced liver disease. Xanthelasma from lipid deposits may be observed on the eyelids and skin around the orbits in patients with cholestatic liver disease. Spider nevi on the face and thorax are not pathognomonic of liver disease, especially in women, but they are suggestive if more than a few are present. Palmar erythema (Fig. 148-2) may be normal in women but suggests liver disease in men. Dupuytren's contracture (see Fig. 155-1 in Chapter 155), the retraction of the palmar fascia with subsequent contracture of the palms and fingers, can be a sign of alcoholic liver disease, although it is also described in persons with epilepsy or diabetes mellitus. Petechiae and ecchymoses reflect impaired production of clotting factors and hypersplenism in advanced liver disease. Patches of white discoloration on the nails may be present in advanced liver disease. Scratch marks from pruritus may be observed on the trunk and extremities of patients with cholestatic liver disease (Fig. 148-3); sparing of the center of the back can lead to a less pigmented butterfly-shaped area, presumably because patients cannot reach that area with their fingernails.

Examination of the Abdomen

Abdominal distention and dilation of collateral veins are the most florid visible signs of advanced liver disease with ascites and portal hypertension. Caput medusae (Fig. 148-4) in the periumbilical area implies recanalization of the umbilical vein due to portal hypertension.

FIGURE 148-4. Caput medusae. Photograph shows a caput medusae accentuated by a large amount of ascites in a patient being prepared for liver transplantation. An extensive plexus of veins is seen emanating from the umbilical region and radiating across the anterior abdominal wall. Note the large vein coursing inferiorly along the right flank *(arrows)*. This is the superficial epigastric vein, which drains into the external iliac vein. (From Henseler KP, Pozniak MA, Le FT, et al. Three dimensional CT angiography of spontaneous portosystemic shunts. *Radiographics.* 2001;21:691-704.)

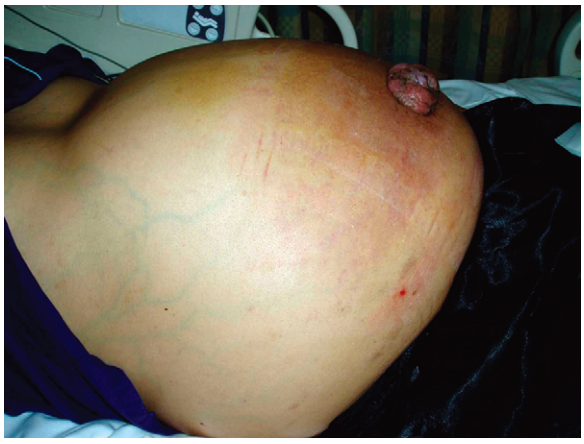

FIGURE 148-5. Ascites.

The presence of ascites (Fig. 148-5) can be assessed by percussion of the abdomen and the detection of shifting dullness or a fluid wave. Shifting dullness results from movement of the fluid to the most dependent portion of the abdomen. The subject should be examined in the supine position, and the abdomen should be percussed from the midline toward the right or left flank. A change from a tympanic sound to a dull sound signifies a change from air to fluid, and the location of that change identifies the surface of the fluid pool. Next, the examiner should percuss below the point at which dullness is elicited and ask the subject to turn toward the examiner. With the subject on his or her side, the examiner percusses again at the same point where tympany converted to dullness. If that spot is now tympanic, shifting dullness has been detected as a result of movement of the air-fluid boundary; this finding supports the presence of ascites. This maneuver should be performed sequentially on each side for confirmation. A fluid wave can be felt by placing the medial border of one hand on the abdomen and tapping the right or left lateral abdominal walls; the resulting wave is felt by the first hand. Scrotal edema and abdominal wall hernias are often present in patients with long-standing ascites. Abdominal tenderness in a patient with ascites suggests peritonitis (e.g., spontaneous bacterial peritonitis or due to a perforated viscus). However, it is important to note that abdominal tenderness is frequently absent, even with spontaneous bacterial peritonitis.

The liver is dull to percussion. Percussion of the right upper quadrant can assess the liver span, which is normally 6 to 12 cm in the midclavicular line. The liver span may be diminished in a patient with cirrhosis, whereas hepatomegaly (Fig. 148-6) is detected in hepatic congestion due to heart failure,

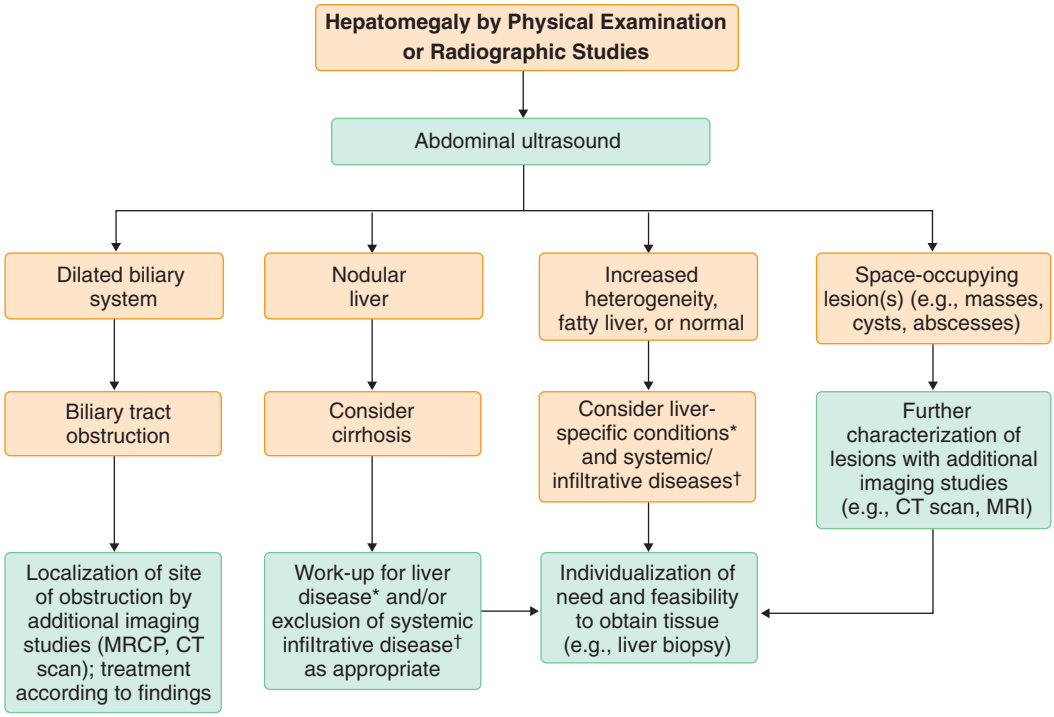

FIGURE 148-6. Diagnostic approach to hepatomegaly. *Conditions to be excluded include viral hepatitis, alcohol- and drug-induced liver disease, steatohepatitis, autoimmune liver diseases, and metabolic disorders, including hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency. †Systemic and infiltrative diseases include amyloidosis, lymphoma, sarcoidosis, and infectious processes such as disseminated tuberculosis and fungemia. CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging.

nonalcoholic fatty liver disease, and cholestatic forms of cirrhosis. The liver is best examined with the patient in the supine position, arms parallel to the sides of the body, and knees bent to relax the abdominal muscles. To assess the liver, palpation should begin in the right lower quadrant of the abdomen and move upward toward the rib cage so that the liver edge is felt on the way up. A normal liver edge is smooth and sometimes slightly tender when palpated. In general, a liver edge that is felt up to 2 cm below the right costal margin is considered normal, but a normal-sized liver can be displaced downward by other abnormalities, such as emphysema. In thin subjects, the liver edge may be felt on deep inspiration, even if it is normal in size.

The liver can feel hard and irregular, as in cirrhosis, or slightly tender, enlarged, and smooth, as in acute viral hepatitis or hepatic congestion. The liver can extend across the midline, and the left lobe can be felt in the epigastrium. When the location of the edge of the liver is uncertain, the scratch test may be helpful. It is performed by placing the bell of the stethoscope on the right upper quadrant over the rib cage and scratching the surface of the abdominal wall from the midabdomen toward the liver; the sound of the scratch is amplified in an area under which the liver lies. In the presence of ascites, the liver edge may be detected by exerting quick pressure with the fingertips below the rib cage.

A palpable gallbladder suggests obstruction of the biliary system, whereas tenderness elicited by palpation during inspiration (Murphy's sign) suggests acute cholecystitis. Marked hepatic tenderness with hepatomegaly is observed in patients with a hepatic abscess (Chapter 154).

Splenomegaly may be suggested by dullness to percussion between the 9th and 11th ribs in the left midaxillary line. A palpable spleen tip is highly suggestive of portal hypertension in a patient with chronic liver disease, although an enlarged spleen can also be detected in acute viral hepatitis and infiltrative disorders that involve both the liver and the spleen (see Table 171-7 in Chapter 171). Rectal examination is obligatory if gastrointestinal bleeding is suspected because of melena, anemia, or unexplained hepatic encephalopathy.

Complete Physical Examination

The presence of rales and elevation of the jugular venous pressure suggest heart failure or pericardial disease as a cause of hepatic congestion. Loss of secondary sexual characteristics in liver disease is reflected by a loss of axillary and pubic hair, as well as feminization of body habitus in a male patient. Testicular atrophy may also be present. Peripheral edema is common in decompensated cirrhosis and may occur before ascites is obvious.

Neuropsychiatric alterations can include subtle changes in personality or more overt hepatic encephalopathy. Constructional apraxia (e.g., inability to draw a five-pointed star or to write legibly) in a fully conscious patient is a typical finding of hepatic encephalopathy. Asterixis, which is characterized by a series of extensor and flexor wrist movements, can be elicited by having the patient extend the arms, with dorsiflexion of the wrists, while separating the fingers for at least 15 seconds. Tremors (Chapter 417) are nonspecific but are also common in advanced cirrhosis.

DIAGNOSTIC STUDIES (TABLE 148-1)

Laboratory Studies

The initial evaluation for suspected liver disease involves a battery of blood tests that reflect hepatic necroinflammation (serum aminotransferases), cholestatic biliary tract dysfunction (alkaline phosphatase, γ-glutamyl transpeptidase), excretory function (bilirubin), and synthetic function (coagulation factors, albumin) (Chapter 149). In hepatocellular dysfunction caused by viral hepatitis (Chapter 150), the aminotransferase levels are elevated, with the serum alanine aminotransferase (ALT) level higher than the aspartate aminotransferase (AST) level. In alcoholic hepatitis (Chapter 155), AST elevation exceeds ALT elevation. In patients with biliary obstruction or cholestatic liver diseases (Chapter 158), such as primary biliary cirrhosis or a cholestatic drug reaction, the bilirubin and generally the alkaline phosphatase levels are elevated. Impairment of synthetic function, such as from cirrhosis or severe acute viral hepatitis, can lead to a low serum albumin level over days to weeks. The prothrombin time, expressed as the international normalized ratio (INR), is a more sensitive test of hepatic synthetic function and becomes prolonged within several hours after a major hepatic insult. Portal hypertension owing to advanced hepatic fibrosis or cirrhosis results in a decreased platelet count due to hypersplenism. Although these general patterns of liver dysfunction are helpful in the initial evaluation of liver disease, they are nonspecific. For example, a patient with a predominantly hepatocellular process commonly has elevated bilirubin and alkaline phosphatase levels and a low serum albumin level if the injury is severe. Nevertheless, these blood tests should identify the predominant pattern of abnormality and help focus further diagnostic evaluation with serologies and abdominal imaging.

Abdominal Imaging

Plain abdominal radiographs generally do not have a major role in the evaluation of suspected liver disease. An exception is a patient with severe abdominal pain in whom it is important to exclude a perforated viscus with free air under the diaphragm.

Ultrasonography should be the initial investigation in patients with obstructive jaundice. It can confirm dilated bile ducts in patients with biliary obstruction and can often identify the cause, such as a pancreatic mass or a

TABLE 148-1 APPROACH TO COMMON HEPATIC COMPLAINTS

PRESENTATION	COMMON SYMPTOMS	COMMON PHYSICAL SIGNS	DIAGNOSTIC STUDIES	COMMON DIAGNOSES
Ascites	Abdominal distention and pain, ankle edema	Flank dullness Shifting dullness Fluid wave	Ultrasound with Doppler Diagnostic paracentesis Urinalysis	Cirrhosis Budd-Chiari syndrome Heart failure Nephrotic syndrome
Hepatic encephalopathy	Sleep disorientation, confusion, coma	Asterixis Altered mentation Fetor hepaticus	Serum ammonia Blood cultures Stool Hemoccult Serum creatinine and electrolytes	Decompensated cirrhosis Acute liver failure Other metabolic encephalopathies (renal, respiratory)
Hepatic mass	None or abdominal pain	Hepatic bruit or rub	α-Fetoprotein Ultrasound CT scan MRI Biopsy	Benign lesions: hemangioma, adenoma, focal nodular hyperplasia Malignant lesions: hepatocellular carcinoma, cholangiocarcinoma, metastases
Abdominal pain	Nausea, vomiting, fever	Right upper quadrant tenderness Palpable gallbladder Murphy's sign	Ultrasound HIDA scan Paracentesis for ascites if present	Biliary colic Acute cholecystitis Hepatic congestion Hepatic metastases

CT = computed tomography; HIDA = hepatobiliary iminodiacetic acid; MRI = magnetic resonance imaging.

gallstone lodged in the common bile duct. Ultrasonography can also determine whether the hepatic parenchyma is diffusely abnormal, such as in a patient with acute viral hepatitis; it can identify bright hepatic echo texture in a patient with nonalcoholic fatty liver disease; or it can show a coarsened echo texture in cirrhosis. In addition to confirming the presence of ascites, ultrasonography can identify other signs of portal hypertension, such as splenomegaly or intra-abdominal varices. Blood flow through the portal and hepatic vessels can be assessed by adding a Doppler flow study. An ultrasound study can identify hepatic masses and distinguish a cystic mass from a solid lesion. Computed tomography (CT) and magnetic resonance imaging (MRI) add greater detail to the assessment of the hepatic vasculature, hepatic masses, and hepatic vascular structures. MRI can also obtain a very detailed cholangiogram (see Fig. 202-3 in Chapter 202), thereby avoiding the more invasive endoscopic retrograde cholangiopancreatography in many patients with suspected bile duct obstruction or disease (Chapters 135 and 136).

Liver biopsy remains the definitive test to assess the severity of hepatic inflammation and the extent of fibrosis in diffuse hepatocellular disease. In addition, it can confirm diagnoses suspected by noninvasive testing, such as autoimmune hepatitis, or it can suggest diagnoses, such as drug hepatotoxicity. Because of its potential complications, such as intra-abdominal bleeding, biopsy is recommended only when less invasive testing has not yielded a definitive diagnosis or prognosis or when additional information, such as quantitative determination of hepatic copper in Wilson disease or hepatic iron in hemochromatosis, is necessary for definitive diagnosis.

Transjugular pressure measurements are indicated in patients with atypical presentations of portal hypertension (e.g., when it is unclear whether liver disease is the cause) or to titrate medications to reduce portal pressure. A catheter is advanced under fluoroscopy into the hepatic vein, and the free hepatic venous pressure is measured. The catheter is then advanced farther until it becomes "wedged" in a small hepatic vein venule. The venule is occluded by a small balloon, and the wedged hepatic vein pressure, which reflects hepatic sinusoidal pressure, is obtained. The portal pressure gradient, which is derived by subtracting the free pressure measurement from the wedged pressure measurement, is normally less than 5 mm Hg. Varices form at a gradient above 10 mm Hg, whereas ascites and variceal hemorrhage occur only when the gradient exceeds 12 mm Hg. A transjugular approach also increases the safety of liver biopsy in the presence of ascites, coagulopathy, or thrombocytopenia when standard percutaneous liver biopsy is hazardous. Endoscopy is indicated to screen for varices in any patient suspected of having cirrhosis to determine the need for prophylaxis against hemorrhage.

149 APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

PAUL BERK AND KEVIN KORENBLAT

JAUNDICE

DEFINITION

Jaundice, from the French *jaune* (yellow), is the yellow-orange discoloration of the skin, conjunctivae, and mucous membranes that results from elevated concentrations of bilirubin in plasma. Mild hyperbilirubinemia may be clinically undetectable, but jaundice becomes evident at plasma bilirubin concentrations of 3 to 4 mg/dL, depending on the patient's normal pigmentation, the conditions of observation, and the bilirubin fraction that is elevated. Optimal interpretation of an elevated plasma bilirubin concentration is based on an appreciation of its sources and disposition.

Bilirubin Metabolism

Bilirubin Production

Bilirubin is the degradation product of the heme moiety of hemoproteins, a class of proteins involved in the transport or metabolism of oxygen (Fig. 149-1). Normal adults produce about 4 mg of bilirubin per kilogram of body weight per day. Between 70 and 90% of bilirubin is derived from the hemoglobin of erythrocytes, which in turn are sequestered and destroyed by the mononuclear phagocytic cells of the reticuloendothelial system, principally in the spleen, liver, and bone marrow. A minor fraction reflects ineffective erythropoiesis, the premature destruction of newly formed erythrocytes within the bone marrow. The remainder results primarily from the turnover of nonhemoglobin hemoproteins such as myoglobin, the P-450 cytochromes, catalase, and peroxidase. Although this occurs principally in the liver, bilirubin has proved to have antioxidant properties, and recent studies suggest that a limited, regulated production of bilirubin from heme may occur in many cell types and contribute to regulating the intracellular antioxidant environment.

The two-step conversion of heme to bilirubin commences with the opening of the heme molecule at its α bridge carbon by the microsomal enzyme *heme oxygenase*, a process that results in the formation of equimolar quantities of carbon monoxide and the green tetrapyrrole biliverdin, the main excretory product of heme in birds, reptiles, and amphibians. Because biliverdin cannot

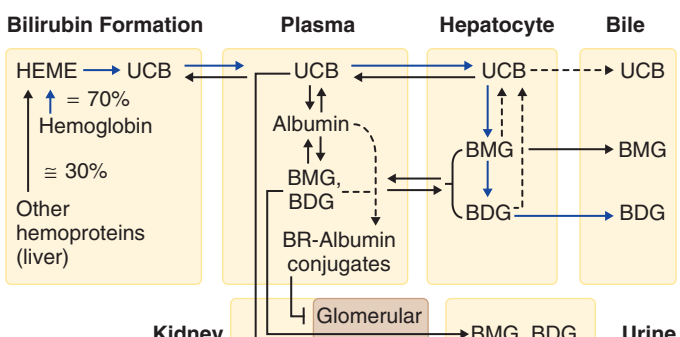

FIGURE 149-1. Overview of bilirubin metabolism. Unconjugated bilirubin (UCB) formed from the breakdown of heme from hemoglobin and other hemoproteins is transported in plasma reversibly bound to albumin and is converted in the liver to bilirubin monoglucuronide (BMG) and diglucuronide (BDG), the latter being the predominant form secreted in bile. BMG and BDG together normally account for less than 5% of normal serum bilirubin. In patients with hepatobiliary disease, BMG and BDG accumulate in plasma and appear in urine. Bilirubin glucuronides in plasma also react nonenzymatically with albumin and possibly other serum proteins to form protein conjugates, which do not appear in urine and have a plasma half-life similar to that of albumin. BR = bilirubin.

cross the placenta, its reduction to bilirubin in mammals by a second enzyme, *biliverdin reductase*, allows its transplacental removal from the fetus into the maternal circulation. The unconjugated bilirubin produced in the periphery is transported to the liver in plasma. Because of its insolubility in aqueous media, it is kept in solution by tight but reversible binding to albumin. A number of compounds, including sulfonamides, furosemide, and radiographic contrast agents, competitively displace bilirubin from its binding sites on albumin, a phenomenon of little clinical significance except in neonates, in whom the resulting increased concentration of unbound bilirubin raises the risk of kernicterus.

Disposition of Bilirubin by the Liver

Bilirubin excretion from the body is a major function of the liver (see Fig. 149-1), wherein specialized microanatomy enhances extraction of tightly protein-bound compounds from the circulation. Hepatic translocation of bilirubin from blood to bile involves four distinct steps: (1) uptake of unconjugated bilirubin, by both an incompletely characterized facilitated transport process and by diffusion; (2) intracellular binding, mainly to various cytosolic proteins of the glutathione-*S*-transferase family; (3) conversion of unconjugated bilirubin to bilirubin monoglucuronides and diglucuronides by a specific uridine diphosphate (UDP)-glucuronosyltransferase isoform designated UGT1A1; and (4) transfer of bilirubin monoglucuronides and diglucuronides into bile by a canalicular membrane adenosine triphosphate (ATP)-dependent transporter designated multidrug resistance–associated protein 2 (MRP2) or canalicular multispecific organic anion transporter (cMOAT). MRP2/cMOAT is a member of the *MRP* gene family, other members of which pump certain drug conjugates, as well as unmodified anticancer drugs, out of cells.

Conjugation to bilirubin monoglucuronides and diglucuronides greatly increases the aqueous solubility of bilirubin and thereby enhances its elimination from the body while simultaneously reducing its ability to diffuse across biologic membranes, including the blood-brain barrier. In newborns, a decreased capacity to conjugate bilirubin leads to unconjugated hyperbilirubinemia (physiologic jaundice of the newborn). If severe, this hyperbilirubinemia may lead to irreversible central nervous system toxicity. Phototherapy by exposure to blue light converts bilirubin to water-soluble photoisomers that are readily excreted in bile, protecting the central nervous system from bilirubin toxicity. Gilbert's syndrome and Crigler-Najjar syndrome types 1 and 2, which result from genetic defects in bilirubin conjugation, are characterized by unconjugated hyperbilirubinemia; in contrast, Dubin-Johnson syndrome, which results from inheritable defects in MRP2/cMOAT (see later), is characterized by conjugated or mixed hyperbilirubinemia.

Enterohepatic Circulation and Excretion of Bilirubin

Bilirubin in Bile

Normal bile contains an average of less than 5% unconjugated bilirubin, 7% bilirubin monoconjugates, and 90% bilirubin diconjugates. The proportion of monoconjugates increases with an increased bilirubin load (hemolysis) or defective conjugation (e.g., Gilbert's and Crigler-Najjar type 2 syndromes). After canalicular secretion, conjugated bilirubin passes down the gastrointestinal tract without reabsorption by either the gallbladder or intestinal mucosa.

Urobilinogen and the Enterohepatic Circulation

Although some bilirubin reaches the feces, most is converted to urobilinogen and related compounds by bacteria within the ileum and colon, where the urobilinogen is reabsorbed, returns to the liver through the portal circulation, and is re-excreted into bile in a process of enterohepatic recirculation. Any urobilinogen not taken up by the liver reaches the systemic circulation and is cleared by the kidneys. Normal urine urobilinogen excretion is 4 mg/day or less. With hemolysis, which increases the load of bilirubin entering the gut and therefore the amount of urobilinogen formed and reabsorbed, or with liver disease, which decreases its hepatic extraction, plasma urobilinogen levels rise, and more urobilinogen is excreted in the urine. Severe cholestasis, bile duct obstruction, or broad-spectrum antibiotics that reduce or eliminate bacterial conversion of bilirubin to urobilinogen markedly decrease the formation and urinary excretion of urobilinogen.

Unconjugated bilirubin ordinarily does not reach the gut except in neonates or by ill-defined alternative pathways in the presence of severe unconjugated hyperbilirubinemia (e.g., Crigler-Najjar type 1). In these circumstances, unconjugated bilirubin is reabsorbed from the gut, thereby amplifying the hyperbilirubinemia.

Measurement of Bilirubin in Plasma

The total plasma bilirubin concentration in normal adults is less than 1 to 1.5 mg/dL, depending on the measurement method used. Modern analytic techniques show that normal plasma contains principally unconjugated bilirubin, with only traces of conjugates. Clinical laboratories typically quantify plasma bilirubin by a reaction in which bilirubin is cleaved by a diazo reagent, such as diazotized sulfanilic acid, to azodipyrroles that are quantitated spectrophotometrically. Bilirubin conjugates react rapidly ("prompt" or "direct"-reacting bilirubin). Unconjugated bilirubin reacts slowly because the site of attack by the diazo reagent is protected by internal hydrogen bonding. Accordingly, accurate measurement of the total plasma bilirubin concentration requires addition of an accelerator, such as ethanol or urea, to disrupt this internal bonding and to ensure complete reaction of any unconjugated bilirubin. The "indirect"-reacting bilirubin is calculated by subtracting the direct-reacting bilirubin from the total. Although physicians traditionally equate the direct-reacting fraction of bilirubin in plasma with conjugated bilirubin and the indirect fraction with unconjugated bilirubin, this approach is, at best, a rough approximation, and the unqualified interpretation of direct and indirect fractions as reflecting conjugated and unconjugated bilirubin, respectively, may lead to diagnostic errors, particularly in the diagnosis of hereditary hyperbilirubinemias. In practice, 10 to 20% of bilirubin in normal plasma gives a prompt (direct) diazo reaction even though more than 95% of total bilirubin in normal plasma is unconjugated. Thus, at virtually any total bilirubin concentration, a direct-reacting fraction of less than 15% of the total can be considered as essentially all unconjugated. When the direct-reacting fraction is greater than 15%, a simple dipstick test for bilirubinuria may clarify the situation. Unconjugated bilirubin is not excreted in urine regardless of the height of its plasma concentration because its binding to albumin is too tight for effective glomerular filtration and it is not secreted by the tubules. The canalicular transport mechanism for excretion of bilirubin conjugates is especially sensitive to injury. Accordingly, in parenchymal liver disease or mechanical bile duct obstruction, bilirubin conjugates within the hepatocyte or biliary tract may reflux into the blood stream, resulting in a mixed or, less often, a purely conjugated hyperbilirubinemia. Conjugated bilirubin, which is normally loosely bound to albumin, is readily filtered at the glomerulus; even modest degrees of conjugated hyperbilirubinemia result in bilirubinuria, which is *always* a pathologic finding. With prolonged conjugated hyperbilirubinemia, some of the conjugated bilirubin binds *covalently* to albumin and produces what is designated the delta (δ) bilirubin fraction. Although δ -bilirubin gives a direct diazo reaction, it is not filterable by the glomerulus and does not appear in the urine; it disappears slowly from the plasma, with the 14- to 21-day half-life of the albumin to which it is bound. δ-Bilirubin accounts for the sometimes slow rate at which conjugated (direct) hyperbilirubinemia resolves as hepatitis improves or biliary obstruction is relieved. Although δ-bilirubin is not easily measured, its presence can be inferred when an elevated direct-reacting bilirubin persists after bilirubinuria resolves.

Bilirubin Kinetics

The plasma disappearance kinetics of radiolabeled bilirubin indicate that the plasma unconjugated bilirubin concentration ([UCB]) reflects a balance between the bilirubin production rate (BRP) and hepatic bilirubin clearance (C_{BR}) according to the relationship:

$$[UCB] \approx BRP / C_{BR}$$

C_{BR} is analogous to the creatinine clearance in the test of kidney function; it is a measure of the rate at which bilirubin is extracted from plasma, and is a true quantitative test of liver function. Whereas BRP and C_{BR} are not easily quantified in clinical settings, investigative measurements have yielded useful pathophysiologic insights. This equation indicates that [UCB] increases linearly with an increase in BRP or hyperbolically with a decrease in C_{BR}, thereby providing a basis for classifying unconjugated hyperbilirubinemias according to their pathogenesis.

FIGURE 149-2. Severe cholestatic jaundice in a patient with primary biliary cirrhosis. The high level of conjugated bilirubin, maintained over a long period, gives a characteristic dark brown-orange pigmentation to the skin and sclerae. Patients with primary biliary cirrhosis usually develop large xanthelasmas and corneal arcus as a consequence of disordered lipid metabolism. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

APPROACH TO THE PATIENT WITH HYPERBILIRUBINEMIA

Hyperbilirubinemia and jaundice (Fig. 149-2) may result from isolated disorders of bilirubin metabolism, liver disease, or obstruction of the biliary tract. Jaundice represents the most visible sign of hepatobiliary disease of many causes (Table 149-1).

TABLE 149-1 DIFFERENTIAL DIAGNOSIS OF HYPERBILIRUBINEMIA AND JAUNDICE

ISOLATED DISORDERS OF BILIRUBIN METABOLISM
Unconjugated hyperbilirubinemia
Increased bilirubin production
Examples: hemolysis, ineffective erythropoiesis, blood transfusion, resorption of hematomas
Decreased hepatocellular uptake
Examples: drugs (e.g., rifampin)
Decreased conjugation
Examples: Gilbert's and Crigler-Najjar syndromes, physiologic jaundice of the newborn, breast milk jaundice, HIV protease inhibitors
Conjugated or mixed hyperbilirubinemia
Decreased canalicular transport: Dubin-Johnson syndrome
Mechanism uncertain: Rotor's syndrome
LIVER DISEASE
Acute or chronic hepatocellular dysfunction
Acute or subacute hepatocellular injury
Examples: viral hepatitis A, B, and C, hepatotoxins (e.g., ethanol, acetaminophen, mushroom [*Amanita phalloides*] poisoning), drugs (e.g., isoniazid, α-methyldopa), metabolic diseases (e.g., Wilson's disease, Reye's syndrome), pregnancy-related (e.g., acute fatty liver of pregnancy, preeclampsia), hepatic ischemia (e.g., hypotension, postoperative, hepatic artery thrombosis)
Chronic hepatocellular disease
Examples: hepatitis B and C, hepatotoxins (e.g., vinyl chloride, vitamin A), nonalcoholic and alcoholic fatty liver disease, autoimmune hepatitis, metabolic disease (Wilson's disease, hemochromatosis, α_1-antitrypsin deficiency)
Hepatic disorders with prominent cholestasis
Familial cholestatic disorders
Single-gene disorders
Examples: benign recurrent intrahepatic cholestasis types 1-3; progressive familial intrahepatic cholestasis types 1-3
Familial cholestatic disorders of unknown pathogenesis
Examples: Aagenaes syndrome, Navajo neurohepatopathy, North American Indian cholestasis
Diffuse infiltrative disorders
Examples: granulomatous diseases (e.g., mycobacterial and fungal infections, sarcoidosis, lymphoma, drugs, Wegener's granulomatosis), amyloidosis, infiltrative malignancies
Inflammation of intrahepatic bile ductules and/or portal tracts
Examples: primary biliary cirrhosis, liver allograft rejection, graft-versus-host disease, drugs (e.g., chlorpromazine, erythromycin)
Miscellaneous conditions
Examples: uncommon presentations of viral or alcoholic hepatitis, intrahepatic cholestasis of pregnancy, contraceptive jaundice, estrogens, anabolic steroids, postoperative cholestasis, cholestasis of sepsis, total parenteral nutrition, bacterial infections, drugs
OBSTRUCTION OF THE BILE DUCTS
Choledocholithiasis
Examples: cholesterol gallstones, pigment gallstones
Diseases of the bile ducts
Inflammation/infection
Examples: primary sclerosing cholangitis, AIDS cholangiopathy, hepatic arterial chemotherapy, postsurgical strictures
Neoplasms (e.g., cholangiocarcinoma)
Extrinsic compression of the biliary tree
Neoplasms
Examples: pancreatic carcinoma, metastatic lymphadenopathy, hepatoma
Pancreatitis with or without pseudocyst formation
Vascular enlargement (e.g., aneurysm, cavernous transformation of portal vein)

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency syndrome.

DISORDERS OF BILIRUBIN METABOLISM

Hyperbilirubinemia in the absence of hepatocellular dysfunction (pure hyperbilirubinemia) may result from either increased bilirubin production or inherited or acquired defects in specific aspects of hepatic bilirubin disposition.

Increased Bilirubin Production

Increased bilirubin production and consequent unconjugated hyperbilirubinemia can be caused by hemolysis, accelerated destruction of transfused erythrocytes, resorption of hematomas, or ineffective erythropoiesis (e.g., lead poisoning, megaloblastic anemias related to deficiency of either folic acid or vitamin B_{12}, sideroblastic anemia, congenital erythropoietic porphyria, or myeloproliferative or myelodysplastic diseases). In these settings, other liver tests are typically normal and the hyperbilirubinemia is modest, rarely exceeding 4 mg/dL; higher values imply concomitant hepatic dysfunction. However, following brisk blood transfusion or resorption of massive hematomas, the increased bilirubin load may be transiently sufficient to lead to frank jaundice. The causes of hemolysis are numerous (Chapters 163 to 166). Besides specific blood disorders, mild hemolysis accompanies many acquired diseases. In the setting of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration. Prolonged hemolysis may lead to the formation of bilirubin gallstones, which may cause cholecystitis, obstruction, or any other biliary tract consequence of calculous disease.

Decreased Hepatic Bilirubin Clearance

DECREASED BILIRUBIN UPTAKE

Several drugs (e.g., rifampin, flavaspidic acid, novobiocin, and various cholecystographic contrast agents) competitively inhibit the hepatocellular uptake of bilirubin. The resulting unconjugated hyperbilirubinemia resolves with cessation of the medication. Decreased hepatic bilirubin uptake is also believed to contribute to the unconjugated hyperbilirubinemia of Gilbert's syndrome, although the principal molecular basis for this syndrome is reduction of bilirubin conjugation.

IMPAIRED BILIRUBIN CONJUGATION

The most frequent cause of decreased bilirubin clearance is decreased bilirubin conjugating activity. Bilirubin conjugation with glucuronic acid is catalyzed by a specific UDP-glucuronosyltransferase, designated UGT1A1, encoded by the *UGT1* gene complex. The *UGT1A1* gene is assembled by alternative splicing of a bilirubin-specific variant of exon 1, designated exon A_1, with four common exons (exons 2 to 5) that encode the shared carboxyl terminal end of all *UGT1*-encoded proteins. Its promoter region normally contains an $A(TA)_6TAA$ TATA boxlike construct.

Genetic Disorders of Bilirubin Conjugation

The hereditary hyperbilirubinemias (Table 149-2) are a group of five syndromes in which hyperbilirubinemia occurs as an isolated biochemical abnormality, without evidence of either hepatocellular necrosis or cholestasis. The molecular defects have been identified in all but Rotor's syndrome.

CRIGLER-NAJJAR SYNDROME TYPES 1 AND 2 AND GILBERT'S SYNDROME

These are hereditary unconjugated hyperbilirubinemias that result from mutations in *UGT1A1*. In Crigler-Najjar type 1, essentially no functional enzyme activity is present, whereas patients with Crigler-Najjar type 2 have up to 10% of normal and patients with Gilbert's syndrome have 10 to 33% of normal, leading to bilirubin concentrations of 18 to 45, 6 to 25, and 1.5 to 4 mg/dL, respectively (see Table 149-2). Because total UGT1A1 enzymatic activity must be reduced to less than 50% of normal to produce unconjugated hyperbilirubinemia, phenotypic expression of mutations in this enzyme requires either homozygosity or double heterozygosity. Each of these disorders is inherited as an autosomal recessive trait. Patients with Crigler-Najjar types 1 and 2 are either homozygotes or double heterozygotes for structural mutations within the coding region. In Western countries, patients with Gilbert's syndrome are typically homozygous for an $A(TA)_7TAA$ promoter mutation. Structural mutations in exon 1 of *UGT1A1* causing modest reductions in UGT1A1 enzymatic activity have been reported in some Japanese patients with Gilbert's syndrome.

Crigler-Najjar type 1 is characterized by striking unconjugated hyperbilirubinemia that appears in the neonatal period, persists for life, and is unresponsive to phenobarbital. The majority of patients (type 1A) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin as the result of mutations in one of the common exons (2 to 5) of the *UGT1* complex. In a smaller subset (type 1B), a mutation in the bilirubin-specific exon A1 limits the defect to bilirubin conjugation. More than 85 structurally diverse *UGT1A1* mutations can cause Crigler-Najjar type 1; their common feature is that they all encode proteins with absent or, at most, traces of enzymatic activity. Before the availability of phototherapy, most patients with Crigler-Najjar type 1 died of bilirubin encephalopathy (kernicterus) in infancy or early childhood. Optimal treatment for a neurologically intact patient includes (1) about 12 hours/day of phototherapy from birth throughout childhood, perhaps supplemented by exchange transfusion in the neonatal period; (2) use of tin-protoporphyrin to blunt transient episodes of increased hyperbilirubinemia; and (3) early liver transplantation, before the onset of brain damage. Transplantation with isolated allogeneic hepatocytes continues to be evaluated as an experimental therapeutic approach.

Bilirubin concentrations are typically lower in Crigler-Najjar type 2, and plasma bilirubin levels can be reduced to 3 to 5 mg/dL by phenobarbital. At least 20 different mutations of *UGT1A1* have been associated with Crigler-Najjar type 2; all encode a bilirubin-UDP-glucuronosyl transferase with markedly reduced but detectable enzymatic activity. Although uncommon in Crigler-Najjar type 2, kernicterus has occurred at all ages, typically associated with factors that temporarily raise the plasma bilirubin concentration above baseline (e.g., fasting, intercurrent illness). For this reason, phenobarbital therapy is often recommended; a single bedtime dose usually maintains clinically safe plasma bilirubin concentrations.

Gilbert's syndrome is the most common hereditary hyperbilirubinemia, with a genotypic prevalence of 12% or less and a phenotypic prevalence of 7% or less. Its high prevalence may explain the frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients. Plasma bilirubin concentrations are most often less than 3 mg/dL, although both higher and lower values are frequent, with increases of two- to three-fold commonly occurring with fasting and intercurrent illness. The phenotypic distinction between mild Gilbert's syndrome and a normal state is often blurred. Phenobarbital normalizes both the bilirubin concentration and C_{BR}. Oxidative drug metabolism and the disposition of most xenobiotics that are metabolized by glucuronidation appear to be normal in Gilbert's syndrome. A critical exception is the antitumor agent irinotecan (CPT-11), whose active metabolite (SN-38) is glucuronidated specifically by UGT1A1. In patients with Gilbert's syndrome, CPT-11 can cause intractable diarrhea, myelosuppression, and other serious toxicities. Life expectancy in Gilbert's syndrome is normal, and the denial of life insurance or employment to these patients is not medically justified.

UNCONJUGATED HYPERBILIRUBINEMIA RELATED TO SELECTIVE INHIBITION OF UGT1A1

This occurs with several human immunodeficiency virus (HIV) protease inhibitors (e.g., indinavir, atazanavir). Abnormal disposition of menthol, estradiol benzoate, acetaminophen, tolbutamide, rifamycin SV, and other agents has not been associated with significant complications, but prudence should be exercised in prescribing agents metabolized by glucuronidation to patients with Gilbert's syndrome.

UNCONJUGATED HYPERBILIRUBIN IN THE NEWBORN PERIOD

Most neonates develop mild unconjugated hyperbilirubinemia between days 2 and 5 after birth because of hepatic immaturity and low levels of UGT1A1. Peak bilirubin levels are typically less than 5 to 10 mg/dL, and levels return to normal within 2 weeks as mechanisms of bilirubin disposition mature. Prematurity, with hemolysis or hepatic immaturity, is associated with higher bilirubin levels that may require phototherapy. The progestational steroid 3α,20β-pregnanediol and certain fatty acids that are found in breast milk (but not serum) of some mothers inhibit bilirubin conjugation and can cause excessive neonatal hyperbilirubinemia (*breast milk jaundice*). By comparison, *transient familial neonatal hyperbilirubinemia* (Lucey-Driscoll syndrome) is caused by a UGT1A1 inhibitor found in maternal serum.

Acquired Conjugation Defects

A modest reduction in bilirubin conjugating capacity occurs in advanced hepatitis or cirrhosis (Chapter 156). However, in this setting, conjugation is better preserved than other aspects of bilirubin disposition, such as

TABLE 149-2 PRINCIPAL FEATURES OF THE HEREDITARY DISORDERS OF BILIRUBIN METABOLISM

FEATURE	*Crigler-Najjar Syndrome* TYPE I	*Crigler-Najjar Syndrome* TYPE II	GILBERT'S SYNDROME	DUBIN-JOHNSON SYNDROME	ROTOR'S SYNDROME
Incidence	Very rare	Uncommon	Up to 12% of population	Uncommon	Rare
Total serum bilirubin (mg/dL)	18-45 (usually >20), unconjugated	6-25 (usually ≤20), unconjugated	Typically ≤4 in absence of fasting or hemolysis; mostly unconjugated	Typically 2-5, less often ≤25; about 60% direct reacting	Usually 3-7, occasionally ≤20; about 60% direct reacting
Defect(s) in bilirubin metabolism*	Bilirubin UGT1A1 conjugating activity markedly reduced: trace to absent	Bilirubin UGT1A1 conjugating activity reduced: ≤10% of normal	Bilirubin UGT1A1 conjugating activity typically reduced to 10-33% of normal; reduced bilirubin uptake in some cases; mild hemolysis in up to 50% of patients	Impaired canalicular secretion of conjugated bilirubin due to MRP2/cMOAT mutation	Impaired hepatic secretion or storage of conjugated bilirubin; molecular defect not known
Routine liver tests	Normal	Normal	Normal	Normal	Normal
Serum bile acids	Normal	Normal	Normal	Usually normal	Normal
Plasma sulfobromophthalein removal (% retention of 5 mg/kg dose at 45 min)†	Normal	Normal	Usually normal (<5%); mild 45-min (<15%) retention in some patients	Slow initial decline in plasma concentration (retention ≤20% at 45 min) with secondary rise at 90-120 min	Very slow initial decline in plasma concentration (45-min retention = 30-45%) without secondary rise
Oral cholecystography	Normal	Normal	Normal	Faint or no visualization of gallbladder	Usually normal
Pharmacologic responses/special features	No response to phenobarbital	Phenobarbital reduces bilirubin by ≤75%	Phenobarbital reduces bilirubin, often to normal	Increased bilirubin concentration with estrogens; diagnostic urine coproporphyrin isomer pattern (total is normal, with isomer I increased to ≥80% of total)	Characteristic urine coproporphyrin excretion pattern (total is increased ≥2.5-fold in ~65% of cases, but isomer I always <80% of total)
Major clinical features	Kernicterus in infancy if untreated; may occur later despite therapy	Rare late-onset kernicterus with fasting	None	Occasional hepatosplenomegaly	None
Hepatic morphology/histology	Normal	Normal	Normal; occasionally increased lipofuscin pigment	Liver grossly black; coarse, dark centrilobular pigment	Normal
Bile bilirubin fractions‡	>90% unconjugated	Largest fraction (mean, 57%) monoconjugates	Mainly diconjugates but monoconjugates are increased (mean, 23%)	Mixed conjugates, reported increase in diconjugates	Increased conjugates
Inheritance (all autosomal)	Recessive	Recessive	Promoter mutation is recessive; missense mutation often dominant	Recessive; rare kindred appears dominant	Recessive
Diagnosis	Clinical and laboratory findings: lack of response to phenobarbital	Clinical and laboratory findings: response to phenobarbital	Clinical and laboratory findings: promoter genotyping; liver biopsy rarely necessary	Clinical and laboratory findings: liver biopsy unnecessary if coproporphyrin studies available; BSP disappearance	Clinical and laboratory findings: urine coproporphyrin analysis; BSP disappearance
Treatment	Phototherapy or tin protoporphyrin as short-term therapy; liver transplantation definitive	Consider phenobarbital if baseline bilirubin ≥8 mg/dL	None necessary	Avoid estrogens; no other therapy necessary	No treatment necessary

*UGT1A1 is the bilirubin specific isoform of the UGT1 family of uridine diphosphate glucuronosyl transferases.
†Sulfobromophthalein (BSP) studies: previously used to help distinguish Dubin-Johnson and Rotor's syndromes if coproporphyrin isomer studies not available. However, BSP is no longer approved for clinical use in the United States.
‡Bilirubin in normal bile: <5% unconjugated bilirubin, with an average of 7% bilirubin monoconjugates and 90% bilirubin diconjugates.
BSP = sulfobromophthalein; cMOAT = canalicular multispecific organic anion transporter; MRP2 = multidrug resistance–associated protein 2.

canalicular excretion. Pharmacologic and metabolic perturbations may also lead to acquired reductions in bilirubin conjugation. Various drugs (e.g., pregnanediol, novobiocin, chloramphenicol, gentamicin, and several HIV protease inhibitors) may cause unconjugated hyperbilirubinemia by inhibiting UGT1A1. In all settings in which UGT1A1 inhibitors cause unconjugated hyperbilirubinemia, the hyperbilirubinemia is greater in patients with underlying Gilbert's syndrome.

Conjugated or Mixed Hyperbilirubinemia

Two phenotypically similar but mechanistically distinct inherited disorders, *Dubin-Johnson syndrome* and *Rotor's syndrome*, are characterized by conjugated or mixed hyperbilirubinemia with normal values for other standard liver tests (see Table 149-2). Dubin-Johnson syndrome results from any of several mutations in the gene encoding the ATP-dependent canalicular organic anion transporter MPR2/cMOAT (see Fig. 149-1). The molecular defect in Rotor's syndrome remains unknown. Despite the conjugated hyperbilirubinemia, patients with these syndromes are not cholestatic and can be distinguished noninvasively by analysis of urine coproporphyrins (see Table 149-2), so liver biopsy is not required. Both syndromes carry a benign prognosis without specific therapy.

LIVER AND BILIARY TRACT DISEASE

Jaundice is a common sign of generalized hepatobiliary dysfunction, both acute and chronic. Icteric hepatobiliary disease is readily distinguished from

the isolated disorders of bilirubin metabolism because the increase in plasma bilirubin concentration occurs in association with other markers of hepatobiliary injury. Liver diseases can be categorized as those in which the primary injury results from inflammation and hepatocellular necrosis, inhibition of bile flow (cholestasis), or a combination of the two. The cholestatic disorders can be further subdivided into those due to mechanical obstruction of the bile duct flow (Chapter 158) and those resulting from intrahepatic cholestasis, which may be the consequence of a multitude of conditions that include familial cholestatic syndromes and infiltrative disorders (Chapters 151 to 156), particularly those involving the intrahepatic biliary tree; sepsis (Chapter 108), and certain other inflammatory or neoplastic conditions; and drug reactions (see Table 149-1). It is important to note that chronic cholestasis from any cause may result in the intrahepatic accumulation of compounds such as bile acids, which may themselves be toxic, causing hepatocellular injury.

Familial Cholestasis Syndromes

Benign recurrent intrahepatic cholestasis (BRIC) is a rare disorder characterized by recurrent attacks of cholestatic jaundice beginning either in childhood or in adulthood and varying in duration from weeks to months. Intervals between attacks may vary from months to years. This benign disorder does not progress to chronic liver disease or cirrhosis. There is complete resolution between episodes; treatment during the cholestatic episodes is symptomatic. Three subtypes result from mutations in different canalicular transporters: *BRIC type 1* from a partial deficiency of the familial intrahepatic cholestasis 1 (FIC1) gene product, also designated ATP8B1; *BRIC type 2* from mutations in the bile salt export pump (BSEP, or ABCB11); and *BRIC type 3* from mutations in multidrug resistance–associated protein 3 (MDR3, ABCB4).

Progressive familial intrahepatic cholestasis (PFIC) is a heterogeneous group of cholestatic disorders of childhood that, by contrast, typically lead to hepatic fibrosis and end-stage liver disease before adulthood. The three best-characterized *PFIC* subtypes are type 1 (Byler's disease) and type 2, resulting from functionally more severe mutations in ATP8B1 and BSEP, respectively; and type 3, due to MDR3 deficiency. All forms of *BRIC* and *PFIC* are inherited as autosomal recessive disorders. Diagnostically, γ-glutamyl transpeptidase (GGT) levels are low despite elevations in alkaline phosphatase in types 1 and 2, whereas GGT and alkaline phosphatase are elevated in parallel in PFIC type 3, as in most other forms of cholestatic liver disease. In contrast to the selective bilirubin transport defect in Dubin-Johnson syndrome, the conjugated hyperbilirubinemia in these syndromes reflects generalized bile secretory failure.

Postoperative Jaundice

This multifactorial syndrome can be caused by increased bilirubin production (e.g., breakdown of transfused erythrocytes, resorption of hematomas) or decreased hepatic clearance (e.g., from bacteremia, endotoxemia, parenteral nutrition, perioperative hypoxia). Hyperbilirubinemia, the main biochemical feature, is often accompanied by a several-fold increase in alkaline phosphatase or GGT levels, or both. Aminotransferases are, at most, minimally elevated, and synthetic function is typically normal. The differential diagnosis includes biliary obstruction or hepatocellular injury related to shock, anesthetic injury (Chapter 152), or viral hepatitis (Chapter 150). Postoperative jaundice per se (Chapter 441) is not a threat to the patient, and it usually resolves in parallel with the patient's overall condition.

Jaundice in Pregnancy

Jaundice in pregnancy (Chapter 247) may result from any liver disease that also affects nonpregnant women or from conditions unique to pregnancy. The unique conditions include a generally modest, self-limited elevation of aminotransferase and bilirubin levels during the first trimester, often in patients with hyperemesis gravidarum; intrahepatic cholestasis of pregnancy (ICP), which occurs during the second and third trimesters and usually resolves spontaneously after delivery; or acute fatty liver or the HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome, in association with preeclampsia in the third trimester (Chapters 153, 178, and 247). ICP, as well as cholestasis occurring recurrently in some women taking oral contraceptives, is increasingly being linked to polymorphisms in the same genes responsible for BRIC and PFIC. Acute fatty liver may resemble fulminant hepatic failure, with early delivery a prerequisite to maternal recovery; a defect in the oxidation of long-chain fatty acids is found in some infants born after these pregnancies.

DIAGNOSTIC TOOLS FOR THE EVALUATION OF LIVER DISEASE

Accurate diagnosis and the distinction between acute and chronic disease are often dependent on appropriate selection and interpretation of a spectrum of laboratory and imaging studies.

Tests used in initial evaluation of liver disease fall into two categories: (1) tests that indicate injury, such as release of intracellular enzymes; and (2) tests that measure, or at least reflect, actual function. Tests that reflect injury usually do not measure liver function and should not be called liver function tests.

The important functions of the liver include clearance, biotransformation and detoxification of potentially toxic metabolites and exogenous compounds, synthesis and export of various plasma proteins, and a critical integrative role in the intermediary metabolism of carbohydrates, amino acids, and lipids. In specific diseases, some of these functions may be markedly compromised, whereas others are little affected. Liver tests must be chosen with care and interpreted within the total clinical context. In specific situations, serial determinations are often helpful to assess the course of disease or effects of therapy.

Serum Enzyme Tests

The levels of hepatic enzymes found in plasma are a measure of hepatocyte turnover or injury. Enzymes released during normal hepatocyte turnover are believed to be the principal basis for normal circulating levels. Cell injury and cell death activate phospholipases that create holes in the plasma membrane, thereby increasing the release of intracellular contents.

Aminotransferases

The aminotransferases (formerly called transaminases) catalyze transfer of the α-amino group of aspartate (aspartate aminotransferase, AST) or alanine (alanine aminotransferase, ALT) to the α-keto group of ketoglutarate, with pyridoxal phosphate (vitamin B_6) as a cofactor. Laboratory methods that assay aminotransferase activity require supplementation with vitamin B_6 to avoid falsely decreased activity in vitamin B_6-deficient subjects.

Normal ranges for serum aminotransferases are usually reported to be up to approximately 40 IU/L (see Appendix), but when particular care is taken to exclude obese patients and others with known fatty liver disease from the sampled population, results suggest that less than 30 IU/L is normal for men and less than 19 IU/L for women. Values can exceed 1000 IU/L in acute hepatocyte injury, for example, from viral infection (Chapter 150) or toxins (Chapter 152). ALT is a purely cytosolic enzyme. Distinct isoforms of AST are present in cytosol and mitochondria. Expression of the mitochondrial isoform and its physiologic export from the hepatocyte are upregulated by ethanol. Circulating levels of AST or ALT (or both) are elevated in most hepatic diseases, and the degree of aminotransferase activity found in plasma roughly reflects the current activity of the disease process. There are, however, critical exceptions, and the sensitivity of aminotransferases as markers of hepatocellular injury varies with the disease in question. A subset of patients with proven chronic hepatitis C have normal aminotransferase levels, approximately 25% of morbidly obese patients with biopsy-proven nonalcoholic steatohepatitis may have normal ALT levels, and aminotransferase levels greater than or equal to 200 to 300 IU/L are uncommon in even the most severe cases of alcoholic hepatitis (Chapter 155). By contrast, aminotransferases of 1000 IU/L or greater are often present in even mild acute viral hepatitis (Chapter 150) or shortly after acute biliary obstruction, for example, during passage of a gallstone (Chapter 158). Conversely, aminotransferase levels may decline during the course of massive hepatic necrosis because liver injury is so extensive that little enzyme activity remains (Chapter 157). In rare circumstances, autoantibodies to AST result in autoantibody-enzyme complexes called macroenzymes that have a delayed clearance, detected as an increase in enzyme concentrations in the absence of cellular turnover.

Aminotransferase levels are useful in several distinct ways. First, they provide a relatively specific screening test for hepatobiliary disease. Although AST levels may be increased with disease of other organs (notably myocardial and skeletal muscle), values ten times the upper limit of normal or greater almost invariably indicate hepatobiliary pathology. Moreover, in the total clinical context, the source of increased aminotransferase activity is usually obvious. Aminotransferase levels are also used to monitor the activity of an acute or chronic parenchymal liver disease and its response to therapy. However, levels in a given patient may correlate poorly with the severity of the disease as assessed by liver biopsy, particularly in chronic hepatitis C

(Chapter 151). Aminotransferases are also often normal in advanced cirrhosis (Chapter 156), in which they are of limited prognostic value. Finally, aminotransferase levels may provide diagnostic clues. AST levels 15 or more times normal are unusual in *chronic* bile duct obstruction unless there is concomitant cholangitis, and AST levels 6 or more times normal are uncommon in alcoholic liver disease in the absence of other causes. In most liver diseases, the ratio of AST to ALT is usually less than or equal to 1. However, ratios are typically 2 or higher in alcoholic fatty liver and alcoholic hepatitis (Chapter 155), reflecting increased mitochondrial AST synthesis and secretion into plasma and selective loss of ALT activity because of the pyridoxine deficiency commonly seen in alcoholism. An elevated AST/ALT ratio also occurs in fulminant hepatitis related to Wilson disease (Chapters 153 and 218).

Alkaline Phosphatase

Alkaline phosphatases are widely distributed enzymes (e.g., liver, bile ducts, intestine, bone, kidney, placenta, and leukocytes) that catalyze the release of orthophosphate from ester substrates at an alkaline pH. The normal activity level in adult serum is highly dependent on the measurement method, age, and sex. Two methods in current use have upper limits of normal in adults of 85 and 110 IU/L (see Appendix). Higher levels are normal in children and in pregnancy. Results must always be compared with the appropriate normal range. In bone, alkaline phosphatase participates in the deposition of hydroxyapatite in osteoid. In other sites, including liver, alkaline phosphatase activity may facilitate movement of molecules across cell membranes. Serum alkaline phosphatase activity usually reflects principally the hepatic and bone isozymes; the intestinal form may account for 20 to 60% of the total after a fatty meal. There is a substantial placental contribution to the alkaline phosphatase level late in pregnancy; the *Regan isozyme,* a variant that appears identical to the placental form, is associated with hepatomas (Chapter 202), lung cancer (Chapter 197), and other tumors.

Elevations in serum alkaline phosphatase activity in cholestatic hepatobiliary disease result from two distinct mechanisms: increased synthesis and secretion of the enzyme and solubilization from the apical (canalicular) surface of hepatocytes and the luminal surface of biliary epithelial cells by the increased local concentrations of bile acids that occur with cholestasis. Serum alkaline phosphatase activity may also be increased in bone disorders (e.g., Paget's disease [Chapter 255], osteomalacia [Chapter 252], bone metastases [Chapter 208]), during rapid bone growth in children, in the later stages of pregnancy, with chronic renal failure (Chapter 132), and, occasionally, in the presence of malignancy not involving bones or liver. The source is often obvious, but when it is not, methods such as heat stability and electrophoretic separation can distinguish hepatobiliary alkaline phosphatase from other forms. A simpler alternative is to measure serum levels of GGT or 5′-nucleotidase (5′-NT), which tend to parallel levels of alkaline phosphatase in hepatobiliary disease but are usually not increased in bone disease. With a serum half-life of approximately 1 week, serum alkaline phosphatase may remain elevated for days to weeks after resolution of biliary obstruction. This delay may be especially misleading when it is accompanied by prolonged direct-reacting hyperbilirubinemia owing to delayed clearance of δ-bilirubin.

Modest increases in serum alkaline phosphatase (three times normal or less) occur in many hepatic parenchymal disorders, including hepatitis and cirrhosis. In the absence of bone disease, larger increases (three to ten times normal) usually indicate obstruction of bile flow. Although the highest levels usually reflect obstruction of the common bile duct, elevations can also occur with obstruction of intrahepatic bile ducts from infiltrative conditions that arise from granulomatous processes (sarcoidosis, *Mycobacterium avium-intracellulare, Mycobacterium tuberculosis*), malignancy (lymphoma, cholangiocarcinoma, or metastatic cancer) or amyloidosis.

Other Hepatic Enzymes

5′-NT is a plasma membrane enzyme that cleaves orthophosphate from the 5′ position on the pentose sugar of adenosine or inosine phosphate. *Leucine aminopeptidase (LAP)* is a ubiquitous cellular peptidase. The serum levels of both usually increase in cholestasis. Accordingly, their major use is to confirm whether an elevated serum alkaline phosphatase is hepatic in origin. Both enzymes may be increased in the later stages of a healthy pregnancy.

γ-Glutamyl transpeptidase (GGT) is present in many tissues. Its serum activity increases in hepatobiliary disease but also after myocardial infarction; in neuromuscular diseases, pancreatic disease (even in the absence of biliary obstruction), pulmonary disease, and diabetes; and during the ingestion of ethanol and other inducers of microsomal enzymes. Nevertheless, because serum GGT levels are usually normal in bone disease, the enzyme may be helpful in confirming the hepatic origin of an elevated alkaline phosphatase. Measurement of GGT has been proposed as a sensitive screening test for hepatobiliary disease and for monitoring abstinence from ethanol. Because of its low specificity, many persons who test positive have no identifiable liver disease on further study. GGT offers no clear advantage over LAP or 5′-NT for identifying the source of increased serum alkaline phosphatase activity except in pregnancy. Serum GGT levels may be normal despite elevated hepatobiliary alkaline phosphatase levels in certain rare disorders, including benign recurrent intrahepatic cholestasis and progressive familial intrahepatic cholestasis types 1 and 2 (see earlier and Chapter 158).

Lactate dehydrogenase (LDH) levels are often elevated in hepatic ischemia; otherwise, the enzyme is too ubiquitous in other body tissues to be diagnostically useful.

Tests Based on Clearance of Metabolites and Drugs

A major liver function is to remove various metabolites and toxins from the blood (Chapter 152). In liver disease, clearance of such molecules may be impaired because of loss of parenchymal cells, diminished bile secretion, biliary obstruction, decreased cellular uptake or metabolism, or reduced or heterogeneous hepatic blood flow. When a metabolite is produced at a relatively constant rate (e.g., bilirubin), its serum level can be a sensitive indicator of liver function. The removal rate from plasma of certain exogenous drugs and dyes can be similarly interpreted.

Bilirubin

The differential diagnosis of hyperbilirubinemia (see earlier) includes generalized liver disease, inherited disorders of bilirubin metabolism (e.g., Gilbert's and Crigler-Najjar syndromes), and nonhepatic conditions (e.g., hemolysis). Higher bilirubin levels correlate with a poorer prognosis in acute alcoholic hepatitis (Chapter 155), fulminant hepatic failure (Chapter 157), primary biliary cirrhosis (Chapter 156), and most forms of chronic liver disease.

Ammonia

Ammonia, a byproduct of amino acid metabolism, is removed from blood by the liver, converted to urea in the Krebs-Henseleit cycle, and excreted by the kidneys (Chapter 117). In the setting of portosystemic shunting, severe hepatic dysfunction (e.g., fulminant hepatic failure), or defects in urea cycle metabolism, ammonia levels rise. Measurements of blood ammonia are sometimes used to confirm a diagnosis of hepatic encephalopathy and to monitor the success of therapy, but the correlation of ammonia levels with the degree of encephalopathy is only approximate (Chapter 157). Correlations may be somewhat better if the measurement is made rapidly on an iced arterial blood sample. Elevated ammonia levels also occur when ammonia production is increased by intestinal flora (e.g., after a high-protein meal or gastrointestinal bleeding), by the kidney (in response to metabolic alkalosis or hypokalemia), or in rare genetic diseases that affect the pathway of urea synthesis (Chapter 212).

Drug Clearance

The rate of hepatic clearance of compounds such as sulfobromophthalein, lidocaine, and aminopyrine from the circulation can be measured chemically or with radiolabeled tracers. Although such tests can quantify hepatic function, they are rarely used in clinical practice.

Tests Reflecting Hepatic Synthetic Function

Coagulation Tests

See also Chapters 37 and 174.

Prothrombin Time

The prothrombin time (PT) reflects the plasma concentrations of both extrinsic and common pathway factors, that is, factors VII, X, and V, prothrombin, and fibrinogen. A prolonged PT most often results from vitamin K deficiency, liver disease, or both. Vitamin K, a fat-soluble vitamin found in many foods, is also synthesized by gut bacteria (Chapter 177). Vitamin K deficiency can be caused by poor dietary intake and malabsorptive states, including fat malabsorption resulting from cholestasis, and also occurs with antibiotic suppression of gut flora, particularly in patients receiving inadequate vitamin K replacement.

The half-lives of clotting factors are typically less than 1 day. Factor VII, which has the shortest half-life, is usually the earliest and most severely depressed during periods of defective hepatic synthesis. Because the PT is

dependent on the level of factor VII, it responds rapidly with changes in hepatic synthetic function; it is useful for following the course of acute liver diseases, in which a significant or growing prolongation of the PT may indicate a poor prognosis. An abnormal PT that is due solely to vitamin K deficiency usually becomes normal within 24 to 48 hours after parenteral repletion. However, if decreased synthesis of clotting factors reflects hepatocyte dysfunction, there may be little or no response to vitamin K. Finally, prolongation of the PT may also reflect disseminated intravascular coagulation (Chapter 178), which should always be considered in the context of both acute liver failure and end-stage chronic liver disease.

Partial Thromboplastin Time

This test reflects both intrinsic and common pathway factors, that is, all classical clotting factors except factor VII, and is, therefore, complementary to the PT. It is especially useful in detecting circulating anticoagulants (Chapter 178) but adds little to the PT in evaluating hepatic synthetic function.

Albumin

Albumin is produced solely by the liver. Its plasma concentration reflects a balance between its synthetic rate (100 to 200 mg/kg/day) and its plasma half-life of about 21 days. The synthetic rate is affected by the patient's nutritional state, thyroid and glucocorticoid hormone levels, plasma colloid osmotic pressure, exposure to hepatotoxins (e.g., alcohol), and presence of systemic disorders or liver disease. Many conditions increase albumin losses and shorten its plasma half-life, including nephrotic syndrome (Chapter 123), protein-losing enteropathy (Chapter 142), severe burns (Chapter 112), exfoliative dermatitis, and major gastrointestinal bleeding (Chapter 137). In cirrhosis with ascites (Chapters 156 and 157), hypoalbuminemia indicates diminished synthesis or redistribution into ascitic fluid. Thus, a reduced serum albumin concentration can confidently be considered an indicator of decreased hepatic synthetic function only when these other factors are not involved.

Examinations of Urine and Stool

Bilirubinuria always indicates a pathologic increase in plasma conjugated bilirubin levels. It is frequently seen with plasma conjugated bilirubin concentrations of 2 to 3 mg/dL, often appearing before the onset of clinical jaundice and persisting after jaundice has resolved. The quantification of urobilinogen in urine or feces is of limited clinical value. By contrast, stool culture or examination for ova and parasites may provide important information in selected patients. Testing of stool for occult blood may lead to discovery of a gastrointestinal lesion related to hepatobiliary disease (e.g., tumors metastatic to liver, ulcerative colitis associated with sclerosing cholangitis) or may explain the onset or worsening of hepatic encephalopathy.

Hematologic Tests in Liver Disease

In moderate to severe acute liver diseases, varying degrees of cytopenia occur in all three cell lineages. The most common finding is of thrombocytopenia from hypersplenism, which can be a surrogate marker of portal hypertension. Anemia may reflect low-grade hemolysis or marrow depression. Bone marrow suppression may be caused by ethanol or drugs, and aplastic anemia may sometimes complicate acute viral hepatitis (Chapters 150 and 168). Zieve's syndrome (hemolytic anemia and hypertriglyceridemia) is a rare but well-characterized complication of severe alcoholic liver disease (Chapters 155 and 156). Modest leukopenia, often with atypical lymphocytes, may also be present. Coagulopathy frequently complicates both acute and chronic liver failure owing to depressed hepatic synthesis of clotting factors or disseminated intravascular coagulation, or both (Chapters 177 and 178).

A modest increase in erythrocyte mean corpuscular volume occurs with alcohol consumption, hemolysis, or on occasion, liver disease per se. Chronic liver disease, especially if cholestatic, may be accompanied by target cells in the peripheral blood smear. Target cells are erythrocytes with an expanded cell membrane that reflects abnormalities in serum lipids. Spur cells (acanthocytes), most often found in advanced alcoholic cirrhosis, reflect a still greater increase in membrane cholesterol.

Tests for Specific Liver Diseases

Patients who present with a picture of acute or chronic parenchymal liver disease are most likely to fall into one of three categories: viral or toxic hepatitis, including alcoholic and nonalcoholic fatty liver disease; autoimmune liver disease; or an inherited metabolic disorder Specific tests for viral antigens, nucleic acids, and antibodies are available for the conventional hepatitis viruses (Chapters 150 and 151) as well as Epstein-Barr virus (Chapter 385), cytomegalovirus (Chapter 384), and herpesviruses (Chapters 382 and 383), which are well-established but less common causes of liver disease. The major hepatic autoimmune diseases include primary biliary cirrhosis (Chapter 158), autoimmune hepatitis (Chapter 151), and various overlap syndromes. The starting point for establishing a specific diagnosis within this category is the search for specific serum autoantibodies, including antimitochondrial antibodies against epitopes of the pyruvate dehydrogenase complex, which are virtually diagnostic of primary biliary cirrhosis (Chapter 158), and antinuclear, anti–smooth muscle, and anti–liver microsomal antibodies, which suggest one of the subtypes of autoimmune hepatitis (Chapter 148). The most prevalent of the hereditary metabolic disorders affecting the liver (Chapter 153) include hemochromatosis (Chapter 219), α_1-antitrypsin deficiency (Chapter 153), and Wilson disease (Chapter 218).

Liver Biopsy

Liver biopsy can be of great help in the diagnosis of diffuse or localized parenchymal diseases, including chronic hepatitis, cirrhosis, and primary or metastatic malignancy in the liver. The value of liver biopsy in acute hepatitis or acute cholestatic jaundice may be primarily prognostic because the histologic changes in these settings, although sometimes suggesting a specific diagnosis, are often nonspecific. However, toxic hepatitis (Chapter 152) related to certain medications may display diagnostic features. Liver biopsy for assessment of diffuse disease can be performed percutaneously after localization of the liver by physical examination or ultrasonographic visualization. When specific lesions, such as tumors, must be sampled, the biopsy can be guided by ultrasonographic or radiographic imaging or performed under direct visualization during laparoscopy or laparotomy. Relative or absolute contraindications include coagulopathy, high-grade biliary obstruction, biliary sepsis, ascites, and right pleural disease. Although liver biopsy remains the standard for assessment of hepatic histology in diffuse disease (Chapter 148), its invasiveness and concern for sampling error have generated interest in noninvasive measures of hepatic diseases. Transient elastography uses ultrasound to assess tissue stiffness as a measure of hepatic fibrosis. Commercially available biomarker panels have also been developed to provide a noninvasive assessment of hepatic fibrosis by blood testing alone. These panels typically include standard laboratory measures of hepatic injury (GGT, total bilirubin) and other serum markers (e.g., haptoglobin, hyaluronic acid, apolipoprotein A1). However, the ability of currently available noninvasive markers to assess the extent of hepatic fibrosis across the clinically relevant histologic spectrum remains to be established. Magnetic resonance elastography is another, emerging technique to characterize liver tissue elasticity, and hence fibrosis, noninvasively.

APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

History, Physical Examination, and Initial Laboratory Studies

Patients with liver disease may present with jaundice or other signs or symptoms, or the disease may be detected in the asymptomatic patient by the finding of abnormal liver tests during a routine evaluation. Regardless of how the patient comes to medical attention, the diagnostic approach (Fig. 149-3) begins with a careful history and physical examination (Chapter 148), as well as screening laboratory studies (complete blood cell count, measurement of plasma bilirubin concentration, assay of ALT, AST, and alkaline phosphatase levels, and PT) to formulate an initial differential diagnosis. The ability to distinguish expeditiously between liver disease and extrahepatic biliary tract obstruction is the major goal of the initial evaluation, in part because the latter may require prompt surgical intervention. Appropriate choice of second-level laboratory tests and imaging studies leads to a definitive diagnosis in most patients. Care in selecting tests, particularly imaging studies, both maximizes the likelihood of making a correct diagnosis and protects the patient from unnecessary discomfort, risk, and expense.

If the patient is asymptomatic and hepatic tests other than bilirubin are normal, hemolysis or an isolated disorder of bilirubin metabolism should be considered. If signs, symptoms, or laboratory abnormalities indicate hepatobiliary disease, certain patterns of findings help to distinguish intrinsic liver disease from biliary obstruction (Table 149-3). Pain in the right upper quadrant accompanied by a predominant increase in serum alkaline phosphatase activity suggests biliary obstruction (Chapter 158), as does a history of prior biliary surgery, right upper quadrant scars, or an abdominal mass. Fever and

TABLE 149-3 OBSTRUCTIVE JAUNDICE VERSUS CHOLESTATIC LIVER DISEASE

FEATURE	SUGGESTS OBSTRUCTIVE JAUNDICE	SUGGESTS PARENCHYMAL LIVER DISEASE
History	Abdominal pain Fever, rigors Previous biliary surgery Older age Acholic stools	Anorexia, malaise, myalgias, suggestive of a viral prodrome Known infectious exposure Receipt of blood products, use of intravenous drugs Exposure to a known hepatotoxin Family history of jaundice
Physical examination	High fever Abdominal tenderness Palpable abdominal mass Abdominal scar	Ascites Other stigmata of liver disease (e.g., prominent abdominal veins, gynecomastia, spider angiomas, asterixis, encephalopathy, Kayser-Fleischer rings)
Laboratory studies	Predominant elevation of serum bilirubin and alkaline phosphatase Prothrombin time that is normal or normalizes with vitamin K administration Elevated serum amylase	Predominant elevation of serum aminotransferases Prolonged prothrombin time that does not correct with vitamin K administration Blood tests indicative of specific liver disease

rigors, indicative of cholangitis, strengthen this conclusion. The incidences of gallstone disease and malignant neoplasm increase with age, although risk factors such as obesity or recent extensive diet-induced weight loss increase the risk of gallstones. Other risk factors (e.g., hepatitis exposure, transfusions, intravenous drug use, alcohol use, certain medications, and family history of genetic diseases) and a predominant elevation in serum aminotransferase levels favor a diagnosis of parenchymal liver disease. Physical evidence of cirrhosis (e.g., spider angiomas, gynecomastia, ascites, splenomegaly) supports the diagnosis of chronic parenchymal disease.

Despite the general validity of these patterns, many exceptions exist. In particular, parenchymal disorders with prominent cholestasis may mimic biliary obstruction. Both alkaline phosphatase and GGT are usually elevated in patients with cholestasis; the combination of an elevated alkaline phosphatase and normal GGT suggests that the alkaline phosphatase is from bone. Conversely, an isolated elevation of GGT may result from certain drugs (e.g., diphenylhydantoin) or alcohol even in the absence of liver disease. Because of the risk of life-threatening infection in the setting of unrelieved biliary tract obstruction, this possibility must always be considered and excluded if an alternative diagnosis is not definitely established.

Imaging Studies

If extrahepatic obstruction is suspected, it should be possible to determine its site and nature in virtually all patients (see Fig. 149-3). A reasonable initial step is the use of a noninvasive study such as ultrasonography or computed tomography (CT) to determine whether the intrahepatic or extrahepatic biliary system is dilated, implying mechanical obstruction. Because of its lesser expense, lack of radiation exposure, portability, and convenience, ultrasonography is often the procedure of choice and is substantially better than CT for detecting gallstones. CT may be preferred when better anatomic definition and information about the general level of obstruction are desired. Still more precise resolution may be obtained with magnetic resonance imaging cholangiopancreatography (MRCP). However, all of these techniques can fail to identify dilated ducts, particularly in patients with cirrhosis or primary sclerosing cholangitis. Conversely, a modest degree of ductal dilation is common in a patient with a previous cholecystectomy and does not necessarily signify current obstruction. Ultrasonography has the disadvantage of being highly operator dependent, whereas optimal CT imaging requires the use of intravenous contrast agents that may be nephrotoxic.

If dilated ducts are found, the biliary tree should be examined by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) (Chapter 136). ERCP involves positioning an endoscope in the duodenum, inserting a catheter through the ampulla of Vater, and injecting contrast medium into the distal common bile duct or pancreatic duct, or both. PTC involves percutaneous passage of a needle through the hepatic parenchyma into a peripheral bile duct, followed by injection of contrast medium into the biliary tree through the peripheral duct. The choice of procedure is based on the suspected site of obstruction (proximal vs. distal); the presence of coagulopathy or a history of prior gastroduodenal surgery that might preclude PTC or ERCP, respectively; the likely need for a therapeutic procedure (e.g., stent placement or endoscopic sphincterotomy); and the skills of available staff. Endoscopic ultrasound (EUS) is a complementary approach that permits internal ultrasonographic analysis of the pancreas, extrahepatic bile ducts, and regional lymph nodes and blood vessels. EUS combined with fine-needle aspiration permits tissue sampling of abnormalities in areas such as the bile ducts and pancreas that typically have been difficult to sample percutaneously.

Selection of Imaging Tests

Liver ultrasound is an ideal screening test to evaluate the liver architecture, assess for surface nodularity and parenchymal mass lesions, and exclude biliary obstruction. Ultrasound is relatively inexpensive in comparison to other imaging modalities, is widely available, and avoids ionizing radiation. The identification of mass lesions on ultrasound commonly prompts further cross-sectional imaging with either CT or magnetic resonance imaging. If there is evidence of biliary obstruction on imaging, or if obstruction is still considered likely despite imaging findings, direct cholangiography by ERCP or PTC, which offer therapeutic as well as diagnostic capabilities, may be an appropriate choice. If obstruction is considered possible but not highly likely, noninvasive imaging with MRCP is a reasonable study. Individual radiology suites have different levels of expertise for these procedures, and the local radiology staff may be quite helpful in recommending the best procedure for a given patient.

APPROACH TO THE ASYMPTOMATIC PATIENT WITH ABNORMAL LIVER TESTS

The apparently healthy patient with an isolated abnormality of aminotransferase or alkaline phosphatase levels requires careful evaluation to identify any underlying disease while avoiding unneeded testing. Often, no significant disease is found despite extensive evaluation. Common causes of abnormal

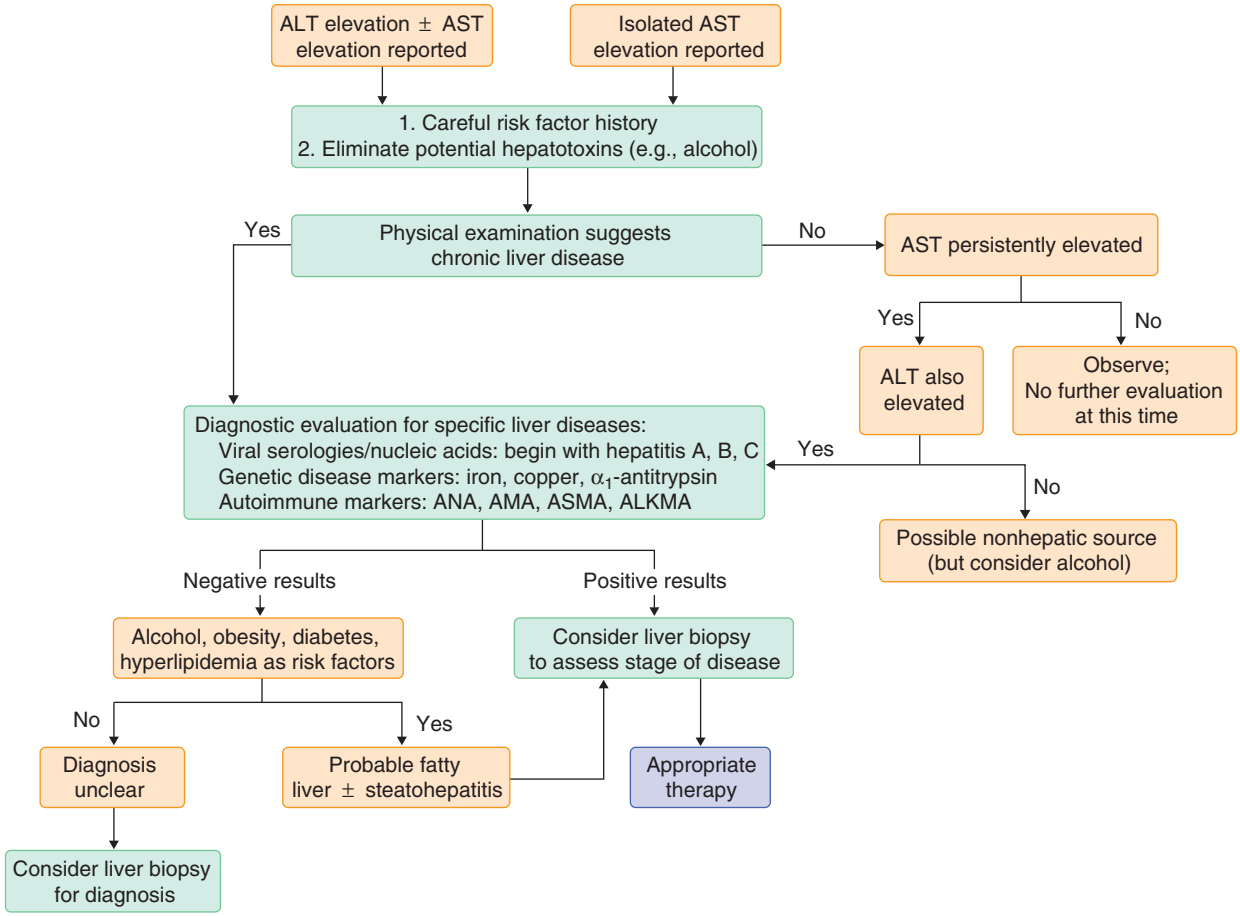

FIGURE 149-4. **Approach to the evaluation of isolated elevated levels of serum alanine aminotransferase (ALT) and/or aspartate aminotransferase (AST) in the asymptomatic patient.** ALKMA = anti-liver/kidney microsomal antibody; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ASMA = anti–smooth muscle antibody.

enzyme tests include obesity, alcohol consumption, chronic hepatitis C, steatohepatitis, bone disease, and muscle injury.

Asymptomatic Aminotransferase Elevation

Epidemiologic data suggest that up to 25% of asymptomatic adult Americans have a mild to moderate elevation of aminotransferase levels. The incidental discovery of such abnormalities is currently the most frequent means by which liver disease is first recognized. Whereas up to one third of such patients have no elevation on subsequent testing, many others prove to have hepatic steatosis or steatohepatitis (Chapter 155) or chronic hepatitis C (Chapter 151) (Fig. 149-4). Further evaluation is generally indicated only in patients with persistent abnormalities. Initial screening should include a careful history of exposure to hepatotoxins (alcohol, prescription drugs, over-the-counter medications, herbs, chemicals, and occupational exposures). If the abnormal test was an AST, a hepatic origin for the enzyme elevation should be confirmed with an ALT determination. If the ALT is normal, a muscle source is likely, or the elevation may reflect the presence of a macroenzyme. If the ALT level is abnormal, the patient should be screened serologically for hepatitis B and C; young women in particular should also be screened for markers of autoimmune liver disease. Older persons should be screened for hemochromatosis with an iron and transferrin level (Chapter 219), whereas younger persons should be screened with ceruloplasmin and urine copper for Wilson disease (Chapter 218). If these tests are negative, screening for α_1-antitrypsin deficiency is indicated (Chapter 153). Malaria (Chapter 353), schistosomiasis (Chapter 363), and other parasitic diseases should be considered in appropriate settings. A substantial fraction of patients prove to have fatty liver, with or without nonalcoholic steatohepatitis (NASH; Chapter 155). AST abnormalities caused by alcohol-induced steatosis should become normal with several weeks of abstinence. If the abnormalities persist for 6 to 12 months without an apparent cause, liver biopsy should be considered.

Asymptomatic Alkaline Phosphatase Elevation

Many patients with isolated elevation of the alkaline phosphatase level have nonhepatic causes, such as pregnancy or bone disease (Fig. 149-5). The

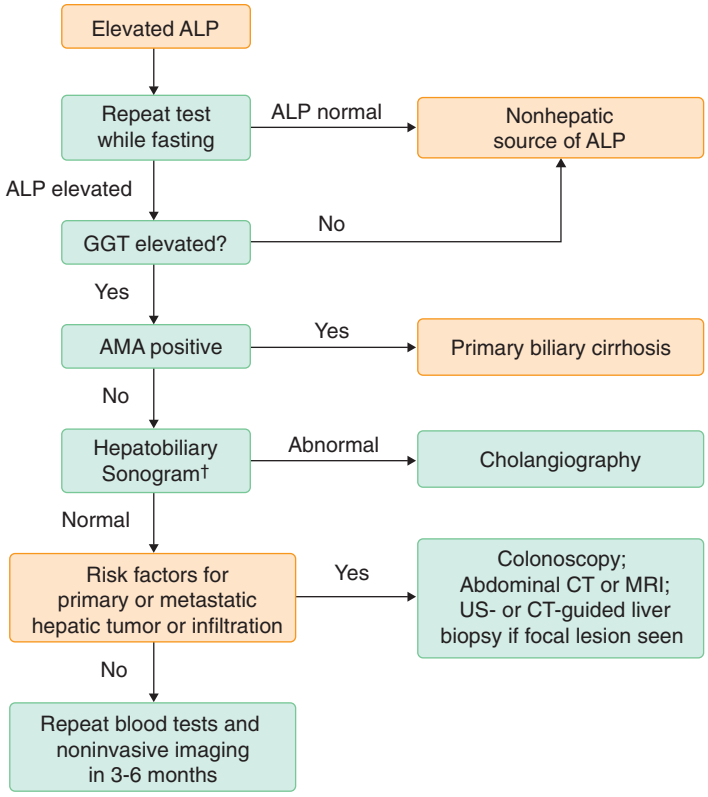

FIGURE 149-5. Approach to the asymptomatic patient with isolated elevated levels of serum alkaline phosphatase (ALP). †In cases with a high index of suspicion of biliary tract disease, such as sclerosing cholangitis, cholangiography may be warranted even in the face of normal ultrasound imaging. AMA = antimitochondrial antibody; CT = computed tomography; GGT = γ-glutamyl transpeptidase; MRI = magnetic resonance imaging; US = ultrasonography.

origin of an elevated alkaline phosphatase should be confirmed with a fasting sample because intestinal alkaline phosphatase may be elevated after a meal. A hepatic source is highly likely if the serum GGT is also abnormal. Women should be screened with an antimitochondrial antibody test; a positive result suggests primary biliary cirrhosis (Chapter 158). A careful history (Chapter 148) identifies patients at risk for intrahepatic cholestasis related to drugs or toxins. Essentially all other patients with persistently abnormal alkaline phosphatase should receive a hepatobiliary sonogram or other noninvasive imaging test. Demonstration of dilated intrahepatic or extrahepatic bile ducts should prompt direct visualization of the biliary tract by ERCP or PTC (Chapters 136 and 158). Evidence of an intrahepatic mass should prompt thorough evaluation for possible malignancy (Chapters 158 and 202). Because colon cancer often metastasizes to liver, colonoscopy may be useful in appropriate cases (Chapter 199). Infiltrative diseases, including schistosomiasis and granulomatous hepatitis (Chapter 154), should also be considered. In the absence of evidence of biliary obstruction or a cause identifiable by noninvasive means, liver biopsy should be strongly considered to complete the evaluation of cholestatic liver test abnormalities.

150 ACUTE VIRAL HEPATITIS

HEINER WEDEMEYER AND JEAN-MICHEL PAWLOTSKY

INTRODUCTION

Infection with a hepatotropic virus causes an acute episode of liver inflammation, referred to as *acute hepatitis,* which can lead to either spontaneous clearance of the infectious agent or its persistence, which in turn leads to chronic infection for a subset of these viruses. Five hepatitis viruses are responsible for the vast majority of acute hepatitis cases (Table 150-1): hepatitis A virus (HAV); hepatitis B virus (HBV); hepatitis C virus (HCV); hepatitis D or delta virus (HDV), which is a defective viroid using the hepatitis B surface antigen (HBsAg) as its envelope; and hepatitis E virus (HEV). Other viruses may also cause acute inflammatory liver disease, including members of the Herpesviridae family such as human cytomegalovirus, Epstein-Barr virus, or herpes simplex virus. It is unclear to what extent other viruses, such as parvovirus B19 or human herpesvirus 6, can also cause acute hepatitis. Patients who present with an acute viral hepatitis syndrome but negative virologic tests are referred to as having non A to E hepatitis, perhaps owing to unknown hepatotropic viruses. The worldwide incidence of acute viral hepatitis is decreasing because of global improvement in hygiene and the development and use of efficient vaccines against HAV and HBV, and perhaps in the future, HEV.

TABLE 150-1 VIRUSES RESPONSIBLE FOR ACUTE VIRAL HEPATITIS AND LIKELIHOOD OF CHRONIC EVOLUTION

VIRUS	EVOLUTION TO CHRONIC VIRAL HEPATITIS
Hepatitis A	Never
Hepatitis B	>90% (perinatal acquisition) to <1% (adult infection)
Hepatitis C	50-80%
Hepatitis D or delta	2% (coinfection) to 90% (superinfection)
Hepatitis E	Occasionally in immunosuppressed patients
Other viruses Human cytomegalovirus Epstein-Barr Herpes simplex Human herpesvirus 6 Parvovirus B19	May establish chronic infection, not associated with chronic hepatitis

GENERAL FEATURES OF ACUTE VIRAL HEPATITIS

PATHOBIOLOGY

Acute viral hepatitis is characterized by acute necroinflammation of the liver. Because none of the hepatotropic viruses is cytopathic, liver injury is thought to be mediated by a strong cytotoxic T-cell-mediated reaction against infected hepatocytes that express viral antigens at their surface. Proinflammatory cytokines, natural killer cells, and antibody-dependent cellular cytotoxicity also appear to play a role in liver necroinflammation. Successful immune elimination may lead to viral clearance, which may or may not be associated with lifelong immunity, depending on the infecting agent. The immune reaction is sometimes so potent that the patient develops subfulminant or even fulminant hepatitis that requires liver transplantation (Chapter 157). In some patients—the proportion varies, according to the virus responsible for acute hepatitis—the immune response fails and chronic infection is established (Chapter 151).

CLINICAL MANIFESTATIONS

After infection, there is an incubation period of a few days to a few weeks, depending on the causative agent (Fig. 150-1). This incubation period is generally characterized by nonspecific symptoms, including fatigue, nausea, loss of appetite, flu-like symptoms, and/or right upper quadrant pain (Table 150-2). The incubation period is often characterized by leukopenia and relative lymphocytosis. Immune-mediated symptoms, including rash, hives, arthralgias, angioneurotic edema, and fever, are observed in 10 to 20% of patients during the preicteric phase.

During the acute stage of the disease, symptoms may vary widely, from asymptomatic to subicteric, icteric or severe, and fulminant. The icteric form, which is not frequent, is characterized by fatigue, anorexia, nausea, dysgeusia, jaundice, dark urine, light colored stool, and weight loss. Physical

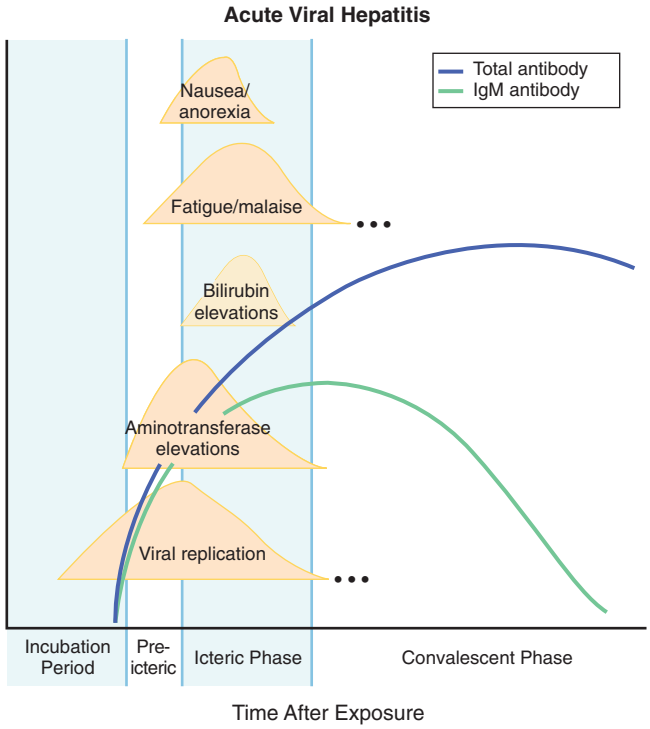

FIGURE 150-1. Typical course of acute viral hepatitis.

TABLE 150-2 CLINICAL MANIFESTATIONS OF VIRAL HEPATITIS

PHASES OF INFECTION	DURATION*	MANIFESTATIONS*
Inoculation	2-20 wk	Virus detectable in blood Aminotransferase and bilirubin levels normal No antibody detectable
Preicteric	3-10 days	Nonspecific symptoms: fatigue, anorexia, nausea, vague right upper quadrant pain Viral titers peak Aminotransferase levels begin to rise Serum sickness–like reaction (≈10-20% of cases) with rash, hives, arthralgias, fever
Icteric	1-3 wk	Jaundice appears; dark urine and light stools seen Nonspecific symptoms worsen Weight loss, dysgeusia, pruritus may occur Hepatosplenomegaly may develop Aminotransferase levels typically >10 times normal Antibodies appear Viral titers decline Rare extrahepatic manifestations (aseptic meningitis, encephalitis, seizures, ascending flaccid paralysis, nephrotic syndrome, seronegative arthritis)
Recovery	Up to 6 mo	Symptoms resolve gradually Antibody levels rise Aminotransferase and bilirubin levels normalize
Chronic	After 6 mo	See Chapter 151

*Varies by virus.

examination reveals jaundice and hepatic tenderness. Hepatomegaly and splenomegaly may be present. On laboratory testing, acute viral hepatitis is characterized by elevated total and direct serum bilirubin levels and aminotransferase levels that are often more than 10 times the upper limit of normal. Cholestatic acute hepatitis is frequently associated with prolonged and fluctuating jaundice and pruritus. After 1 to 3 weeks, on average, both clinical and laboratory signs progressively improve and return to normal. Some patients, however, may experience a relapse before definitive resolution.

Fulminant forms of acute viral hepatitis are characterized by signs of hepatic failure, including changes in personality, aggressive behavior, sleeping disorders, and hepatic encephalopathy (Chapter 157). Coma can supervene rapidly, and widespread hemorrhage may develop.

DIAGNOSIS

The diagnosis of acute hepatitis is suspected based on elevated serum aminotransferase levels, which are generally more than 10 times the upper limit of normal (Table 150-3). Total and direct bilirubin levels are elevated if the acute hepatitis is subicteric or icteric. Alkaline phosphatase levels may be elevated in cases of cholestatic hepatitis.

Serologic and eventually molecular testing identifies the causal agent. Liver biopsy is generally not required. All cases of acute hepatitis should be reported to the local, state, or national health department as soon as possible after diagnosis.

TREATMENT Rx

In addition to virus-specific therapy for HBV and HCV, patients with acute viral hepatitis should avoid alcohol consumption. Sexual contact should be avoided if the partner is not protected. Patients with subfulminant or fulminant hepatitis should be evaluated for possible liver transplantation and supported in an intensive care unit setting (Chapter 157).

PROGNOSIS

Prognosis depends on the degree of prolongation of the prothrombin time, as well as how high the bilirubin and lactate levels are. A factor V level below 40% or any signs of encephalopathy are indications for hospitalization. Death is extremely rare and occurs only in fulminant cases. Other signs of poor prognosis are persistently worsening jaundice, ascites, and an acute decrease in the size of the liver. Serum aminotransferase levels and viral genome levels have no prognostic value.

HEPATITIS A

The Pathogen

HAV is a member of the Picornaviridae family, genus *Hepatovirus*. The hepatitis A viral particle is a 27-nm nonenveloped icosahedral nucleocapsid that expresses the hepatitis A antigen and contains a positive-stranded RNA genome approximately 7.5 kb long. At least four different HAV genotypes have been described in humans (genotypes I, II, III, and VII), with genotype I predominating worldwide. Other genotypes have been isolated in nonhuman primates. It is currently unclear to what extent different genotypes are associated with distinct clinical courses of infection.

EPIDEMIOLOGY

HAV infection has a worldwide distribution, and infections can be sporadic or occur in epidemic outbreaks. The incidence of acute cases and the seroprevalence vary according to the hygiene, sanitation, housing, and socioeconomic standards of the region, with seroprevalences as low as about 13% in Sweden but up to 100% in many developing countries. In developing countries, infection generally occurs at a young age, and most of the population has been exposed and is protected after age 10 years. In developed countries, however, infection can occur at any age, and the prevalence of exposed, immune subjects slowly increases with age. In the United States, the incidence of acute hepatitis A has declined from 12.0 cases per 100,000 individuals in 1995 to 1.0 case per 100,000 individuals in 2007.

HAV is generally transmitted via the oral-fecal route, most often directly from person to person or through the ingestion of fecally contaminated food or water. Transmission by blood transfusion has been reported, and isolated cases of apparent perinatal transmission have been described. High-risk groups for acute hepatitis A include travelers to developing countries, children in daycare centers and their parents, men who have sex with men, injection drug users, hemophiliacs who receive plasma products, and persons in institutions.

PATHOBIOLOGY

The genome serves as a messenger RNA and contains a single open reading frame that encodes both structural and nonstructural viral proteins. After attachment to a specific receptor at the surface of hepatocytes, the virus penetrates into cells and is uncoated. Subsequent events occurring exclusively in the cytoplasm include translation of the single open reading frame into a polyprotein that is later processed to generate the mature viral proteins; replication in a membrane-bound replication complex that generates new viral genomes, which are subsequently used for viral protein production and viral particle assembly; and packaging of newly formed genomes into new particles that are exported out of the cells. The virus is secreted into bile and, to a lesser extent, serum.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 15 to 45 days (see Table 150-2). In most cases, acute infection takes a mild, often unrecognized course. The incidence of symptomatic, icteric cases increases with the age at infection. Acute hepatitis A in adults may require hospitalization in up to 13% of cases; prolonged courses of 6 to 9 months have been reported in 10% of adult patients with a diagnosis of acute hepatitis A. Hepatitis A is the most common cause of relapsing cholestatic hepatitis.

DIAGNOSIS

The diagnosis of acute hepatitis A is based on the detection of anti-HAV immunoglobulin (Ig) M in serum by enzyme immunoassay. IgM serum levels peak during the second month of infection (Fig. 150-2). HAV RNA can be transiently detected in stool and other body fluids by polymerase chain reaction (PCR) 3 to 10 days before the onset of illness and for 1 to 2 weeks thereafter; however, HAV RNA testing is generally not necessary. When the infection resolves, anti-HAV IgM disappears after 4 to 12 months, but anti-HAV IgG persists for life and confers definitive protection against infection.

TREATMENT

Rx

Because HAV infection is self-limited, no specific antiviral treatment is required. In severe cases, patients may need to be hospitalized. If liver function is deteriorating, patients may need to be assessed for liver transplantation, which is the only therapeutic option for acute liver failure (Chapter 157).

PREVENTION

HAV vaccines consist of inactivated hepatitis A antigen purified from cell culture. Two doses of the vaccine at a 6- to 18-month interval are recommended. All vaccines are highly immunogenic, and virtually all healthy persons who are vaccinated develop protective anti-HAV antibodies. Patients with chronic liver disease also respond to vaccination but may display lower anti-HAV titers. An accelerated vaccine schedule, with vaccination on days 0, 7, and 21, is also effective and may be recommended for those planning to travel to endemic areas. HAV vaccines are well tolerated, and no serious adverse events have been linked with their administration; they can be safely administered with other vaccines or immune globulins without compromising the development of protective antibodies. A combination HAV and HBV vaccine is also available. Seroconversion rates are lower in patients with human immunodeficiency virus (HIV) infection and in other immunocompromised individuals.

HAV vaccination is recommended for nonimmune individuals who plan to travel to endemic countries, medical health professionals, men who have sex with men, persons who are in contact with hepatitis A patients, and individuals with chronic liver diseases. A childhood vaccination program leads to a significant decline in HAV infection, justifying its use as part of control efforts in endemic countries. Serologic testing for anti-HAV IgG can be performed before vaccination in adults born in endemic countries and in individuals older than 50 years born in industrialized areas; persons with detectable IgG are protected and should not be vaccinated. For postexposure prophylaxis, both HAV vaccination and immune globulin are effective; although immune globulin confers a slightly lower rate of infection, they should be used together.

Long-term follow-up studies after complete HAV vaccination show that anti-HAV titers sharply decline during the first year after vaccination but remain detectable in almost all individuals for at least 10 years. Protective anti-HAV antibody titers persist for at least 27 years after the successful vaccination of children and young adults.

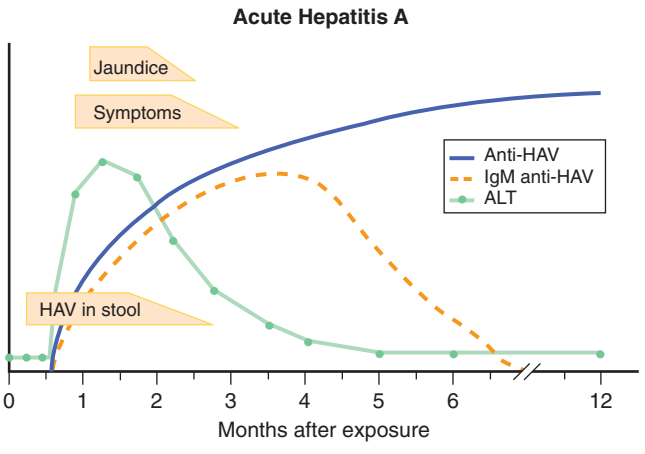

FIGURE 150-2. Serologic course of acute hepatitis A. ALT = alanine aminotransferase; HAV = hepatitis A virus; IgM = immunoglobulin M.

PROGNOSIS

Acute hepatitis A infection generally resolves without complications in 3 to 4 weeks and never evolves to chronic infection. Prolonged elevations of serum aminotransferase levels have been reported. Relapses a few weeks after the acute case have also been observed. Prolonged courses may occur in children and immunosuppressed individuals.

Cholestatic hepatitis A is unusual and has a good prognosis, with full recovery within a few weeks. Fulminant hepatitis A is rare, occurring in less than 0.1% of cases, but its incidence and mortality increase with the patient's age at acquisition. In the United States, 4% of all cases of fulminant hepatitis are caused by HAV infection. Overall, mortality of acute hepatitis A is 1.8% in patients older than 50 years. In patients with chronic hepatitis B, superinfection with HAV is associated with a 6- to 23-fold higher morbidity and mortality.

ACUTE HEPATITIS B

The Pathogen

HBV is a member of the Hepadnaviridae family, genus *Hepadnavirus*. The infectious virion, the Dane particle, is 42 to 47 nm in diameter. It possesses an envelope and a capsid or core that contains the partially double-stranded, circular DNA genome. The HBV genome is the smallest known human virus genome, with approximately 3000 nucleotides.

EPIDEMIOLOGY

Two billion individuals—that is, one third of the human population—have been in contact with HBV, and more than 350 million individuals have chronic infection. In the United States, approximately 0.5% of the population is chronically infected. HBV virions are produced and circulate in very high amounts in HBV-infected individuals, who are highly contagious. Four principal routes of transmission are responsible for acute HBV infections: (1) sexual transmission, which is the principal route in industrialized areas; (2) perinatal mother-to-infant transmission, which is associated with a very high (>90%) rate of chronic infection and is the principal cause of HBV transmission in Asia; (3) horizontal transmission through nonsexual interindividual contact, which is frequent at a young age in Africa and is associated with evolution to chronicity in approximately 15% of cases; and (4) percutaneous transmission by blood and blood products, unsafe medical or surgical materials, or injection drug use.

In industrialized countries, groups at high risk for HBV infection include individuals born in areas where HBV is endemic, including immigrants and adopted children; individuals who were not vaccinated as infants and whose parents were born in regions where HBV is endemic; household and sexual contacts of HBsAg-positive individuals; persons who have ever injected drugs; persons with multiple sexual partners or a history of sexually transmitted disease; men who have sex with men; inmates of correctional facilities; patients infected with HCV or HIV; patients undergoing renal dialysis; recipients of blood or blood products before 1987; and health care workers.

PATHOBIOLOGY

The HBV genome contains at least four overlapping open reading frames that encode a number of structural and nonstructural viral proteins. The pre-S/S gene encodes the three surface proteins—small (S), middle (M), and large (L)—which express HBsAg. The pre-C/C gene encodes the core protein that expresses the hepatitis B core (HBc) antigen and the hepatitis B e (HBe) protein, a nonstructural protein that plays a role in immune tolerance to HBV replication. The P gene encodes the HBV polymerase, whose two motifs—a reverse transcriptase motif and an RNAse H motif—code for two enzymes

involved in HBV replication. Finally, the X gene encodes the X protein, which is a transactivator involved in HBV replication that bears oncogenic properties. The blood of infected patients contains not only infectious viruses but also a large excess of empty, noninfectious HBV envelopes.

The complex HBV life cycle involves multiple steps: fixation to an as yet unidentified receptor complex at the surface of hepatocytes; internalization; fusion and release of the nucleocapsid containing the HBV DNA genome and the associated HBV polymerase molecule in the cell cytoplasm; transport into the nucleus, where decapsidation occurs and the DNA genome molecule is released; transformation of the viral genome by the viral polymerase into a covalently closed circular DNA, which is the episomal form responsible for persistence of the HBV genome in the nucleus of infected hepatocytes; generation of messenger RNAs and viral protein synthesis; generation of a pregenomic RNA, which serves as a template for reverse transcription that generates the long DNA strand; degradation of the pregenomic RNA by the RNAse H activity of the viral polymerase; DNA-dependent DNA polymerase activity of the reverse transcriptase motif, which synthesizes the short complementary DNA strand in newly formed nucleocapsids; and, finally, budding into the endoplasmic reticulum, maturation, and export of newly formed virions.

Eight HBV genotypes (A through H), which differ by approximately 8% of their genomic nucleotide sequence, have different geographic distributions and may be associated with different clinical outcomes. Genotype A predominates in northern and western Europe, whereas genotype D is the most frequent genotype in the Mediterranean area and in eastern Europe. In non-Asian populations in the United States, genotype A predominates in men who have sex with men, whereas genotype D is the most frequent in intravenous drug users. In Asia and in Asian immigrants living in industrialized countries, genotypes B and C predominate. Genotype C has been associated with a higher incidence of severe liver disease and hepatocellular carcinoma compared with genotype B in Asia, perhaps because this genotype spread earlier than the others.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 30 to 150 days. Jaundice has been reported in up to one third of adult patients with acute hepatitis B, but most cases are unrecognized. Among symptomatic patients (see Table 150-2), the manifestations are similar to those of other causes of acute viral hepatitis.

DIAGNOSIS

Four markers should be sought for the diagnosis of acute hepatitis B: HBsAg, total anti-HBc antibodies, anti-HBc IgM, and anti-HBs antibodies (Table 150-4). Acute hepatitis B is characterized by the simultaneous presence of both HBsAg and anti-HBc IgM (Fig. 150-3). Total anti-HBc antibodies are also present, whereas anti-HBs antibodies are not. During the convalescence phase, patients lose HBsAg before the appearance of anti-HBs antibodies; they have isolated anti-HBc antibodies, and the diagnosis is based on the presence of anti-HBc IgM. Recovery is characterized by the appearance of anti-HBs antibodies. The presence of both total anti-HBc and anti-HBs antibodies characterizes recovery from acute hepatitis B. Anti-HBc IgG remains at high levels for the patient's lifetime, whereas anti-HBs antibody titers may fluctuate and become undetectable after several years. Quantitative HBsAg assessment may be useful during the course of acute hepatitis B because if the HBsAg level does not rapidly decrease, the patient is at risk for chronic evolution. Patients who remain HBV DNA– and/or HBeAg-positive 6 weeks after the onset of symptoms are likely to develop chronic infection.

TABLE 150-4 SEROLOGIC PROFILES OBSERVED IN DIFFERENT PHASES OF ACUTE, SELF-RESOLVING HEPATITIS B

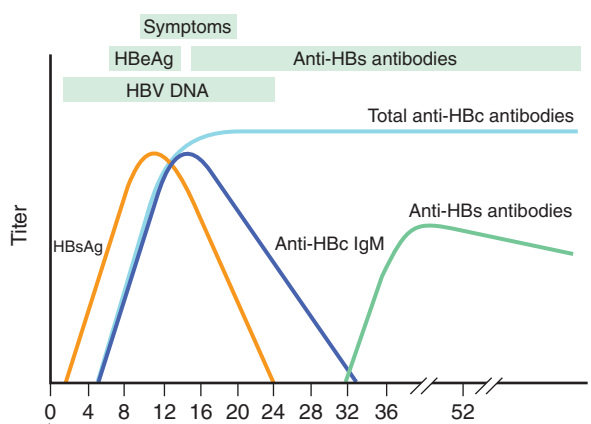

FIGURE 150-3. Kinetics of hepatitis B virus (HBV) markers during acute self-resolving hepatitis B. The arrow indicates infection. HBc = hepatitis B core; HBeAg = hepatitis B e antigen; HBs = hepatitis B surface; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M.

TREATMENT

Rx

Acute HBV infection usually does not require antiviral therapy, and most patients spontaneously clear the infection. Antiviral therapy with lamivudine can decrease HBV DNA levels more rapidly but does not result in better clinical or biochemical improvement and may be associated with lower levels of protective anti-HBs at 1 year.■ However, nonrandomized data in patients with severe acute or fulminant hepatitis B suggest that early antiviral therapy (lamivudine 100 mg daily) is safe and may reduce the need for liver transplantation.

PREVENTION

Because not everyone has been vaccinated, individuals who are aware that they are infected with HBV should take steps to avoid transmitting the infection to others. This is accomplished by ensuring that their sexual contacts and household members are vaccinated; using barrier protection during sexual intercourse; not sharing instruments such as toothbrushes, razors, and combs; cleaning blood spills with detergent or bleach; and not donating blood, organs, or sperm.

Prevention of HBV infection is based on vaccination. Universal infant vaccination programs have been initiated in many countries. High-risk individuals (e.g., health care workers, dialysis patients, family members and sexual partners of HBV carriers, pregnant women, and men who have sex with men) should be screened for HBV infection by HBsAg and anti-HBs antibody testing, and seronegative persons should be vaccinated.

Vaccination consists of the administration of recombinant HBsAg in three injections at 0, 1, and 6 months in adults. A lower dose is given at the same time points in newborns, children, and adolescents. Adults on dialysis require four injections at months 0, 1, 2, and 6. HBV vaccination elicits a potent neutralizing response, characterized by the presence of anti-HBs antibodies at titers greater than 10 U/L (protective titer). The seroconversion rate is higher than 90% in healthy individuals. HBV vaccines are well tolerated. Injection site reactions within 1 to 3 days, as well as mild general reactions, are common and transient. Postvaccination testing for anti-HBs antibodies to document seroconversion is not routinely recommended. However, persons who remain at risk for HBV infection, such as infants of HBsAg-positive mothers, health care workers, dialysis patients, and sexual partners of HBV carriers, should be tested to determine their response to vaccination.

Three percent to 10% of vaccinated subjects respond poorly or do not respond, especially smokers, obese patients, and elderly individuals. Nonresponders should receive another full course of vaccination, often with an increased dose. Other options include intradermal application and the coadministration of adjuvants and cytokines. One to two thirds of vaccinated individuals lose their anti-HBs antibodies after 10 to 15 years. It is unclear whether these subjects are still protected. Thus, persons at risk should receive booster immunization if anti-HBs antibodies have been lost.

When nonimmune persons or vaccinated individuals with an anti-HBs titer below 10 IU/L have contact with HBV-contaminated materials (e.g., needles) or have sexual intercourse with an HBV-infected person, active-passive immunization (i.e., infusion of hepatitis B immune globulin) plus active immunization (vaccination) is recommended within 48 hours after exposure. Vaccination alone is sufficient in persons with anti-HBs antibody titers between 10 and 100 IU/L, and no action is required if the anti-HBs titer is above 100 IU/L.

Infants born to HBsAg-positive mothers must receive hepatitis B immune globulin and be vaccinated within 12 hours of birth; this regimen reduces the rate of vertical HBV transmission from 95% to less than 5%. Mothers with HBV DNA levels above 5×10^7 IU/mL should also be treated during pregnancy with a potent nucleoside/nucleotide analogue with no teratogenic risk; the safest drugs in this setting are lamivudine and tenofovir, with the latter being more potent and having a higher barrier to resistance. Cesarean section is not needed if active-passive immunization is to be performed. Mothers of vaccinated infants can breast-feed, unless oral antiviral medications are present in the breast milk.

PROGNOSIS

Fulminant hepatitis is more frequent in acute HBV infection than in other types of acute viral hepatitis, with an incidence of about 0.1%. Factors associated with adverse outcomes of acute hepatitis B include advanced age, female sex, and perhaps some strains of virus. Whether infection with a precore mutant strain is associated with more severe or fulminant disease is still debated.

Among patients infected at birth, the rate of spontaneous recovery after an acute HBV infection is less than 5%, whereas adult infections spontaneously resolve in 95 to 99% of cases. Spontaneous resolution confers lifelong immunity, which is usually characterized by the presence of anti-HBs antibodies. Anti-HBs antibodies may become undetectable several years after resolution, but patients rapidly produce protective antibodies if they are re-exposed to HBV.

ACUTE HEPATITIS C

The Pathogen

HCV is a member of the Flaviviridae family, genus *Hepacivirus*. The genome is a single-stranded, positive, linear RNA molecule whose 5′ end contains an internal ribosome entry site involved in polyprotein translation; the genome also includes one single open reading frame and a short 3′ noncoding region involved in replication. The genome is contained in a protein capsid or core, which itself is surrounded by a lipid bilayer envelope into which two inserted viral glycoproteins mediate attachment of the viral particle to receptor molecules at the surface of target cells.

EPIDEMIOLOGY

HCV is present in all continents, and an estimated 120 to 130 million individuals, or 3% of the world population, are chronically infected. In industrialized countries, the incidence of HCV infection has declined considerably owing to blood screening and measures to prevent viral infections in intravenous drug users. However, about 35,000 new cases of acute hepatitis C still occur annually in the United States. In Germany, approximately 8 new infections per 100,000 inhabitants occur each year. HCV prevalence is higher in developing areas of the world, where the main route of HCV infection is unsafe medical or surgical procedures; only about 50% of blood products are screened for anti-HCV antibodies in these countries, and about 40% of all injections are given via reused equipment. Egypt's estimated 9% prevalence is the highest worldwide, owing to unsafe injection campaigns for the treatment of schistosomiasis. Although the incidence of acute hepatitis C has declined in Egypt during the past 15 years, up to 10% of cases of acute hepatitis are still caused by HCV.

HCV is transmitted almost exclusively by infected blood. Preventive screening with highly sensitive enzyme immunoassays and, more recently, nucleic acid testing has virtually eliminated the risk of post-transfusional HCV infection (theoretical risk: 1 in 2 million donations in the United States, 1 in 8 million donations in France). As a result, the principal route of HCV transmission in industrialized countries is now intravenous drug use, which is responsible for 60 to 80% of new cases. The incidence of HCV infection in this high-risk group is as high as 39 per 100 person years. In this context, imprisonment is an important risk factor for acquiring HCV infection in industrialized countries.

Nosocomial transmission through the use of improperly decontaminated materials or the contaminated hands or gloves of health care workers is responsible for a substantial number of new infections worldwide. HCV can also be transmitted by tattooing, piercing, or acupuncture if standard precautions are not implemented. Although HCV can be acquired after accidental needlestick exposure, the risk of infection is low (<1%), and health care workers have only a slightly higher prevalence of HCV than the general population. HCV can be transmitted to household members who share instruments such as scissors, razors, and combs. Sexual transmission is unusual, but outbreaks of acute hepatitis have been reported in HIV-positive communities of men who have sex with men. The risk of mother-to-infant transmission of HCV is less than 5% and is generally related to exposure to the mother's blood in the perinatal period. Cesarean sections are not recommended, and breast-feeding is not contraindicated. The risk of perinatal transmission is higher when the mother is coinfected with HIV. Other factors possibly associated with high transmission rates include the level of HCV viremia and maternal intravenous drug abuse. In 10 to 30% of cases, no apparent risk factor for HCV infection is identifiable, suggesting other potential sources of "community-acquired" hepatitis C.

PATHOBIOLOGY

Entry of HCV into cells is pH dependent through clathrin-mediated endocytosis and is followed by fusion. Decapsidation of viral nucleocapsids liberates free genomic RNAs into the cell cytoplasm, where they serve, together with newly synthesized RNAs, as messenger RNAs for synthesis of the HCV polyprotein. The post-translational processing of the HCV polyprotein results in the generation of at least 10 proteins, including 3 structural proteins (the core protein and the two envelope glycoproteins) and 7 nonstructural proteins. Infection with HCV leads to rearrangements of intracellular membranes, a prerequisite to the formation of the replication complex that associates viral proteins, cellular components, and nascent RNA strands in close proximity. HCV replication is catalyzed by a virally encoded RNA-dependent RNA polymerase within the replication complex. The positive-strand genome RNA serves as a template for the synthesis of a negative-strand intermediate of replication. Then, negative-strand RNA serves as a template to produce numerous strands that have a positive polarity and will subsequently be used for polyprotein translation, synthesis of new intermediates of replication, or packaging into new virus particles. Viral particle formation is initiated by the interaction of the core protein with genomic RNA. Budding of newly formed virions in the endoplasmic reticulum lumen leads to the formation of coated particles. Newly produced virus particles leave the host cell via constitutive secretory pathways.

Phylogenetic analyses of HCV strains isolated in various regions of the world have identified six main HCV genotypes, designated 1 through 6. These HCV types comprise a large number of subtypes, identified by lowercase letters (1a, 1b, etc.). The genotypes' nucleotide sequences differ by between 31 and 34%, and their amino acid sequences differ by approximately 30%; in contrast, the subtypes' nucleotide sequences differ by between 20 and 23%, with marked differences in particular genomic regions. The high prevalence and diversity of HCV genotype 3 and 6 strains in Asia and of genotype 1, 2, and 4 strains in Africa suggest that these types and subtypes emerged and diversified in these regions. In industrialized countries, a small number of HCV genotypes, including 1a, 1b, 2a, 2b, 2c, 3a, and 4a, have been introduced and spread rapidly among exposed populations. Subtypes 1a and 1b predominate all over the world. The most common genotypes in the United States are 1a and 1b (approximately 75%), 2a and 2b (approximately 15%), and 3a (approximately 7%). Genotype 3a is more prevalent in western Europe, where it accounts for up to 35% of cases, especially among intravenous drug users. Genotype 4 is highly prevalent in the Middle East and Africa. Its incidence and prevalence are increasing in intravenous drug users in industrialized countries. Genotype 5 is rare outside South Africa, and genotype 6 is rare outside Southeast Asia. Infections with different genotypes do not differ in terms of the clinical manifestations, progression, or disease severity (although this is debated), but the HCV genotype is a major determinant of the response to interferon-α–based therapies.

CLINICAL MANIFESTATIONS

HCV RNA becomes detectable in the serum 3 to 7 days after exposure. HCV RNA levels rise rapidly during the first weeks, followed by serum aminotransferase levels 2 to 8 weeks after exposure. Anti-HCV antibodies arise late in the course of acute hepatitis C and may not be present at the onset of symptoms and serum aminotransferase elevation.

TABLE 150-5 PATTERNS OF HEPATITIS C VIRUS (HCV) MARKERS AND THEIR SIGNIFICANCE DURING ACUTE HEPATITIS C

ANTI-HCV ANTIBODIES	HCV RNA	DIAGNOSIS
–	–	Not acute hepatitis C
–	+	Acute hepatitis C
+	–	Probably not acute hepatitis C (retest in a few weeks)
+	+	Difficult to differentiate acute from chronic hepatitis C

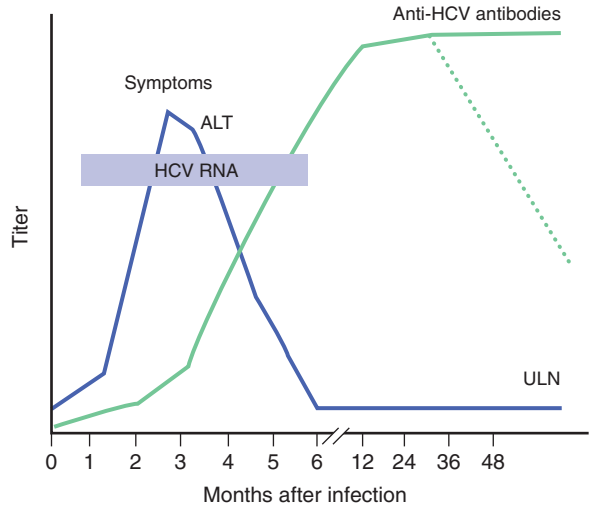

FIGURE 150-4. Kinetics of hepatitis C virus (HCV) markers during acute self-resolving hepatitis C. ALT = alanine aminotransferase; ULN = upper limit of normal.

After an incubation period that ranges from 15 to 120 days, acute hepatitis C usually remains asymptomatic and is undiagnosed. Nonspecific symptoms such as fatigue, low-grade fever, myalgias, nausea, vomiting, or itching may be present. Jaundice occurs in only 20 to 30% of patients, usually 2 to 12 weeks after infection. Serum aminotransferase levels commonly exceed 10 times the upper limit of normal in the acute stage, even in the absence of symptoms. Fulminant hepatitis C has been reported but appears to be exceptional in the absence of another chronic underlying liver disease.

DIAGNOSIS

When acute hepatitis C is suspected, patients should be tested for both anti-HCV antibodies by enzyme immunoassay and HCV RNA with a sensitive molecular biology technique (i.e., an HCV RNA assay with a lower limit of detection of ≤50 IU/mL). Four marker profiles can be observed, based on the presence or absence of either marker (Table 150-5). The presence of HCV RNA in the absence of anti-HCV antibodies is strongly indicative of acute HCV infection, which will be confirmed by seroconversion (i.e., the appearance of anti-HCV antibodies) a few days to weeks later. Acutely infected patients can have both HCV RNA and anti-HCV antibodies at the time of diagnosis; in this case, it is difficult to distinguish acute hepatitis C from an acute exacerbation of chronic hepatitis C or acute hepatitis of another cause in a patient with chronic hepatitis C.

Acute hepatitis C is very unlikely if both anti-HCV antibodies and HCV RNA are absent or if anti-HCV antibodies are present without HCV RNA (Fig. 150-4). Patients in the latter group should be retested in a few weeks, however, because HCV RNA may be temporarily undetectable owing to transient, partial control of viral replication before the infection becomes chronic (Fig. 150-5). Apart from such cases, the presence of anti-HCV antibodies in the absence of HCV RNA is generally seen in patients who have recovered from a past HCV infection. Nevertheless, this pattern cannot be differentiated from a false-positive enzyme immunoassay result, the exact prevalence of which is unknown.

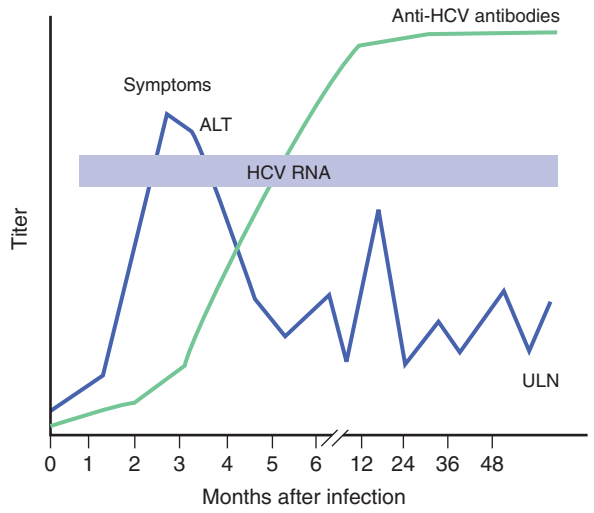

FIGURE 150-5. Kinetics of hepatitis C virus (HCV) markers during acute hepatitis C that evolves toward chronic infection. ALT = alanine aminotransferase; ULN = upper limit of normal.

TREATMENT

Rx

Treatment of acute hepatitis C should be considered not only because it prevents chronic HCV infection, which can lead to serious clinical sequelae, but also because HCV viremia, which is associated with a risk of transmitting HCV to other persons, may have social, legal, and economic consequences, especially for infected health care workers. Treatment can be delayed for up to 3 months in patients with symptomatic acute hepatitis C, whereas immediate therapy is recommended if patients are infected with genotype 1 and have asymptomatic disease. Treatment of acute hepatitis C is based on the use of pegylated interferon-α2a or -α2b at doses of 180 µg/week or 1.5 µg/kg/week, respectively. Treatment should be administered for 24 weeks, but a shorter duration may be sufficient in patients with baseline parameters that predict a rapid viral clearance, such as symptomatic disease, high alanine aminotransferase levels, and low HCV RNA levels. Ribavirin should be added in patients who have a delayed or slow HCV RNA decrease with treatment, genotype 1 infection, and/or low or normal baseline alanine aminotransferase levels. With this treatment, 70% to more than 90% of patients have sustained viral clearance. If treatment fails to clear the virus, patients can be retreated with a combination of pegylated interferon-α2a (180 µg/week) or -α2b (1.5 µg/kg/week) and ribavirin (0.8 g/day) for 48 weeks.

After accidental needlestick exposure, neither immune globulin nor preemptive therapy with pegylated interferon-α is recommended. Patients should be monitored with HCV RNA and aminotransferase level testing at baseline, week 2, and 4 and 6 months after exposure. Patients who have documented infection should be treated as above.

PREVENTION

Prevention of HCV transmission is based on standard precautions such as screening of blood and blood products, application of standard medical and surgical hygiene procedures, and safe use of syringes and materials for drug preparation in drug users. Needle exchange programs and education regarding the risks of drug use (including intranasal cocaine) and the risk of transmission from shared injection equipment are important.

No prophylactic vaccine is available against HCV. Phase I vaccine studies using HCV peptides, HCV proteins, or recombinant vectors expressing HCV proteins have induced HCV-specific T-cell responses or antibodies in healthy individuals, but full protection against infection by heterologous strains appears unlikely.

PROGNOSIS

About 50 to 80% of patients are unable to clear HCV spontaneously and develop chronic infection. Spontaneous recovery is more frequent if infection is acquired at birth (approximately 50%) and if acute hepatitis is symptomatic. It is unclear whether the genotype influences recovery rates. Other factors associated with better rates of spontaneous recovery include female sex, early decline of HCV RNA levels, and high aminotransferase or bilirubin levels. Patients who spontaneously recover may retain detectable anti-HCV antibodies for years to decades, but they are not protected against HCV reinfection.

ACUTE HEPATITIS D OR DELTA

The Pathogen

HDV, which is a satellite of HBV, can be transmitted only to patients who are acutely or chronically infected with HBV. Its single, negative-strand, circular RNA genome of approximately 1700 nucleotides folds in native conditions into a nearly complementary rod-like structure that contains a ribozyme. The HDV genome encodes one single structural protein, the hepatitis D (HD) protein, which expresses HDAg. The 36-nm infectious HDV virion comprises the HD protein and the genome, both enclosed within an HBsAg coat derived from empty HBV envelopes.

EPIDEMIOLOGY

Five percent of chronic HBV carriers, or 15 million to 20 million individuals worldwide, are also infected with HDV. The prevalence of HDV infection in HBV-infected patients varies according to the geographic area because it is transmitted primarily through parenteral exposure. As a result, its prevalence is relatively higher in HBsAg-positive intravenous drug users in Western countries, where approximately 8 to 12% of HBsAg-positive patients are infected with HDV. By comparison, the prevalence of HDV has decreased substantially in southern Europe, probably owing to universal HBV vaccination programs, improvement in hygiene and living conditions, and implementation of standard precautions to prevent HIV infection. The incidence of HDV is increasing in Russia, eastern Europe, Japan, and India.

PATHOBIOLOGY

HDV uses host RNA polymerase II for its replication, following the rolling circle model. Within cells, HDV RNA is associated with multiple copies of the HD protein to form a ribonucleoprotein complex. This complex is exported by the HBV envelope, which contains the three HBV envelope proteins, into the Golgi apparatus before being secreted.

HDV has at least eight genotypes, which differ from one another by at least 15% of their nucleotide sequences. Genotype I is the most prevalent HDV worldwide. Additional genotypes have recently been identified in Africa.

CLINICAL MANIFESTATIONS

HDV can be acquired at the same time as HBV (coinfection) or by a chronic HBsAg carrier (superinfection). Coinfection is characterized by one or two episodes of acute hepatitis, depending on the respective amounts of HBV and HDV present in the inoculum; acute hepatitis can range from mild to fulminant. In contrast, when chronic HBV carriers are superinfected by HDV, acute hepatitis D is generally severe, often fulminant, and chronic.

DIAGNOSIS

Three markers of HDV infection are total anti-HD antibodies, anti-HD IgM, and HDV RNA; each can be detected and quantified by real-time PCR. All HBsAg-positive patients should be tested.

In patients with an HBV-HDV coinfection, HDV RNA is only transiently present and is often missed. Anti-HBc IgM indicates concomitant acute HBV infection.

In HDV superinfection of a chronic HBsAg carrier, no anti-HBc IgM is present. HDV RNA is found in serum or plasma before and during the acute episode, whereas both total anti-HD antibodies and anti-HD IgM are present during the acute phase. Both serologic markers remain at high levels if the disease becomes chronic.

TREATMENT Rx

No treatment of acute hepatitis D has been evaluated so far.

PREVENTION

The most effective means of preventing HDV infection is HBV vaccination, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and behavioral precautions should be practiced to avoid superinfection with HDV.

PROGNOSIS

In patients who are acutely coinfected with HBV and HDV, only about 2% become chronic HDV carriers. In contrast, when HDV infection is acquired by chronic HBV carriers, about 90% also become chronic carriers of HDV.

ACUTE HEPATITIS E

The Pathogen

HEV is the sole known member of the genus *Hepevirus* in the Hepeviridae family. HEV is a small, nonenveloped virus. Its genome is a positive sense, single-stranded RNA molecule. Five HEV genotypes have been described: genotypes 1 and 2 appear to be strictly human, whereas genotypes 3 and 4 appear to be of swine origin but can also infect humans.

PATHOBIOLOGY AND EPIDEMIOLOGY

HEV transmission is principally oral-fecal. HEV is endemic in most developing areas of the world, where acute infections are sporadic or occur during large epidemics related to the contamination of drinking water. Genotype 1 has been found principally in Asia and North Africa, whereas genotype 2 has been isolated in cases from Central America and western Africa. No animal reservoir is known for these genotypes, and transmission appears to be linked to the contamination of food or drinking water. In industrialized countries, HEV genotypes 1 and 2 are not present. HEV genotypes 3 and 4 are endemic in swine, and zoonotic transmission appears to be the main route of transmission in Europe, the United States, and Asia. Diagnosed cases of acute hepatitis E have increased constantly in western Europe and North America in recent years, and high HEV seroprevalences have been described in special at-risk populations, such as butchers or farmers. Transmission may be favored by the consumption of uncooked meat and direct contact with infected animals.

CLINICAL MANIFESTATIONS

The incubation period is 15 to 60 days. HEV infection causes only mild, nonspecific symptoms in the majority of cases, especially if the infection is acquired early in life. Immunocompetent individuals clear the virus spontaneously. The peak of viremia occurs early during infection, whereas the peak of aminotransferase activity is reached approximately 6 weeks after infection. Severe disease is more frequent in pregnant women and in patients with underlying chronic liver disease, who may rarely progress to fulminant hepatic failure.

DIAGNOSIS

Diagnosis of acute hepatitis E is based on the detection of anti-HEV IgM antibodies, but current assays lack sensitivity and specificity. HEV RNA can also be detected in feces, serum, or plasma, where its presence is transient. Anti-HEV IgG generally persists for life after acute infection.

TREATMENT Rx

Treatment of acute hepatitis E is not recommended because the vast majority of patients recover spontaneously. Severe and fulminant cases should be referred to specialized units.

PREVENTION

Improved public hygiene is the best defense against hepatitis E in developing countries. Travelers to areas of the world where HEV is endemic, particularly pregnant women, should be cautioned about drinking the water and eating uncooked food. An efficient prophylactic vaccine based on recombinant HEV proteins was 100% effective in a phase 3 trial.■ However, the duration of protection is uncertain, so the vaccine's efficacy in preventing the spread of HEV has yet to be determined.

PROGNOSIS

Acute cases can be severe in elderly patients, and fulminant cases are frequent among pregnant women who are infected during large-scale water-borne epidemics. HEV genotypes 3 and 4 are less virulent than genotypes 1 and 2. Sporadic cases in industrialized areas are generally benign. HEV does not commonly evolve into chronic infection, but immunosuppressed patients and HIV-positive individuals can become chronic carriers.

OTHER TYPES OF ACUTE VIRAL HEPATITIS

Infection by members of the Herpesviridae family, such as cytomegalovirus (Chapter 384), Epstein-Barr virus (Chapter 385), and herpes simplex virus (Chapter 382), should be considered in the differential diagnosis of unclear

episodes of elevated liver enzymes in the absence of markers of acute hepatitis virus infection, especially in immunocompromised individuals. For instance, cytomegalovirus infection can be associated with graft loss after liver transplantation (Chapter 157). Parvovirus B19 (Chapter 379) may persist in the liver and worsen liver disease in patients with chronic hepatitis B and perhaps in patients with chronic HCV infection. Human herpesvirus 6 variant A has been linked with syncytial giant-cell hepatitis.

Non A to E Hepatitis

Rare patients develop acute hepatitis of presumed viral cause but have no markers of known hepatitis viruses. Some of these cases may be due to variants of known hepatitis viruses, in particular HBV, that are not detected by the usual serologic and molecular methods. However, the existence of other, unknown hepatotropic viruses cannot be excluded.

151 CHRONIC VIRAL AND AUTOIMMUNE HEPATITIS

JEAN-MICHEL PAWLOTSKY AND JOHN MCHUTCHISON

DEFINITION

Chronic hepatitis is defined by chronic necroinflammation of the liver and may be due to various causes, including hepatotropic viruses, autoimmunity, alcohol (Chapter 155), and metabolic disorders (Chapter 153). Chronic infection by hepatitis viruses is by far the main cause of chronic hepatitis worldwide, with more than 500 million individuals chronically infected with hepatitis B virus (HBV) or hepatitis C virus (HCV). Chronic viral hepatitis B and C are the leading cause of cirrhosis (Chapter 156) and hepatocellular carcinoma (Chapter 202) worldwide and account for more than 1 million deaths per year. Chronic HBV infection can be associated with infection by hepatitis D virus (HDV). Hepatitis A virus does not cause chronic hepatitis. Hepatitis E virus (HEV) does not cause chronic hepatitis, except rarely in patients who undergo liver transplantation.

CLINICAL MANIFESTATIONS

The clinical symptoms of chronic viral and autoimmune hepatitis are typically nonspecific, and many patients have no symptoms. Fatigue, sleep disorders, and right upper quadrant pain may be present. Often the diagnosis is made when liver test abnormalities are identified by blood testing during a routine health evaluation or assessment for an unrelated problem or at the time of voluntary blood donation. More advanced symptoms include poor appetite, nausea, weight loss, muscle weakness, itching, dark urine, and jaundice. Patients can progress to full-blown cirrhosis (Chapter 156), with its typical clinical manifestations. If cirrhosis is present, weakness, weight loss, abdominal swelling, edema, bruisability, gastrointestinal bleeding, and hepatic encephalopathy with mental confusion may arise. Other findings may include spider angiomas, palmar erythema (see Fig. 148-2 in Chapter 148), ascites (see Fig. 148-5 in Chapter 148), edema, and skin excoriations (see Fig. 148-3 in Chapter 148).

TABLE 151-1 DIAGNOSIS OF CHRONIC HEPATITIS

DIAGNOSIS	SCREENING TESTS	CONFIRMATORY TESTS
Chronic hepatitis B	HBsAg	HBV DNA, HBeAg
Chronic hepatitis C	Anti-HCV antibodies	HCV RNA
Chronic hepatitis D	Anti-HDV antibodies	HDV RNA
Autoimmune hepatitis	ANA (anti-LKM1)	Exclusion of other causes and patterns of clinical disease
Drug-induced liver disease	History	Rechallenge, if necessary, is considered safe
Wilson disease	Ceruloplasmin	Urine copper concentration
Cryptogenic hepatitis	Exclusion of other causes	

ANA = antinuclear antibody; anti-LKM1 = anti–liver-kidney microsomal 1 antibody; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HDV = hepatitis D virus.

DIAGNOSIS

Levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are usually two to five times the upper limit of normal. The ALT level is generally higher than the AST level, but both can be normal in mild or inactive disease or 10 to 25 times the upper limit of normal during acute exacerbations. Biologic tests can establish the specific diagnosis (Table 151-1).

Alkaline phosphatase and γ-glutamyl transpeptidase levels are usually minimally elevated unless cirrhosis is present. Serum bilirubin and albumin levels and the prothrombin time are normal unless the disease is severe or advanced. Serum immunoglobulin levels are mildly elevated or normal in chronic viral hepatitis but may be very elevated in autoimmune hepatitis. Results that suggest the presence of advanced fibrosis are a platelet count below 160,000, AST levels higher than ALT levels, elevation in serum bilirubin, decrease in serum albumin, prolongation of the prothrombin time, elevation in α-fetoprotein levels, and presence of rheumatoid factor or high globulin levels.

Hepatic ultrasound can determine the texture and size of the liver and spleen, exclude hepatic masses, and assess the gallbladder, intrahepatic bile ducts, and portal venous flow. Computed tomography and magnetic resonance imaging of the liver are helpful if a mass or other abnormality is found by ultrasound. Hepatic elastography can assess liver stiffness as a marker of fibrosis.

Liver biopsy is usually critical for diagnosis and to determine the severity of disease. Hepatocellular necrosis is typically eosinophilic degeneration or ballooning degeneration throughout the parenchyma, greater in the periportal area, spotty, or piecemeal. Fibrosis also typically begins in the periportal regions and can link adjacent portal areas or portal and central areas (bridging fibrosis), distort the hepatic architecture, and lead to cirrhosis and portal hypertension. The histologic grade of chronic hepatitis can be determined by combining scores for periportal necrosis and inflammation, lobular necrosis and inflammation, and portal inflammation. Recently, ultrasound-based methods or serologic markers have proved accurate for the assessment of mild disease and cirrhosis, but they are less accurate for identifying moderate to severe inflammation, except in patients with chronic hepatitis C. Patients with suspected chronic viral or autoimmune hepatitis should be evaluated carefully for fatty liver, alcohol- (Chapter 155) or drug-induced (Chapter 152) liver disease, and metabolic liver diseases (Chapter 153), each of which can coexist with hepatitis. Liver biopsy can exclude other diagnoses that mimic chronic hepatitis, including fatty liver, alcoholic liver disease, steatohepatitis (Chapter 155), drug-induced liver disease (Chapter 152), sclerosing cholangitis (Chapter 158), iron overload (Chapter 219), and veno-occlusive disease (Chapter 145).

TREATMENT AND PROGNOSIS

Rx

Chronic HBV infection is not curable, but it can usually be controlled by appropriate antiviral drugs. HCV infection is curable, but less than 50% of patients who have access to therapy are cured. Autoimmune hepatitis responds to immunosuppression with corticosteroids and azathioprine.

CHRONIC HEPATITIS B

EPIDEMIOLOGY

More than 350 million individuals, or 8.5% of the world's population, are chronic HBV carriers. Two billion individuals, or one human being out of three, have been in contact with the virus. In North America, western and northern Europe, and Australia, less than 2% of the population are chronic hepatitis B surface antigen (HBsAg) carriers. In the United States, the prevalence is approximately 0.4%; that is, about 1.25 million Americans are infected. In eastern Europe, South America, the Mediterranean basin, and the Indian subcontinent, the prevalence of chronic HBsAg carriage is between 2 and 8%. Highly endemic areas, with a rate of chronic HBsAg carriage exceeding 8%, include China, Southeast Asia, sub-Saharan Africa, and the native populations of the Far North of America.

HBV is the main cause of primary liver cancer (hepatocellular carcinoma, Chapter 202) worldwide, with about 350,000 new cases attributable to HBV every year. Hepatocellular carcinoma is more likely in the presence of underlying cirrhosis, but HBV has oncogenic properties of its own, and hepatocellular carcinoma can occur in noncirrhotic HBV patients.

PATHOBIOLOGY

HBV is not a cytopathic virus. Rather, liver injury in chronic hepatitis B is a consequence of the local immune response at the immune elimination phase. In particular, liver injury is related to cytotoxic T cells that recognize and kill infected hepatocytes that express HBV antigens at their surface and to the local production of cytokines. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. The hepatitis B X protein may also directly activate fibrogenesis. As a result, many patients with chronic hepatitis B have progressive fibrosis, which may evolve into cirrhosis.

The rate of chronicity after an acute HBV infection is more than 95% among patients infected at birth. This risk diminishes as the age at acquisition increases, and it is less than 5% in those infected as adults. Chronic HBV infection is defined by HBsAg carriage that persists for more than 6 months after the acute episode. Chronic HBsAg carriage typically evolves through three phases: immune tolerant, immune elimination, and inactive.

The immune tolerant phase is generally short if the infection occurred during adulthood, but it persists for years to decades in patients infected at birth or during early childhood. At the immune tolerant stage, the immune response of the host "tolerates" HBV infection and does not cause liver inflammation or hepatocyte destruction. The immune tolerant phase is characterized by the presence of hepatitis B e antigen (HBeAg), very high levels of HBV DNA in blood, normal serum or plasma aminotransferase levels, and no or minimal inflammatory activity on liver biopsy.

The immune elimination phase is characterized by an active immune response that causes necroinflammatory lesions and triggers hepatic fibrogenesis and progressive fibrosis. ALT and AST levels are increased, but HBV DNA levels are lower than during the immune tolerant phase and frequently fluctuate. The immune elimination phase has a variable duration, ranging from a few weeks to several decades. HBeAg, when present, defines HBeAg-positive chronic hepatitis B; it can be cleared and replaced by anti-HBe antibodies, defined as HBe seroconversion; or it can be absent while anti-HBe antibodies are present and to define HBeAg-negative chronic hepatitis B. Patients with HBeAg-positive chronic hepatitis B are infected with a wild-type virus and are able to secrete the HBe protein. Patients with HBeAg-negative chronic hepatitis B are infected with so-called precore mutant viruses, which cannot produce the HBe protein because they have a stop codon in the pre-C gene, and/or with core promoter mutant viruses, which produce considerably lower amounts of HBe protein.

The inactive HBsAg carriage phase is the result of successful immune elimination leading to HBe seroconversion. ALT and AST levels are normal, HBV DNA is undetectable or at very low levels, and patients without preexisting cirrhosis have normal liver histology.

CLINICAL MANIFESTATIONS

Chronic hepatitis B is usually asymptomatic. The most common symptom is fatigue, but sleep disorders, difficulty concentrating, and upper right quadrant pain are often observed. Chronic hepatitis B is characterized biologically by elevated aminotransferase levels, and ALT levels can fluctuate substantially during the immune elimination phase. Moderate cholestasis, with mildly elevated alkaline phosphatase and γ-glutamyl transpeptidase levels, can also be present, especially in patients with cirrhosis.

HBeAg-negative chronic hepatitis B is generally more severe than the HBeAg-positive variety. The incidence of spontaneous HBe seroconversion among HBeAg-positive patients is 8 to 12% per year when they are in the immune elimination phase; HBe seroconversion often follows a transient ALT flare. Some of these patients evolve toward inactive HBsAg carriage, whereas others switch into an HBeAg-negative form of chronic hepatitis B, with elevated ALT levels and an HBV DNA level greater than 2000 IU/mL.

The annual incidence of cirrhosis varies from 2 to 10% in patients with chronic HBV infection, with a cumulative incidence of approximately 20% at 5 years. The risk of cirrhosis is two- to four-fold higher in HBeAg-negative patients compared with HBeAg-positive ones, probably because they are older and have more severe disease at the time of diagnosis. The annual incidence of hepatocellular carcinoma in patients with chronic hepatitis B varies from 1% in patients without cirrhosis to 2 to 8% in cirrhotic patients, with the higher rates occurring in older patients. Patients with cirrhosis (Chapter 156) and/or hepatocellular carcinoma (Chapter 202) have the typical signs associated with these conditions. Rarely, chronic HBV infection is associated with extrahepatic manifestations, including glomerulonephritis (Chapter 123), most often in children, and polyarteritis nodosa (Chapter 278), mostly in adults.

DIAGNOSIS

Serologic markers used to diagnose chronic hepatitis B (Table 151-2) include HBsAg, anti-HBs antibodies, total anti–hepatitis B core (HBc) antibodies and anti-HBc immunoglobulin M (IgM), HBeAg, and anti-HBe antibodies. Molecular markers include HBV DNA and HBV resistance substitutions; real-time polymerase chain reaction (PCR)–based assays are the best way to detect and quantify HBV DNA

Chronic HBV infection is defined by the persistence of HBsAg in the serum for more than 6 months after the acute episode. The majority of subjects with isolated anti-HBc antibodies are not viremic. However, some individuals who test positive for anti-HBc antibodies, but not for HBsAg or anti-HBs antibodies, may be viremic; in these cases, the virus's amino acid

substitutions in the HBsAg sequence make HBsAg undetectable with current enzyme immunoassays. Other individuals may have such low-level HBV replication in their livers that HBV DNA is not detectable in blood ("occult" hepatitis B).

Serum or plasma ALT and HBV DNA levels are important markers of severity and prognosis. The assessment of severity, including the grade of necroinflammation and the stage of fibrosis, is based on the liver biopsy (Fig. 151-1). Noninvasive assessment using serologic markers or transient elastography can discriminate cirrhosis from mild hepatitis and fibrosis; although they are not accurate enough for intermediate stages, these methods will likely replace liver biopsy in the pretreatment assessment of the severity of chronic hepatitis B in many patients in the future.

PREVENTION AND TREATMENT

Rx

Patients with chronic hepatitis B should be vaccinated against hepatitis A virus, abstain from alcohol, and avoid immunosuppressive therapies unless absolutely necessary. HBV-infected patients who require corticosteroids or chemotherapy for other conditions should receive lamivudine 100 mg daily as prophylaxis against reactivation of hepatitis B.

The goals of therapy are to suppress HBV replication, reduce the histologic activity of chronic hepatitis, and lessen the risk of cirrhosis and hepatocellular carcinoma. HBV infection cannot be completely eradicated because of the persistence of covalently closed circular DNA in the nucleus of infected hepatocytes. As a result, therapy attempts to reduce HBV DNA levels as much as possible—ideally, below the limit of detection of real-time PCR assays (10 to 15 IU/mL)—to ensure a degree of viral suppression that will lead to biochemical remission, histologic improvement, and prevention of complications.

Two different types of drugs for the treatment of chronic hepatitis B are pegylated interferon-α (IFN-α) and nucleoside/nucleotide analogues. Pegylated IFN-α2a, administered subcutaneously at a dose of 180 µg once a week for 48 weeks, improves various markers of HBV infection in both HBeAg-positive (Table 151-3) and HBeAg-negative (Table 151-4) patients. Pegylated IFN-α2b (1.5 µg/kg) is very similar to IFN-α2a and is used by many liver experts, although it is not currently approved for HBV. The most frequent side effects of IFN-α are flu-like symptoms after the injections, fatigue, anorexia, weight loss, and alopecia. The most concerning side effects are neutropenia, thrombocytopenia, anxiety, irritability, depression, and even suicidal ideation.

Nucleoside analogues (lamivudine, telbivudine, and entecavir) require triple phosphorylation to be active, whereas nucleotide analogues (adefovir and tenofovir) need only two phosphorylations to be active. These drugs are given orally once a day at the following dosages: 100 mg for lamivudine, 600 mg for telbivudine, 0.5 mg for entecavir, 10 mg for adefovir (administered as the pro-drug adefovir dipivoxil), and 300 mg for tenofovir (administered as the pro-drug tenofovir disoproxil fumarate). All have short-term benefits on various markers of HBV infection in HBeAg-positive (see Table 151-3) and HBeAg-negative (see Table 151-4) patients. Entecavir and tenofovir are two of the most potent inhibitors of HBV replication, and they are less likely to select for resistant HBV variants. These drugs are generally well tolerated. However, adefovir is nephrotoxic at doses higher than those used for HBV therapy, renal impairment and decreases in mineral bone density are rarely seen with tenofovir, myopathy is a rare complication of telbivudine, and peripheral neuropathy has been observed when telbivudine is combined with pegylated IFN-α.

Patients should be considered for treatment when their HBV DNA levels are greater than 2000 IU/mL and/or their serum ALT levels are abnormal if the liver biopsy shows moderate to severe active necroinflammation and/or fibrosis. Indications for treatment must also take into account the patient's age and health status and the availability of antiviral agents in individual countries. Patients in the immune tolerant phase and those with mild hepatitis on liver biopsy should not be treated, but follow-up ALT levels and HBV DNA assays are mandatory. Patients with compensated cirrhosis and detectable HBV DNA may be considered for treatment even if their ALT levels are normal and/or their HBV DNA levels are below 2000 IU/mL. Patients with decompensated cirrhosis require urgent antiviral treatment.

Two treatment strategies can be considered: a 48-week course of pegylated IFN-α or long-term oral treatment with nucleoside/nucleotide analogues. Whether their combined use improves the rate of sustained virologic response after treatment is currently under study. Pegylated IFN-α can provide a sustained virologic response, defined as a sustained HBe seroconversion (clearance of HBeAg, which is replaced by anti-HBe antibodies) and an HBV DNA level that remains below 2000 IU/mL after a 48-week course of treatment; however, an ALT flare can be observed at the time of HBeAg loss in patients in whom treatment is successful. Pegylated IFN-α treatment should be reserved for patients with the best chance of a sustained virologic response off treatment—HBeAg-positive patients with high baseline ALT levels (more than three times the upper limit of normal) and HBV DNA levels below 2.10^6 IU/mL. Pegylated IFN-α therapy is contraindicated in patients with advanced cirrhosis and in immunosuppressed patients. Patients infected with HBV genotypes A and B generally respond better to IFN-α therapy than do patients infected with genotypes C and D, but the predictive value of the HBV genotype for an individual patient is weak. Patients who fail to achieve a sustained virologic response after a single course of pegylated IFN-α are candidates for nucleoside/nucleotide analogue therapy.

Long-term treatment with nucleoside/nucleotide analogues is indicated in the majority of patients with chronic hepatitis B. Tenofovir or entecavir, which are the most potent drugs with an optimal resistance profile, are recommended as first-line monotherapies. HBV DNA should be suppressed to undetectable levels (<10 to 15 IU/mL) with a sensitive real-time PCR-based assay. If

the HBV DNA level is reduced but still detectable in a compliant patient, the other agent may be added; however, the long-term safety of combined tenofovir and entecavir is unknown. When HBeAg-positive patients seroconvert to negative or HBeAg-negative patients lose their HBsAg, treatment should be continued for an additional 6 to 12 months. In all other cases, treatment should be continued for life, and adherence is particularly important.

Virologic breakthroughs—defined by a subsequent increase of the HBV DNA level of 1 log or more above the nadir level—in adherent patients are due to HBV resistance to the administered antiviral drug or drugs. HBV DNA levels most often increase back to baseline levels, and the virologic breakthrough is generally followed a few weeks later by a biochemical breakthrough in which a previously normal ALT level rises above normal. The cumulative rates of resistance in newly treated patients are 70% at 5 years for lamivudine, 17% at 2 years for telbivudine, 1.2% at 6 years for entecavir, 29% at 5 years for adefovir, and 0% at 2 years for tenofovir. These figures illustrate the high genetic barrier against resistance of entecavir and tenofovir. In a patient who develops resistance to any of the available nucleoside/nucleotide analogues, adding a second drug without cross-resistance is the only efficient strategy, although the long-term safety of some of these combinations is not known. In patients with lamivudine, telbivudine, or entecavir resistance, tenofovir should be added. Patients who have resistance to adefovir should be switched to tenofovir and also given lamivudine, telbivudine, or entecavir. In patients with tenofovir resistance, any of these three drugs should be added. The combination of tenofovir and emtricitabine, a nucleoside analogue similar to lamivudine, in a single tablet (approved for HIV but not for HBV therapy) is also a valid option in cases of resistance to any of these drugs.

In patients with cirrhosis, nucleoside/nucleotide analogue therapy is the only option because pegylated IFN-α is contraindicated if cirrhosis is decompensated. Because resistance in this population can be life threatening, some experts recommend de novo treatment with two potent drugs without cross-resistance. In those with decompensated disease, efficient antiviral treatment most often stabilizes the patient's condition and can also delay or obviate the need for liver transplantation. If transplantation is needed, post-transplant administration of anti-HBV immune globulins in combination with a potent nucleoside/nucleotide analogue prevents recurrent HBV in the vast majority of cases.

PROGNOSIS

Every year, approximately 0.5% of inactive HBsAg carriers spontaneously lose HBsAg, and most of them acquire anti-HBs antibodies. Reactivations are possible in inactive HBV carriers, especially if they become immunosuppressed, such as during chemotherapy or corticosteroid administration. HBV reactivations often evolve into a subfulminant or fulminant form.

The risk of cirrhosis in chronic hepatitis B is 2 to 10% per year, and it is significantly associated with a higher HBV DNA level, older age, alcohol consumption, coinfection with other hepatotropic viruses, and coinfection with HIV. The cumulative incidence of liver decompensation is about 15 to 20% at 5 years in patients with compensated cirrhosis. The complications of cirrhosis, including hepatocellular cancer, are among the main causes of mortality in HBV-infected patients, and the annual incidence of death is about 3 to 4%.

The likelihood of developing hepatocellular carcinoma is about 1% per year in patients without cirrhosis and 2 to 8% per year in those with cirrhosis, and it is significantly associated with a higher HBV DNA level, male sex, old age, reversion from anti-HBe-positive to HBeAg-positive, and coinfection with other hepatotropic viruses. HBV carriers at risk for hepatocellular cancer should be screened every 6 to 12 months, ideally with an ultrasound examination and an α-fetoprotein level.

CHRONIC HEPATITIS C

EPIDEMIOLOGY

HCV, which is present on all continents, is estimated to cause chronic infection in approximately 170 million individuals, or 3% of the world's population. The prevalence of chronic HCV infection, which varies geographically, is estimated to be about 1.3% in the United States (affecting 3.2 million individuals), 3.5% in Asia, 1.9% in the Americas overall, 5.2% in Africa, 1.7% in Europe, and 1.8% in Oceania. The highest prevalence is in Egypt (9% overall, but up to 40% in certain rural areas), where infection was initially spread by intramuscular injections for schistosomiasis during treatment campaigns several decades ago.

PATHOBIOLOGY

Acute HCV infection evolves into chronic infection in 50 to 80% of cases. Even patients who spontaneously recover and maintain detectable anti-HCV antibodies are not protected against reinfection. Persistence of infection is related to a qualitatively and quantitatively altered $CD4^+$ T-helper cell and cytotoxic T lymphocyte response that fails to eradicate infection. The plasticity of the viral genomes is responsible for the coexistence of closely related but genetically different viral populations in equilibrium in the patient's replicative environment. This genetic diversity allows continuously generated variant viral populations to be selected by timely changes in the replicative environment.

Chronic HCV infection is responsible for necroinflammatory lesions of varying severity, sometimes associated with steatosis, which is the accumulation of triglycerides in hepatocytes. HCV is not a cytopathic virus. Liver injury in chronic hepatitis C is related to the action of immune effectors that recognize and kill infected hepatocytes that express HCV antigens at their surface. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. Fibrosis progresses at nonlinear rates that are generally faster in older patients, in males, and in the presence of chronic alcohol intake, viral coinfections, or immunosuppression. The severity of chronic hepatitis is independent of the HCV RNA level and of the HCV genotype. This chronic inflammation and progression of fibrosis predispose patients to cirrhosis (Chapter 156) and hepatocellular carcinoma (Chapter 202).

CLINICAL MANIFESTATIONS

Acute hepatitis C (Chapter 150) is most often asymptomatic and therefore undiagnosed. The most common symptom associated with chronic HCV infection is fatigue, but it may remain unapparent for years. ALT levels are usually moderately elevated and fluctuate, but they can remain normal for weeks to months despite active hepatitis on liver biopsy. Moderate cholestasis can be present in patients with cirrhosis. Patients with cirrhosis (Chapter 156) and/or hepatocellular carcinoma (Chapter 202) have the typical signs associated with these conditions.

HCV is the main cause of type II and type III mixed cryoglobulinemia (Chapter 193). Low levels of circulating cryoglobulins, which contain HCV RNA, anti-HCV antibodies, rheumatoid factor, and low levels of complement, can be found in 50 to 70% of cases, whereas elevated rheumatoid factor (Chapter 272) is found in 70% of cases. Less than 1% of HCV-infected patients develop symptoms of cryoglobulinemic vasculitis, including fatigue, myalgias, arthralgias, rash (purpura, hives, and leukocytoclastic vasculitis), neuropathy, and membranoproliferative glomerulonephritis. Cryoglobulinemia can be severe and lead to end-stage renal disease or severe neuropathies, and long-term cryoglobulinemia has been linked to non-Hodgkin's B-cell lymphomas (Chapter 191).

Low titers of antinuclear and anti–smooth muscle antibodies can be found in HCV-infected patients, but they do not have any clinical significance. HCV has been reported to trigger the symptoms of porphyria cutanea tarda (Chapter 217), and an association with lichen planus (Chapter 446) has been suggested.

DIAGNOSIS

Chronic HCV infection is defined by the persistence of HCV RNA for more than 6 months. In patients with clinical and/or biologic signs of chronic liver disease, chronic hepatitis C is diagnosed by the simultaneous presence of anti-HCV antibodies and HCV RNA. Detectable HCV replication in the absence of anti-HCV antibodies is observed almost exclusively in patients who are profoundly immunosuppressed, on hemodialysis, or agammaglobulinemic. The level of HCV replication does not correlate with the severity of liver disease or with the risk of progression to cirrhosis or hepatocellular carcinoma.

The HCV genotype, which has important therapeutic implications, should be determined. Anti-HCV IgM, which is found in about 50% of patients with chronic hepatitis, is of no significance. Laboratory testing often reveals high levels of monoclonal rheumatoid factor and cryoglobulins.

TREATMENT Rx

Chronic HCV infection is curable. The goal of therapy is to achieve a sustained virologic response, defined by undetectable HCV RNA 24 weeks after the end of therapy using a sensitive HCV RNA assay with a lower limit of detection of 50 IU/mL or less.

The decision to treat chronic hepatitis C depends on a precise assessment of the severity of liver disease, the presence of absolute or relative contraindications to therapy, and the patient's willingness to be treated. Treatment typically requires a liver biopsy, but serologic markers of liver fibrosis and/or fibrogenesis and transient elastography have been validated in large series of patients with chronic hepatitis C.

In patients with no indication for therapy or with contraindications to therapy, repeated assessments of aminotransferase levels are recommended on a yearly basis. Assessment of liver inflammation and fibrosis by liver biopsy or noninvasive serologic or ultrasound-based testing is indicated for patients with persistent or intermittently elevated aminotransferase levels.

The current standard treatment for chronic hepatitis C is the combination of ribavirin (0.8 to 1.4 g/day orally) with either pegylated IFN-α2a (180 μg subcutaneously once weekly) or pegylated IFN-α2b (1.5 μg/kg subcutaneously once weekly). The most common side effects of IFN-α are influenza-like symptoms (which can be prevented by acetaminophen), neutropenia, thrombocytopenia, irritability, difficulty concentrating, memory disturbances, thyroiditis, hair loss, sleep disorders, and weight loss. The principal side effect of ribavirin is hemolytic anemia. As a result of these side effects, dose modification is frequently required during therapy. Ribavirin should be decreased in 200-mg increments in patients with severe anemia. For IFN-induced side effects, the pegylated IFN-α dose should be decreased stepwise, from 180 to 135 to 90 μg/week for pegylated IFN-α2a, and from 1.5 to 1.0 to 0.5 μg/kg/week for pegylated IFN-α2b.

The main contraindications to therapy with pegylated IFN-α and ribavirin are decompensated liver disease, renal failure, severe immunosuppression, solid organ transplantation, cytopenias, severe psychiatric disease, and active substance abuse. Ribavirin is also contraindicated in patients with anemia, significant coronary or cerebrovascular disease, or renal insufficiency. Because ribavirin is teratogenic, it is essential that adequate contraception be practiced during therapy and for at least 6 months thereafter in both men and women.

In patients for whom therapy is deemed appropriate, the HCV genotype guides treatment and its duration (Fig. 151-2). Patients infected with HCV genotype 1 require 48 weeks of treatment and a higher, body-weight-based dose of ribavirin (1.0 to 1.4 g/day). Treatment should be tailored to the actual virologic response using a sensitive assay, such as a real-time PCR. The HCV RNA level should be measured before therapy and 4 and 12 weeks after its initiation. The lack of a virologic response (no change or an HCV RNA level that decreases by less than a factor of 100 [2 $\log_{10}$]) at 12 weeks indicates that the patient has virtually no chance of achieving a sustained virologic response and should stop treatment. In contrast, treatment must be continued if such a decline in HCV RNA level is observed at week 12. Patients who achieve a rapid virologic response (undetectable HCV RNA at week 4) can stop therapy after 24 weeks if their baseline HCV RNA level is below 400,000 IU/mL. Patients who do not achieve a complete virologic response (i.e., HCV RNA is still detectable) at week 4 but do so at week 12 should be treated for 48 weeks; then they can stop therapy. It is now generally accepted that patients with a slow virologic response (HCV RNA has decreased by more than 2 $\log_{10}$ but is still detectable at week 12) should be treated for 72 weeks because prolonged therapy significantly reduces the incidence of post-treatment relapse.

Patients infected with HCV genotypes 2 and 3 require 24 weeks of treatment, but at a lower ribavirin dose of 0.8 g/day. In patients who respond to treatment with an undetectable HCV RNA but relapse after the end of therapy, another 48 weeks of treatment with a higher, weight-based dose of ribavirin (1.0 to 1.4 g/day) is recommended.

Patients infected with HCV genotypes 4, 5, and 6 require 48 weeks of treatment and a higher, body-weight-based dose of ribavirin (1.0 to 1.4 g/day). The same approaches to monitoring and dose adjustment used for genotype 1 probably apply to these genotypes, but they have not been validated in sufficiently large cohorts of patients.

Currently, about 40 to 50% of patients infected with HCV genotypes 1 and 4 and 80% of patients infected with genotypes 2 and 3 achieve a sustained virologic response with the standard combination of pegylated IFN-α and ribavirin; rates for genotypes 5 and 6 are unknown. Predictors of a sustained virologic response include a baseline HCV RNA level less than 800,000 IU/mL, lack of extensive fibrosis or cirrhosis, young age, female sex, nonblack race, and single nucleotide polymorphisms in the host genome. However, none of these negative predictive factors should be used to deny treatment. Long-term maintenance therapy with a low dose of pegylated IFN-α is not beneficial, except perhaps in a small proportion of patients whose HCV RNA levels remain very low or undetectable on treatment.

The results of pegylated IFN-α and ribavirin therapy can be improved by reducing body weight and insulin resistance. Erythropoietin can control ribavirin-induced anemia and minimize ribavirin dose reductions. Granulocyte colony-stimulating factor can be used to reverse severe IFN-induced neutropenia. Careful management of anxiety, sleeping disorders, and depression is also important. Retreatment of patients who do not achieve a sustained virologic response with the same dose of pegylated IFN-α and ribavirin yields sustained virologic response rates of about 10 to 15%; retreatment with higher doses can be tried with careful monitoring and attention to side effects.

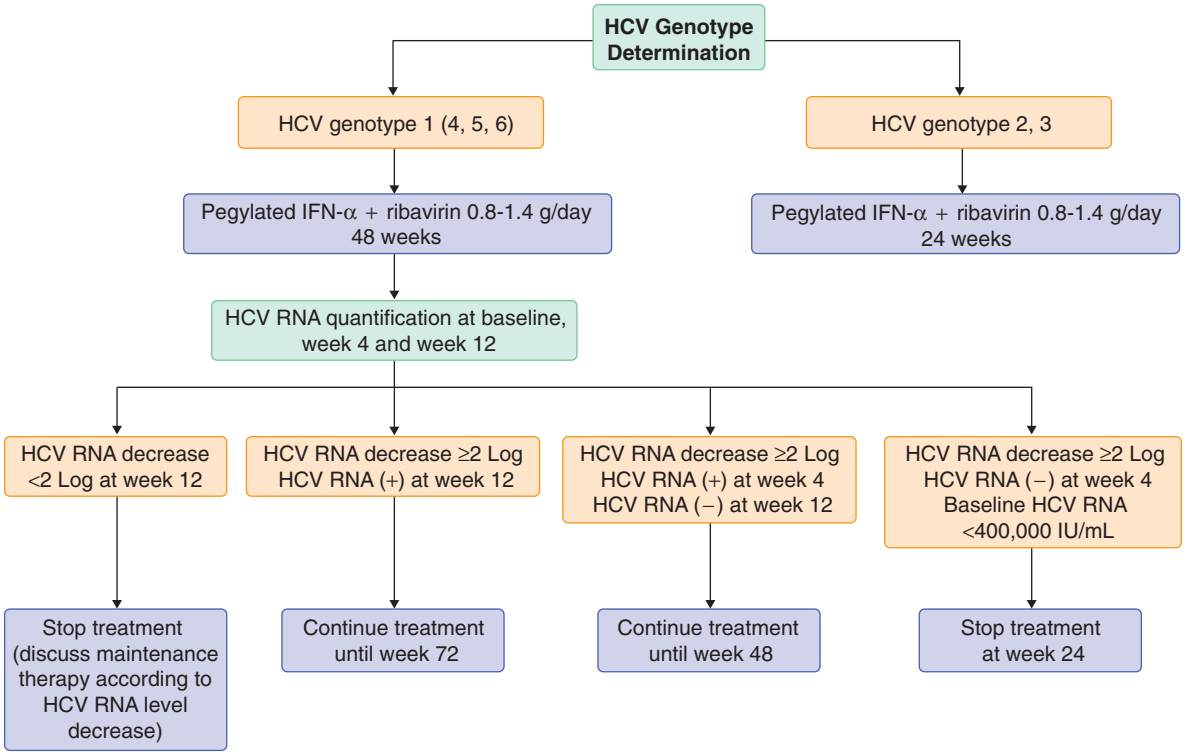

FIGURE 151-2. Pegylated interferon-α (IFN-α) and ribavirin treatment algorithm in patients with chronic hepatitis C, according to the hepatitis C virus (HCV) genotype.

New HCV drugs in trials include novel IFNs, alternatives to ribavirin, and direct-acting antiviral drugs that target various functions of the HCV life cycle. Telaprevir 750 mg three times daily or boceprevir 800 mg three times daily, in combination with the standard doses of pegylated IFN-α and ribavirin, has resulted in sustained virologic response rates of 70% in never-treated patients infected with HCV genotype 1 and in about 50% of patients who did not respond to a first course of standard two-drug therapy.[7,8] However, telaprevir frequently causes rashes and pruritus, and boceprevir can aggravate ribavirin-related anemia; furthermore, these drugs have little or no efficacy for genotypes 3 and 4. Similarly, the addition of boceprevir to standard therapy increases viral response in both never-treated[9] and previously treated[10] patients with genotype 1.

In patients with end-stage liver disease, liver transplantation (Chapter 157) is the only option. However, the graft becomes infected in 100% of patients who are viremic at the time of transplantation. Treatment with pegylated IFN-α and ribavirin is difficult in the post-transplant setting and yields disappointing results.

PROGNOSIS

Spontaneous HCV clearance in patients with chronic hepatitis C is exceptional. The HCV RNA level has no prognostic value in chronic hepatitis C.

It is estimated that 20% of patients with chronic hepatitis C develop cirrhosis; this occurs, on average, after 20 years of progression. Cirrhosis remains compensated for many years in the vast majority of patients, but decompensation occurs at an annual rate of 2 to 5% in cirrhotic patients. After a first decompensation, the mortality rate related to portal hypertension, hepatocellular insufficiency, and hepatocellular carcinoma is 10% per year, with a 50% survival rate at 5 years. The risk of death increases with advancing age, male gender, and the severity of cirrhosis.

Hepatocellular carcinoma is rare in patients with chronic hepatitis C without cirrhosis. In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2 to 4% per year, most often in patients with compensated cirrhosis. HCV has become the most common cause of hepatocellular carcinoma in most industrialized countries.

Long-term follow-up shows that HCV does not recur in greater than 99% of patients who achieve a sustained virologic response, even in those who are immunosuppressed or receive chemotherapy. However, the liver disease may continue to evolve even after the infection has been eradicated. In addition, patients with chronic hepatitis C should abstain from alcohol and, unless there are other contraindications, should be vaccinated for hepatitis A and B (Chapter 17).

CHRONIC HEPATITIS D

EPIDEMIOLOGY

HDV infection occurs only in HBsAg carriers. Only approximately 2% of patients acutely coinfected with HDV and HBV develop chronic hepatitis D. In chronic HBV carriers superinfected by HDV, however, 90% of patients become chronic HDV carriers.

CLINICAL MANIFESTATIONS

Chronic hepatitis D is generally severe, with more than 80% of patients developing cirrhosis. Compared with patients who have chronic hepatitis B alone, patients with chronic infection with both HBV and HDV are three times as likely to develop hepatocellular carcinoma and twice as likely to die.

DIAGNOSIS

Markers of HDV infection should be sought at least once in every chronic HBsAg carrier. Both total anti-HD antibodies and anti-HD IgM remain at high levels in chronic HDV infection, and HDV RNA is present. Although all chronic HDV carriers also are chronic HBsAg carriers, chronic HDV carriers generally have low or undetectable HBV DNA levels because HDV inhibits HBV replication.

TREATMENT

Rx

High doses (9 million units three times/week for 1 year) of standard, nonpegylated IFN-α result in sustained normalization of ALT levels 24 weeks after the end of therapy in approximately 50% of cases, sometimes for as long as 20 years. Some patients clear HDV RNA and, eventually, HBsAg.

Pegylated IFN-α2b, 1.5 μg/kg once weekly for 12 months, provides a sustained virologic response in 20 to 40% of cases.[11] Although there is no clear consensus, most experts now recommend 1 year of pegylated IFN-α as first-line treatment of chronic HDV infection.

PREVENTION

Chronic HDV infection is best prevented by preventing primary HBV infection, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and

behavioral precautions should be practiced to avoid superinfection with HDV. Once acute HDV infection occurs, no secondary prevention strategy is successful.

CHRONIC HEPATITIS E

Although HEV infection was long thought to be self-limited, it can persist and cause liver inflammation in solid organ transplant recipients who harbor HEV RNA in their blood and liver tissues, either from a latent virus reactivated by immunosuppression or from a virus transmitted at the time of transplantation. All cases of chronic infection have been in immunosuppressed patients.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Chronic hepatitis E occurs after transplantation. Diagnosis is based on the detection of anti-HEV IgM antibodies, but current assays lack sensitivity and specificity. HEV RNA can also be detected in blood or feces, where its presence is transient. Solid organ transplant recipients with chronic hepatitis E harbor repeatedly positive anti-HEV antibodies and HEV RNA in blood.

TREATMENT AND PREVENTION

Rx

There is no validated treatment of chronic HEV infection. Whether candidates for transplantation or immunosuppressive therapies should be vaccinated to prevent chronic HEV infection remains to be determined.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic inflammatory liver disorder characterized by the presence of autoantibodies in serum, high levels of serum immunoglobulins, and a frequent association with other autoimmune diseases.

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoimmune hepatitis typically presents between the ages of 15 and 25 years or between the ages of 45 and 60 years, and it is more common in women. Along with primary biliary cirrhosis (Chapter 158) and primary sclerosing cholangitis (Chapter 158), autoimmune hepatitis is one of the three major autoimmune liver diseases.

Autoimmune hepatitis is believed to be caused by autoimmune reactions against normal hepatocytes in genetically predisposed persons or persons exposed to unidentified triggers of an autoimmune process against liver antigens. Associations are seen with the human leukocyte antigen (HLA) class I B8 and class II DR3 and DR52a loci. In Asians, autoimmune hepatitis is associated with HLA DR4.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Autoimmune hepatitis tends to be more severe at its onset than chronic hepatitis B or C, and it progresses to end-stage liver disease if not treated with immunosuppression. Although it is occasionally detected by elevated serum aminotransferase levels on a routine health evaluation, most patients present with fatigue and jaundice. Elevations of bilirubin or alkaline phosphatase indicate more severe or advanced disease. Patients typically have marked elevations in serum gamma globulin, specifically immunoglobulin G, as well as autoantibodies directed at non-organ-specific cellular constituents.

Type 1 (classic) autoimmune hepatitis is characterized by the presence of titers of 1 : 80 or higher (>1 : 20 in children) of antinuclear, anti–smooth muscle, antiactin, and anti-asialoglycoprotein receptor antibodies. Type 2 autoimmune hepatitis is characterized by similar elevations of anti–liver-kidney microsomal 1 antibodies and anti–liver cytosol 1 antibodies, without antinuclear or anti–smooth muscle antibodies. Liver biopsy shows features that are typical of all chronic types of hepatitis, except plasma cell infiltrates.

TREATMENT

Rx

The clinical symptoms and liver test abnormalities of autoimmune hepatitis generally respond promptly to prednisone, usually at a dose of 20 to 30 mg/day, with a decrease in serum aminotransferase levels to the normal or near-normal range within 1 to 3 months; higher doses may be required in patients with more severe disease. Lack of a biochemical or clinical response should lead to reevaluation of the diagnosis. Azathioprine 50 to 100 mg can be combined with prednisone or added later to reduce long-term steroid side effects. Maintenance doses, which are typically required indefinitely, are often 5 to 10 mg/day of prednisone combined with 50 to 150 mg/day of azathioprine. Sometimes patients can be maintained on azathioprine (2 mg/kg/day) alone. After 3 years or more of remission, therapy can be carefully withdrawn, but severe and even fatal flares can occur weeks to months later.

PROGNOSIS

The prognosis is generally related to the histologic stage of the disease. Patients who initially respond to therapy may do well for many years. Patients who progress to end-stage liver disease require liver transplantation (Chapter 157).

CRYPTOGENIC CHRONIC LIVER DISEASE

Cryptogenic chronic liver disease refers to chronic hepatitis or cirrhosis of unknown cause after excluding hepatitis B, C, D, and E; autoimmune hepatitis; steatohepatitis (Chapter 155); alcoholic liver disease (Chapter 155); drug-induced hepatitis (Chapter 152); and inherited and metabolic liver diseases (Chapter 153). Tests to exclude these conditions include serum levels of α_1-antitrypsin, iron, and ceruloplasmin and, if necessary, urine and liver copper concentrations. In its later stages, nonalcoholic steatohepatitis may be associated with little or no fat.

TOXIN- AND DRUG-INDUCED LIVER DISEASE

WILLIAM M. LEE

DEFINITION

Toxin-induced and drug-induced hepatotoxicity, defined as any degree of liver injury caused by a drug or a toxic substance, is a frequent cause of acute

liver injury and accounts for more than 50% of all cases of acute liver failure with hepatic encephalopathy in the United States. Hepatotoxicity has been described with many drugs, although the number of cases is low, given the number of prescriptions written.

EPIDEMIOLOGY

Few data are available on the epidemiology of toxin- and drug-induced liver disease. The precise number of drug-induced liver injuries in the United States is unknown, but European data on adverse drug reactions indicate about 22 cases of drug-induced liver disease per 1 million people per year. In developing parts of the world, drug-induced liver disease is much less common and is related to fewer drugs. It is estimated that less than 10% of actual cases are reported, so the true incidence of toxin- and drug-induced liver disease may be impossible to determine.

PATHOBIOLOGY

The liver is central to the metabolism of exogenous substances. Most drugs and xenobiotics cross the intestinal brush border because they are lipophilic. *Biotransformation* is the process by which lipophilic therapeutic agents are rendered more hydrophilic by the liver, resulting in drug excretion in urine or bile. In most instances, biotransformation changes a nonpolar to a polar compound through several steps. Foremost are oxidative pathways (e.g., hydroxylation) mediated by the cytochromes (CYPs) P-450 (Chapter 28). The next step is typically esterification to form sulfates and glucuronides, a process that results in the addition of highly polar groups to the hydroxyl group. These two enzymatic steps are referred to as *phase I* (CYP oxidation) and *phase II* (esterification). Other important metabolic pathways involve glutathione-*S*-transferase, acetylating enzymes, and alcohol dehydrogenase, but the principal metabolic pathways for most pharmacologic agents involve CYPs and subsequent esterification.

Pathogenesis

The exact details of the pathogenesis of liver injury are unclear for most drugs. A single drug may cause toxic effects in several ways. One overarching approach suggests that high-energy unstable metabolites of the parent drug, the result of CYP activation, bind to cell proteins or DNA and disrupt cell function. Perhaps the best example is acetaminophen. Although used universally for non-narcotic pain relief, acetaminophen, when taken in large quantities, causes profound centrilobular necrosis. The metabolic pathway of acetaminophen involves phase I and phase II reactions, glutathione detoxification, and the formation of reactive intermediates (E-Fig. 152-1). The presence of alcohol, which competes for CYP P-450 2E1, not only inhibits the formation of *N*-aminoparaquinoneamine (NAPQI) but also induces the enzyme so that its half-life is slowed and more enzyme is present. After the cessation of alcohol ingestion, NAPQI formation is enhanced by the presence of the induced enzyme and the lack of competition from alcohol. Toxicity is a dynamic process and may be most pronounced in the 24 hours after the cessation of alcohol. Glucuronidation and sulfation occur as the initial detoxifying step because the parent compound contains a hydroxyl group. Glucuronidation and sulfation capacity greatly exceeds daily needs, so even patients with very advanced liver disease continue to have adequate glucuronidation capacity, which explains why no obvious enhancement of toxicity is observed when cirrhotic patients take acetaminophen.

Genetics

Enzyme Polymorphism

Although acetaminophen is a dose-related toxin, the rarity of idiosyncratic drug toxicity (1 in 10,000 patients) suggests the importance of environmental and host factors (Table 152-1). Genetically variant CYP isoenzymes may partially explain the observed individual variation in response to drugs. An example is debrisoquine, an antihypertensive drug marketed in Europe that is hydroxylated by CYP2D6, an isoform that is totally absent in 5% of normal individuals. Lack of CYP2D6 greatly prolongs the half-life of the parent compound in affected individuals. Another example is the phenomenon of fast versus slow acetylation, which affects different ethnic groups and has been implicated in the differential metabolism of isoniazid. Most of the known genetic variants that occur relatively frequently, however, cannot explain the formation of a toxic intermediate in only a rare individual.

Most drugs are small organic compounds, unlikely to evoke an immune response. Although some toxic drug reactions are associated with an obvious allergic response, most are not. Nevertheless, immune mechanisms not associated with systemic allergic immunoglobulin E (IgE) reactions or skin hypersensitivity might be involved. Studies suggest that the products of CYP P-450 metabolism, the highly reactive intermediates formed within the microsomes, covalently bind to the enzyme itself to form a drug-hapten adduct that disables the enzyme and injures the cell. Haptenization then evokes an immune response directed against the newly formed antigen or neoantigen. P-450s have been shown to traffic to the plasma membrane, thereby allowing the drug–P-450 adduct to become the target of a subsequent cytolytic attack. It is unclear whether the targets are these adducts or the smaller peptides processed and presented by the major histocompatibility complex class I and class II schemes. The association among neoantigens, autoantibodies, and hepatotoxic drugs implicates an immunologic mechanism.

Regardless of whether an individual drug causes significant cell necrosis, the drug–P-450 adducts can evoke an immune response. Any subsequent drug–P-450 adduct present on the hepatocyte surface would evoke a further response. Responses may be antibody mediated or occur as a result of direct cytolytic attack by primed T cells. Specific genetically determined components of the immune response may be important. A specific human leukocyte antigen (HLA) haplotype has been associated with amoxicillin-clavulanate–induced hepatitis, and polymorphisms have been identified for the interleukin-10 promoter and for tumor necrosis factor-α. For every patient with a severe injury caused by drugs, there are often many more individuals with asymptomatic aminotransferase elevations that subsided despite continuing the drug—sometimes referred to as an adaptive response.

Other Mechanisms

In drug-induced cholestasis, disruption of specific transport proteins or processes in hepatocytes or cholangiocytes may be the key event. Estrogen may cause multiple canalicular membrane transport changes that affect, among others, the canalicular bile salt pump. Uncoupling or inhibition of mitochondrial respiration may lead to microvesicular steatosis.

Hepatotoxic Agents

Although there are a few dose-related toxins, most drugs involved in liver disease cause idiosyncratic, unpredictable toxicity.

TABLE 152-1 FACTORS THAT MAY INFLUENCE THE METABOLIC FATE OF DRUGS

AGE
The elderly seem to be affected more often; adults are more susceptible than children to some drugs (acetaminophen, halothane, isoniazid) and less susceptible to others (aspirin, valproic acid)
ALCOHOL, ACUTE AND CHRONIC INGESTION
Induction of CYP2E1 affects drugs metabolized by this pathway, including acetaminophen and isoniazid
GENDER
Females are affected more often, but the reason is unknown
PREGNANCY
Effects of drugs in pregnancy have been poorly studied
PREEXISTING LIVER DISEASE
Hepatic disease may *protect* against idiosyncratic reactions and may *enhance* the toxicity of dose-dependent hepatotoxins (e.g., acetaminophen)
RENAL DISEASE
Slowed disappearance of the parent compound yields higher concentrations and affects P-450 (e.g., enhancement of tetracycline toxicity in renal disease)
CERTAIN FOODS
Grapefruit has an unknown substance that interferes with the metabolism of some drugs
CONCOMITANT DRUGS
Drug-drug interactions are common causes of adverse effects (e.g., valproate and chlorpromazine together lead to enhanced cholestasis)
GENETIC FACTORS
Enzyme polymorphisms (e.g., enhanced phenytoin liver disease in patients with defective epoxide hydrolase activity), HLA phenotypes (e.g., nitrofurantoin susceptibility)

TABLE 152-2 DRUGS AND TOXINS IN WHICH A DOSE-RESPONSE EFFECT IS OBSERVED

DRUG OR TOXIN	RESPONSE
Acetaminophen	Total dose, single vs. multiple time points
Amiodarone	Total dose over time
Bromfenac	Toxicity occurs only after extended use
Cocaine	Dose-related vascular collapse
Cyclophosphamide	Dose related, worse with previous ALT elevations
Cyclosporine	Cholestasis with toxic blood levels, CYP3A phenotype
Methotrexate	Aminotransferase, fibrosis; single dose/total dose
Niacin	Large doses cause vascular collapse
Oral contraceptives	Prolonged use causes hepatic adenomas
Tetracycline	Total dose, renal dysfunction
Toxins (yellow phosphorus, carbon tetrachloride, *Amanita* toxin, bacterial toxins)	Total dose

ALT = alanine aminotransferase.

TABLE 152-3 TYPES OF TOXIN AND DRUG REACTIONS

REACTION TYPE	IMPLICATED DRUGS OR TOXINS
Autoimmune (attack on cell surface markers)	Lovastatin, methyldopa, nitrofurantoin
Cholestatic (attack on bile ducts)	Anabolic steroids, carbamazepine, chlorpromazine, estrogen, erythromycin
Fibrosis (activation of stellate cells leads to fibrosis)	Methotrexate, vitamin A excess
Granulomatous (macrophage stimulation)	Allopurinol, diltiazem, nitrofurantoin, quinidine, sulfa drugs
Hepatocellular (damage to smooth endoplasmic reticulum and immune cell surface)	Acetaminophen, *Amanita* poisoning, diclofenac, isoniazid, lovastatin, nefazodone, trazodone, venlafaxine
Immunoallergic (cytotoxic cell attack on surface determinants)	Halothane, phenytoin, sulfamethoxazole
Mixed (see above)	Amoxicillin-clavulanate, carbamazepine, cyclosporine, herbs, methimazole
Oncogenic (hepatic adenoma formation)	Oral contraceptives, androgenic agents
Steatohepatitis (mitochondrial dysfunction: β-oxidation and respiratory chain)	Amiodarone, perhexiline maleate, tamoxifen
Vascular collapse (ischemic damage)	Cocaine, ecstasy, nicotinic acid
Veno-occlusive disease (endotheliitis of sinusoidal endothelial cells)	Busulfan, cytoxan

Intrinsic (Dose-Dependent) Agents

Acetaminophen (see later) and a few other agents seem to have a clear dose-response effect, although idiosyncrasy usually plays a role as well (Table 152-2). Some toxins, such as α-amanitine produced by *Amanita* mushrooms, cause dose-related injury. *Amanita* poisoning may occur after ingestion of the mushrooms *Amanita phalloides* (death cap) or *Amanita virosa* (deadly agaric). The dose-dependent toxic effect on the liver is attributed to amatoxin, an ingredient of the mushrooms that enhances the toxic effect by its enterohepatic recirculation characteristics; the toxic effect is exerted on each cycle of the recirculation through the liver.

Idiosyncratic Reactions

Drug reactions occur in 1 in 1000 to 1 in 200,000 patients. Characteristics of these idiosyncratic reactions include their infrequent occurrence, varying time intervals between the initial exposure and the reaction, and varying severity of reactions in affected individuals. There are also similarities such as "class effects" (similar drugs exhibit similar features; see Table 152-3), a consistent pattern for each drug, and the fact that rechallenge with a responsible agent usually leads to a more severe reaction with a shorter latency than seen after the initial exposure.

Antibiotics, anticonvulsants, and nonsteroidal anti-inflammatory drugs (NSAIDs) are associated more frequently with drug-induced liver disease, whereas hormones, antihypertensive drugs, digoxin, and antiarrhythmic drugs are implicated rarely. In some cases, idiosyncratic reactions are so infrequent that a drug continues to be used if its effectiveness or uniqueness makes the risk acceptable. An example is isoniazid, which is among the few drugs implicated in drug-induced liver injury in developing countries. In individuals receiving isoniazid as a single agent for tuberculosis prophylaxis, increased aminotransferase levels may develop in 15 to 20%, but severe hepatic necrosis develops in only 0.1 to 1% (Chapter 332)—a rate that is high in comparison to idiosyncratic drug reactions, yet low enough for isoniazid, because of its effectiveness, to remain a key drug.

CLINICAL MANIFESTATIONS

Patients may have few or nonspecific complaints despite elevated aminotransferase levels. Clinical features include nausea, fatigue, occasional right upper quadrant pain, and nonspecific symptoms similar to those seen in other forms of acute hepatitis (Chapter 150). Fever or pharyngitis (typically seen in phenytoin reactions) may be present. No specific physical findings to raise suspicion of drug toxicity are noted, except possibly a rash. Any patient in whom jaundice develops is at risk for having a severe or fatal outcome, and patients who continue taking the drug despite jaundice are at highest risk.

DIAGNOSIS

Abnormal aminotransferase levels with the use of a new drug should raise the suspicion of a drug-induced reaction and prompt immediate discontinuation of the drug rather than awaiting diagnostic tests to confirm or exclude the diagnosis. Immediate discontinuation of medication at the first sign of liver disease can prevent most fatal liver injuries.

Evaluation of a patient with a suspected drug reaction is directed toward establishing the timeline for all drugs or herbs the patient may have taken. Responsible drugs have usually been started between 5 and 90 days before the onset of symptoms. Evidence of viral hepatitis (Chapters 150), gallstones (Chapter 158), alcoholic liver disease (Chapter 155), pregnancy (Chapter 247), severe right heart failure (Chapter 58), or a period of hypotension (Chapter 106) points to these specific causes. Less commonly, cytomegalovirus (Chapter 384), Epstein-Barr virus (Chapter 385), or herpesviruses (Chapter 383) can cause hepatic injury, primarily in immunosuppressed individuals. If all these causes can be excluded, the temporal relationship fits, and the patient begins to improve after withdrawal of the drug, the diagnosis is more secure. Liver biopsy is of limited value because the histologic picture in most cases of drug-induced liver injury is no different from that of viral hepatitis (Chapter 150). Nevertheless, an occasional liver biopsy specimen in an enigmatic case might reveal eosinophils or granulomas, consistent with a drug reaction.

Types of Drug Reactions

Although most liver injury involves direct hepatocyte necrosis or apoptosis (hepatocellular injury), some drugs injure primarily the bile ducts or canaliculi and cause cholestasis without significant damage to hepatocytes. Other drugs affect sinusoidal cells or present a particular pattern of liver injury affecting multiple cell types (mixed type). Another approach to drug reactions emphasizes the histologic changes involved and the cell type (Table 152-3 and Fig. 152-1).

Hepatocellular Reactions

Hepatocellular reactions are the most common type of drug-induced liver disease and account for 90% of cases (Table 152-4). They are characterized by a pattern of serum liver test results that reflect hepatocellular injury. Usually, improvement is quick after discontinuation of the drug (1 to 2 months), and fulminant, acute liver failure with hepatic encephalopathy develops in only a few patients.

Histologic findings include necrosis and cellular infiltration. The necrosis may be zonal (e.g., induced by acetaminophen or carbon tetrachloride) or diffuse (e.g., induced by halothane), and the inflammatory response consists of lymphocytes or eosinophils. Massive necrosis may cause acute liver failure and death.

Acetaminophen toxicity is the most common form of acute liver failure in the United States and is the best understood example of direct hepatocyte toxicity. The incidence of acetaminophen poisoning varies widely throughout

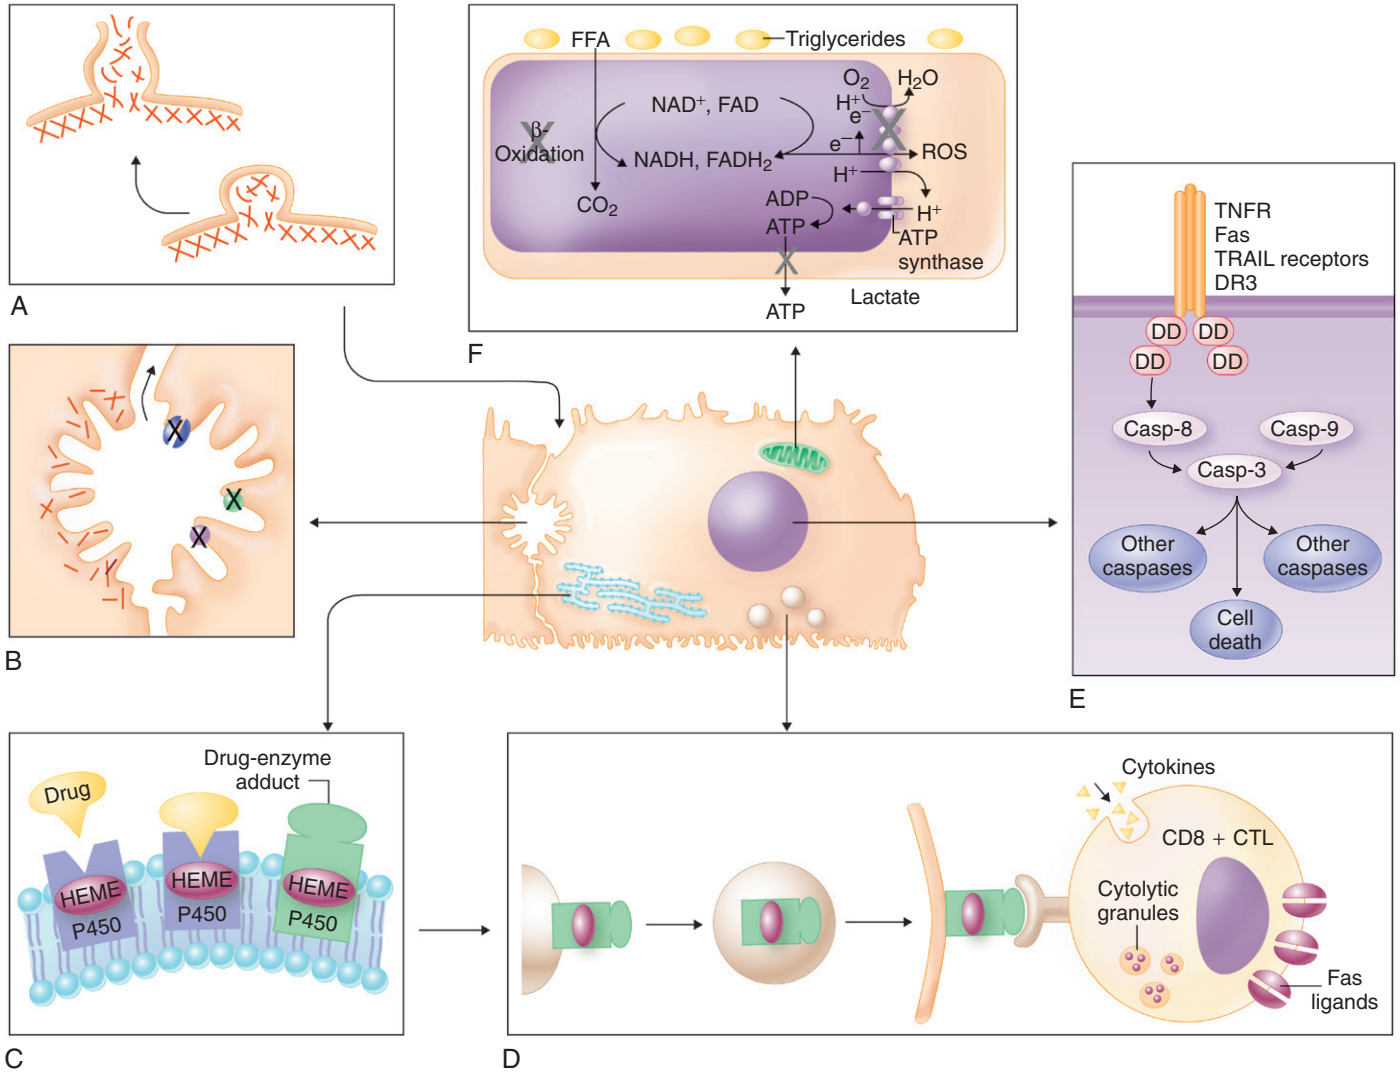

FIGURE 152-1. Mechanisms of liver injury. Each form of liver injury targets specific organelles, although multiple organelles may be affected. The hepatocyte in the center may be affected in at least six ways. **A,** Disruption of intracellular calcium leads to actin fibril disassembly at the hepatocyte surface, which results in blebbing of the cell membrane and subsequent rupture and cell lysis. **B,** In cholestatic diseases, disruption of actin filaments may occur with the loss of villous processes. Interference with ion pumps limits the excretion of bilirubin and other organic compounds. **C,** Most hepatocellular reactions involve the cytochrome P-450 system. The high-energy reaction involved may lead to binding of drug to enzyme and create a new adduct. **D,** Enzyme-drug adducts may traffic to the cell surface and serve as target immunogens for cytolytic attack by T cells. **E,** Activation of apoptotic pathways results in cell death. **F,** Inhibition of β-oxidation or respiration in mitochondria results in microvesicular fat accumulation and lactic acidosis, a pattern characteristic of a variety of agents, including nucleoside analogues, tetracycline, and aspirin. ATP = adenosine triphosphate; FAD = flavin adenine dinucleotide; FFA = free fatty acid; NAD = nicotinamide adenine dinucleotide; ROS = reactive oxygen species; TNFR = tumor necrosis factor receptor. (**A,** Adapted from Farrell GC. *Drug-Induced Liver Disease*. Edinburgh: Churchill Livingstone; 1994: 44; **B,** Adapted from Trauner M, Meier PJ, Boyer J. Mechanisms of disease: molecular pathogenesis of cholestasis. *N Engl J Med*. 1998;339:1217-1227; **C,** Adapted from Watkins Zimmerman HJ. *Hepatotoxicity*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000; **D,** From Robin M-A, Le Roy M, Descatoire V, Pessayre D. Plasma membrane cytochromes P450 as neoantigens and autoimmune targets in drug-induced hepatitis. *J Hepatol.* 1997;26(Suppl 1):23-30; **E,** From Reed JC. Apoptosis-regulating proteins as targets for drug discovery. *Trends Mol Med.* 2001;7:314-319; **F,** Adapted from Pessayre D, personal communication.)

the world, but it is becoming more frequent and widespread. Liver injury occurs predictably after an intentional suicidal overdose (Chapter 110); it also occurs when acetaminophen is used in excessive doses or sometimes even in therapeutic doses for pain relief. Enhanced toxicity occurs when patients are fasting or are chronic alcohol users because of enzyme induction and depletion of glutathione by alcohol and fasting; by comparison, acute alcohol intake may protect against acetaminophen toxicity during the period of alcohol ingestion. Thereafter, a rebound increase in available CYP2E1 results in increased toxicity in the 12 hours after ingestion because of enzyme induction (see E-Fig. 152-1). Patients with an unintentional acetaminophen overdose may fare worse than suicidal patients because the former seek treatment later in their course, even though suicidal patients take larger doses. The better outcome after an acute overdose may be explained by earlier medical attention and the use of *N*-acetylcysteine, an effective antidote. Nevertheless, one fifth of suicide attempts using acetaminophen are associated with severe liver injury and the potential for a fatal outcome.

The extremely elevated aminotransferase values (often >6000 IU/L, and sometimes as high as 30,000 IU/L) observed in suicidal and unintentional acetaminophen ingestion help distinguish these cases from viral hepatitis or other drug injury. The antidote *N*-acetylcysteine (Chapter 110) may be given by nasogastric tube on admission and for the next 72 hours to provide glutathione substrate. The standard treatment is intravenous *N*-acetylcysteine beginning at a dose of 140 mg/kg in 300 mL of 5% dextrose given over 1 hour, followed by a dose of 70 mg/kg in 5% dextrose given over a 1-hour period every 4 hours for 48 hours. A loading dose of 140 mg/kg can be given orally, followed by 70 mg/kg every 4 hours for 17 doses (72 hours). Expected survival rates are greater than 80%, although liver transplantation is occasionally required.

Cholestatic Reactions

Cholestatic reactions have been described for many drugs. Cholestasis is best defined as failure of bile to reach the duodenum, and common symptoms are jaundice and pruritus. *Pure cholestasis,* with no signs of hepatocellular necrosis, is seen almost exclusively in patients taking oral contraceptives, anabolic steroids, or sex hormone antagonists such as tamoxifen. Acute *cholestatic hepatitis* is characterized histologically by cholestasis (dilated canaliculi, brown granules in the cytoplasm of hepatocytes), some degree of liver cell necrosis and bile duct injury, and inflammatory infiltration by polymorphonuclear leukocytes. Drugs that cause this type of reaction include carbamazepine, trimethoprim-sulfamethoxazole, and captopril.

TABLE 152-4 SCORING SYSTEM TO ASSESS CAUSALITY OF HEPATOCELLULAR REACTIONS

FACTOR	SCORE*
TEMPORAL RELATIONSHIP OF START OF DRUG TO START OF ILLNESS	
Initial treatment: 5-90 days; subsequent treatment course: 1-15 days	+2
Initial treatment: <5 or >90 days; subsequent treatment course: >15 days	+1
From cessation of drug: ≤15 days†	+1
COURSE	
ALT decreases ≥50% from peak within 8 days	+3
ALT decreases ≥50% from peak within 30 days	+2
If the drug is continued, inconclusive	0
RISK FACTORS	
Alcohol‡	+1
No alcohol‡	0
Age ≥ 55 yr	+1
Age < 55 yr	0
CONCOMITANT DRUG	
Concomitant drug with suggestive time of onset	−1
Concomitant drug known to be a hepatotoxin with suggestive time of onset	−2
Concomitant drug with further evidence of involvement (rechallenge)	−3
NUMBER OF NONDRUG CAUSES	
Hepatitis A, B, or C; biliary obstruction; alcoholism (AST ≥ 2 × ALT); recent hypotension; and CMV, EBV, and HSV infection all excluded	+2
4-5 causes excluded	+1
<4 causes excluded	−2
Nondrug cause highly probable	−3
PREVIOUS INFORMATION ON HEPATOTOXICITY OF DRUG IN QUESTION	
Package insert mentions	+2
Published case reports but not on package label	+1
Reaction unknown	0
RECHALLENGE	
Positive (ALT doubles with drug alone)§	+2
Compatible (ALT doubles, compounding features)§	+1
Negative (increase in ALT but ≤ 2 × ULN)§	−2
Not done	0

*Causality is highly probable (score >8), probable (score 6-8), possible (score 3-5), unlikely (score 1-2), or excluded (score ≤0).
†For cholestatic reactions, ≤30 days.
‡For cholestatic reactions, alcohol, or pregnancy.
§For cholestatic reactions, substitute alkaline phosphatase (or total bilirubin) for ALT.
ALT = alanine aminotransferase; AST = aspartate aminotransferase; CMV = cytomegalovirus; EBV = Epstein-Barr virus; HSV = herpes simplex virus; ULN = upper limit of normal.
Adapted from Danan G, Benichou C. Causality assessment of adverse reactions to drugs. I. A novel method based on the conclusions of international consensus meetings: application to drug-induced liver injuries. *J Clin Epidemiol.* 1993;46:1323-1330; Benichou C, Danan G, Flahault A. Causality assessment of adverse reactions to drugs. II. An original model for validation of drug causality assessment methods: case reports with positive rechallenge. *J Clin Epidemiol.* 1993;46:1331-1336.

Generally, drug-induced cholestasis takes longer to resolve than drug-induced hepatotoxicity. In some cases, segments of the intrahepatic biliary tree may be destroyed progressively, the so-called vanishing bile duct syndrome that occurs after a protracted course (>6 months) of drug-induced cholestasis. The result is a state of chronic cholestasis that resembles primary biliary cirrhosis (Chapter 158). Approximately 30 drugs have been implicated in the vanishing bile duct syndrome, including chlorpromazine and ajmaline. A sclerosing cholangitis–like syndrome with jaundice caused by intrahepatic and extrahepatic strictures in the bile ducts is sometimes observed in patients receiving intra-arterial floxuridine chemotherapy for hepatic metastases of colorectal cancer.

Immunoallergic Reactions

Drugs also may be associated with definite allergic reactions. A combined toxic-immunologic mechanism is involved in liver injury caused by halothane, a fluorinated hydrocarbon anesthetic that causes severe, often fatal liver injury after multiple exposures (Chapter 440). Other fluorinated hydrocarbons, including isoflurane and desflurane, occasionally result in the same response. Although halothane has never been withdrawn, its use has been limited by the advent of safer agents. Hypersensitivity reactions, such as fever, eosinophilia, and rash, are common. Halothane may induce fever, eosinophilia, and antimitochondrial antibodies. Direct cytotoxicity and immune-mediated toxicity are observed, consistent with the clinical observation that severe halothane toxicity occurs with repeated exposure. Although evidence of injury can usually be identified within 1 week of the first exposure, the interval to toxicity is shortened and the damage is more severe with each successive exposure, as befits an immune reaction.

Phenytoin (Chapter 410) induces the simultaneous onset of fever, rash, lymphadenopathy, and eosinophilia. The mechanisms responsible for the combined allergic and hepatotoxic reaction are unknown, but the slow resolution of the illness suggests that the allergen remains on the surface of the hepatocyte for weeks or months. A concurrent mononucleosis-like picture is frequently confused with a viral illness or streptococcal pharyngitis. If phenytoin is not discontinued promptly despite signs of hepatitis, a severe Stevens-Johnson drug eruption (Chapters 447 and 448) and prolonged fever may result. As with any therapeutic agent, rapid recognition of the presence of a toxic drug reaction and immediate discontinuation of the compound are key to limiting hepatic damage. Systemic features of an allergic reaction may not be obvious, even when eosinophilia or granulomas are present on liver biopsy.

Steatohepatitis

Steatosis in the liver (Chapter 155) can be present in a microvesicular or macrovesicular pattern. Macrovesicular steatosis, the most common form, is characterized histologically by a single vacuole of fat filling up the hepatocyte and displacing the nucleus to the cell's periphery. Macrovesicular steatosis is typically caused by alcohol, diabetes, or obesity. Sometimes drugs such as corticosteroids or methotrexate may cause these hepatic changes. Amiodarone (Chapters 64 and 65) has been associated with a picture resembling alcoholic hepatitis, occasionally with progression to cirrhosis. The pathophysiology involves accumulation of phospholipids in the liver, eyes, thyroid, and skin. Treatment is primarily withdrawal of the drug and observation, although the half-life of amiodarone is prolonged. Tamoxifen, which has been used in long-term regimens for the prevention of recurrent breast cancer (Chapter 204), has also been associated with steatohepatitis evolving to cirrhosis.

In microvesicular steatosis, hepatocytes contain numerous small fat vesicles that do not displace the nucleus. Valproic acid, an anticonvulsant (Chapter 410), causes hepatotoxicity, either as a result of microvesicular fat deposition, resembling Reye's syndrome, or in a more chronic, indolent fashion associated with macrovesicular fat accumulation. Toxicity is more severe and frequent in children. These lesions are associated with disruption of mitochondrial DNA, resulting in anaerobic metabolism that leads to lactic acidosis in the most severe cases. Macrovesicular and microvesicular lesions may be observed concomitantly in some patients, and microvesicular lesions are more often associated with a poor prognosis. Hepatocellular necrosis may also be present. Acute fatty liver of pregnancy (Chapter 153) and Reye's syndrome are two examples of severe liver diseases caused by microvesicular steatosis.

Drugs involved in microvesicular steatosis include valproate, tetracycline, and fialuridine. Aspirin use in children has been associated with Reye's syndrome, but the incidence of Reye's syndrome has decreased dramatically since warnings were issued concerning aspirin use in children.

Effects of Sex Steroids

Anabolic steroids, such as methyltestosterone, may cause cholestasis. Androgens may cause peliosis hepatis and benign or malignant tumors. Oral contraceptives (Chapter 246) may cause cholestasis, hepatic adenomas, or Budd-Chiari syndrome (hepatic vein thrombosis). Antiandrogens used to treat prostate cancer (Chapter 207), such as flutamide and nilutamide, and antipituitary drugs, such as cyproterone acetate, have also been associated with severe hepatocellular injury.

Other Drug Reactions

Other less severe drug reactions involving the liver include granulomatous reactions, fibrosis, ischemic injury, and chronic autoimmune liver injury (see Table 152-3). The type of reaction observed can be helpful in determining the probable agent because most drugs have a specific injury profile.

A pattern of veno-occlusive disease with obliteration of small intrahepatic veins, sinusoidal congestion, and necrosis is observed frequently in bone marrow transplant patients (Chapter 181) who receive chemotherapy with cyclophosphamide (Cytoxan) or busulfan. Symptoms, including rapidly accumulating ascites, painful hepatomegaly, and jaundice, develop soon after the chemotherapeutic regimen has begun. Rarely, herbal medicines (Chapter 38) such as pyrrolizidine alkaloids (*Crotalaria* and *Senecio* found in Jamaican bush tea) may cause veno-occlusive disease.

Toxins are associated with direct injury to hepatocytes in a dose-dependent fashion. Organic solvents such as carbon tetrachloride and trichloroethylene (Chapter 110) cause centrilobular injury. Yellow phosphorus, found in firecrackers and rat poisons, is a rare cause of liver injury from either accidental or intentional exposure. Symptoms of poisoning are similar to those of any other type of hepatitis.

Mushroom poisoning (Chapter 110), which follows the ingestion of *A. phalloides* and related species, typically occurs in amateur mushroom fanciers in a dose-related fashion. The associated muscarinic effects, including severe diarrhea, vomiting, and profuse sweating, predominate in the first hours after ingestion. Hepatic failure follows if antidotes (see later) are not given. The overall prognosis for spontaneous recovery is poor; liver transplantation may be life-saving.

Differential Diagnosis

The differential diagnosis of toxin- and drug-induced liver injury includes almost the entire spectrum of liver diseases. Because the clinical picture of drug-induced liver injury ranges from pure hepatocellular to pure cholestatic variants, a high index of suspicion must be maintained, even when toxin- or drug-induced liver injury is not obvious initially.

For dose-dependent hepatotoxins, the diagnosis may be easier to establish than for idiosyncratic drug reactions. Serum levels of acetaminophen, a thorough history, and characteristic biochemical abnormalities (high aminotransferase levels) usually reveal an acetaminophen overdose, whereas a diagnosis of *Amanita* poisoning depends on the history, symptoms of gastroenteritis (muscarinic reaction), and positive mushroom identification.

For idiosyncratic drug reactions, the diagnosis is sometimes more difficult to establish. A standardized reporting form called the RUCAM (Roussel-Uclaf causality assessment method; see Table 152-4), developed by an international panel, provides a worthwhile scoring system. These guidelines outline the steps an experienced clinician might use to assess the likelihood of a drug reaction. Causality assessment factors typically include the temporal relationship, course after cessation of the drug, risk factors, concomitant drugs, a search for nondrug causes (viral hepatitis), previous information concerning the drug, and response to rechallenge, which is typically not required.

TREATMENT

Rx

Prompt discontinuation of a suspected drug is mandatory. Available antidotes should be used for acetaminophen (*N*-acetylcysteine) and *Amanita* poisoning (penicillin 300,000 to 1 million U/kg/day intravenously and thioctic acid 5 to 100 mg every 6 hours intravenously have been recommended, but there are no controlled trials). General supportive therapy ranges from intravenous fluid replacement to intensive monitoring and treatment of patients with hepatic encephalopathy secondary to acute liver failure (Chapter 157). Liver transplantation (Chapter 157) is performed in more than 50% of patients with idiosyncratic drug-induced acute liver failure because the survival rate in this setting without transplantation is less than 20%.

FUTURE DIRECTIONS

Research in pharmacogenomics may allow the patient's own genetic information to guide individualized drug therapy and monitoring of idiosyncratic drug reactions. The genetic information would probably concentrate initially on enzymes with variant alleles associated with poor metabolism, such as CYP1A2 or CYP2C19 for isoniazid, CYP2C9 for piroxicam, or CYP2D6 for nortriptyline. Better postmarketing surveillance of all drugs to identify those with previously unappreciated hepatotoxicity should be a high priority.

PREVENTION

It is reasonable to consider a drug reaction whenever an episode of apparent hepatitis is unexplained, particularly if a new agent has been introduced in the previous 3 months. It is prudent to defer embracing new drugs during their first year of introduction, particularly if they show no unique advantages over accepted formulations. Physicians must strive to instill in their patients a healthy level of alertness with regard to drug-induced liver injury, particularly for agents with known hepatotoxicity. Monitoring of aminotransferase levels on a monthly basis is suggested for known hepatotoxins such as isoniazid or diclofenac, but it is unlikely to be cost-effective when adverse reactions occur less frequently, such as in only 1 in 50,000 patients. Because many drug reactions develop within days, monitoring provides no guarantee. Most fatal drug reactions could have been prevented if the offending agent were withdrawn immediately, at the first sign of illness.

INHERITED AND METABOLIC DISORDERS OF THE LIVER

BRUCE R. BACON

DEFINITION

Inherited liver diseases (Table 153-1) include hereditary hemochromatosis, (Chapter 219), Wilson disease (Chapter 218), α_1-antitrypsin deficiency (Chapter 88), and cystic fibrosis. Metabolic liver diseases include nonalcoholic fatty liver disease (NAFLD), which is the most common cause of abnormal liver enzymes in Western societies; in addition, 3 to 5% of overweight or obese individuals in the United States may have nonalcoholic steatohepatitis (NASH) (Chapter 155), which has the potential to progress to advanced fibrosis. A variety of systemic metabolic abnormalities are less common causes of liver dysfunction or abnormal liver tests (Chapter 149).

INHERITED LIVER DISEASES

Hereditary Hemochromatosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Hereditary hemochromatosis (Chapter 219) is the most common inherited disorder of the liver. The responsible gene for this inherited disorder of iron metabolism is *HFE,* which encodes for a major histocompatibility complex type 1 protein. Genetic testing is available for the two major mutations (C282Y, H63D) responsible for *HFE*-linked hereditary hemochromatosis. Large-scale population studies demonstrate that C282Y homozygosity is found in about 1 in 250 individuals of northern European descent, about 60% of whom have phenotypic expression of the disease. About 10% of the population are asymptomatic heterozygotes.

CLINICAL MANIFESTATIONS

Most individuals with hereditary hemochromatosis have no symptoms and are identified by screening laboratory tests or family studies. When

TABLE 153-1 INHERITED AND METABOLIC DISORDERS OF THE LIVER

symptoms are present, they are frequently nonspecific and include lethargy, fatigue, weight loss, and weakness. More organ-specific symptoms include right upper quadrant abdominal pain or arthralgias of the hands, hips, and knees. Occasionally, patients present with signs of advanced liver disease.

DIAGNOSIS

When symptoms and signs suggestive of hereditary hemochromatosis are present, it is reasonable to consider this diagnosis and order appropriate laboratory studies. Conversely, when abnormal iron studies (Chapter 162) are identified by routine screening or in patients being evaluated for anemia, hereditary hemochromatosis should be considered even in the absence of signs or symptoms.

Definitive diagnosis is relatively straightforward. Transferrin saturation (iron ÷ transferrin or total iron binding capacity × 100%) and ferritin levels are typically elevated in symptomatic patients in both the fasting and nonfasting states. Ferritin, which is an acute phase reactant, can be elevated without increased iron stores in acute illnesses, cancer, inflammatory arthritides, chronic viral hepatitis, and alcoholic and nonalcoholic fatty liver disease.

In patients with elevated transferrin saturation or ferritin levels, genetic testing should be performed. Detection of a C282Y homozygote or a compound heterozygote (C282Y/H63D) confirms the diagnosis of hereditary hemochromatosis. If the ferritin level is greater than 1000 µg/L, the patient should be considered for liver biopsy (Fig. 153-1) to determine whether fibrosis is present. Sensitive magnetic resonance imaging techniques can help determine hepatic iron concentrations when liver biopsy cannot be performed. On liver biopsy, iron deposition is found in periportal hepatocytes, with a periportal to pericentral gradient, and Kupffer cells are spared.

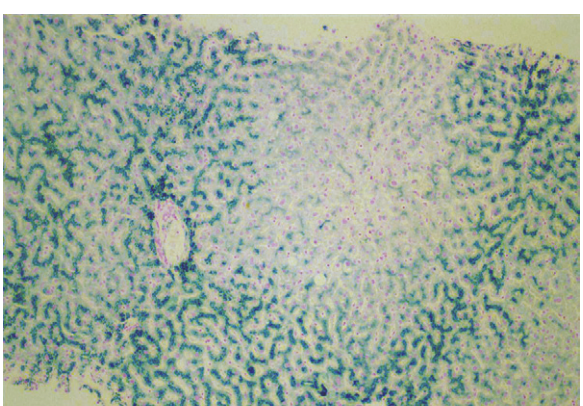

FIGURE 153-1. Liver biopsy in hemochromatosis (Perls Prussian blue stain for iron). Iron deposition is found in a periportal distribution, predominantly in parenchymal cells (hepatocytes).

TREATMENT AND PROGNOSIS

Rx

Treatment of hereditary hemochromatosis is simple, safe, effective, and inexpensive. It consists of weekly phlebotomy of 1 unit of blood, which contains about 200 to 250 mg of iron, and is designed to reduce total body iron stores with a goal of reducing ferritin levels to 50 to 100 µg/L. Most patients require maintenance phlebotomy of 1 unit of blood every 2 to 3 months. Screening with iron studies and genetic testing should be offered to all first-degree relatives of identified probands. Complications of the disease can be avoided if patients are diagnosed and treated before they develop fibrosis.

α_1-Antitrypsin Deficiency

EPIDEMIOLOGY AND PATHOBIOLOGY

α_1-Antitrypsin deficiency has been identified in all populations, but the disorder is most common in individuals of northern European descent. In North America, about 1 in 1500 to 2000 individuals is affected by the disorder.

α_1-Antitrypsin is a 52-kD glycoprotein produced in hepatocytes, epithelial cells of the lungs, and phagocytes. It inhibits serine proteases, primarily neutrophil elastase. When patients are deficient in α_1-antitrypsin, increased amounts of neutrophil elastase degrade elastin and can lead to progressive lung injury and premature emphysema (Chapter 88). α_1-Antitrypsin deficiency causes liver disease in infancy, early childhood, adolescence, and adulthood.

More than 75 variants have been identified in the proteinase inhibitor (Pi) gene located on chromosome 14. Some alter protein structure, thereby interfering with hepatocellular export. As a result, deformed polymers of α_1-antitrypsin aggregate and accumulate in the endoplasmic reticulum of the hepatocyte. Conventional nomenclature identifies normal variants as PiMM; individuals with these variants have normal blood levels of α_1-antitrypsin. The most common abnormal variants of functional significance are identified as S and Z. Individuals who are homozygous for the Z mutation (PiZZ) have α_1-antitrypsin levels that are only about 15% of normal; these patients are susceptible to liver and/or lung disease, but only about 25% of PiZZ patients develop end-organ disease. Individuals with PiSZ are at risk for developing liver disease and cirrhosis. Null variants have undetectable α_1-antitrypsin and are susceptible to premature lung disease but not liver disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In adults, symptoms of liver disease may be absent, or patients may complain of symptoms ranging from fatigue to complications of chronic decompensated liver disease (Chapter 148). The diagnosis is most frequently considered in patients who present with abnormal liver enzymes (Chapter 149) or as part of an evaluation for the cause of cirrhosis (Chapter 156). Coexistent lung disease at a relatively young age or a family history of liver and/or lung disease can provide clues to the diagnosis. Lung disease is not necessarily present.

The diagnosis is confirmed by a reduced serum level of α_1-antitrypsin, which can be measured specifically or assumed based on a low level of α_1-protein on serum protein electrophoresis, accompanied by Pi determinations. Most patients with liver disease have either the PiZZ or the PiSZ variant; some patients with PiMZ have reduced α_1-antitrypsin levels, but they are usually not low enough to cause disease. Liver biopsy, which is performed to determine the degree of hepatic fibrosis, shows characteristic periodic acid–Schiff–positive, diastase-resistant globules in the periphery of the hepatic lobule (Fig. 153-2).

TREATMENT AND PROGNOSIS

Rx

Unfortunately, there is no specific therapy for α_1-antitrypsin deficiency, so treatment is supportive. Other causes of liver injury, such as excessive alcohol ingestion, should be avoided. Evidence of other liver diseases (e.g., viral hepatitis B and C, hemochromatosis, NAFLD) should be sought, and such diseases should be treated if possible. Smoking, which can worsen the progression of lung disease but not liver disease in patients with α_1-antitrypsin deficiency, should be discontinued. In patients with lung disease, weekly infusions of α_1-antitrypsin given indefinitely can halt further lung damage.

The natural history of α_1-antitrypsin deficiency is variable because many individuals with the PiZZ variant never develop disease, whereas others develop cirrhosis in childhood, ultimately leading to liver transplantation. The risk of hepatocellular cancer is increased in patients with cirrhosis. If decompensated liver disease develops, liver transplantation (Chapter 157) should be curative. Following the transplant, patients express the Pi phenotype of the donor.

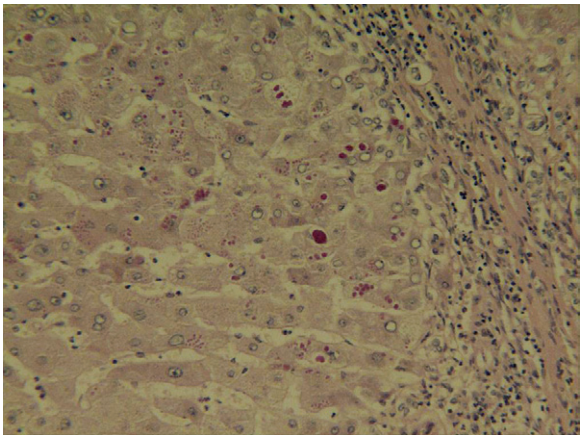

FIGURE 153-2. Liver biopsy in α_1-antitrypsin deficiency. On a periodic acid–Schiff, diastase-resistant stain, α_1-antitrypsin globules, with a characteristic magenta color, are found at the periodic of the lobule.

Wilson Disease

Wilson disease (Chapter 218), which is an inherited disorder of copper metabolism, leads to a progressive accumulation of copper in the liver and in various other tissues, ultimately causing toxicity and organ damage. The Wilson disease gene (*ATP7B*) encodes for a P-type ATPase that is involved in copper transport and is required for the removal of copper from hepatocytes into hepatic bile.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Wilson disease usually presents before age 35 years, but it can present in middle age or later. The clinical presentation is quite variable, and hepatic manifestations include chronic hepatitis, hepatic steatosis, and cirrhosis in adolescents and young adults. Patients who present with neurologic manifestations such as dysarthria or choreic or athetoid movement disorders always have concomitant liver disease. On physical examination, patients classically have Kayser-Fleischer rings (see Fig. 218-1 in Chapter 218) owing to copper deposition in Descemet's membrane in the cornea.

Diagnosis includes demonstration of a reduced ceruloplasmin level and an increased 24-hour urine copper excretion. In the presence of neurologic findings and clinical evidence of liver disease, a liver biopsy is not required. If a liver biopsy is obtained, however, the classic findings include an elevated hepatic copper level, hepatic steatosis, chronic hepatitis, and cirrhosis. The genetic diagnosis of Wilson disease is difficult because there are more than 200 mutations in *ATP7B,* with different degrees of frequency and penetration in certain populations.

TREATMENT AND PROGNOSIS

Rx

Treatment consists of copper chelation using medications such as D-penicillamine (1 to 1.5 g/day indefinitely) and trientine. Zinc acetate (75 to 250 mg/day) has been used as maintenance therapy. Medical treatment should be lifelong because discontinuation of therapy has been associated with severe relapses, liver failure, and death. Liver transplantation (Chapter 157), which is indicated for either decompensated cirrhosis or fulminant liver failure, cures the underlying metabolic defect and restores normal copper homeostasis.

Cystic Fibrosis

Cystic fibrosis (Chapter 89) can cause chronic liver disease in adults, although its principal manifestations are chronic lung disease and pancreatic insufficiency. Some adult patients with cystic fibrosis develop biliary cirrhosis with portal hypertension. Combined lung-liver transplantation is recommended for these patients. Ursodeoxycholic acid (13 to 15 mg/kg/day) improves symptoms and liver test abnormalities but is not curative.

METABOLIC LIVER DISEASES

Nonalcoholic Fatty Liver Disease

NAFLD (Chapter 155), which is seen most commonly in obese, diabetic, and hyperlipidemic nonalcoholic patients, has a prevalence ranging from 15 to 30% in the United States. Not all obese patients have fatty liver disease, but NASH occurs in about 3 to 5% of the overweight and obese population, and liver fibrosis is increased in up to 40% of these individuals. Most patients with hepatic steatosis have stable, nonprogressive disease, but NASH can progress to cirrhosis. Many patients who were previously described as having cryptogenic cirrhosis are now thought to have NASH, especially because catabolic cirrhosis reduces macrovesicular steatosis, so late biopsy may show just a bland cirrhosis.

Symptoms usually include fatigue and/or vague right upper quadrant discomfort, most likely due to a distended hepatic capsule. However, most patients come to medical attention as a result of incidentally identified elevated liver enzymes or the finding of a fatty liver on imaging studies for other purposes.

Critical to the diagnosis of NAFLD is a careful history to be sure that alcohol ingestion is less than 20 g/day. Routine laboratory testing for other common liver diseases (e.g., hepatitis B and C, hemochromatosis), as well as less common ones (e.g., Wilson disease, α_1-antitrypsin deficiency, autoimmune liver diseases), should be performed. Imaging studies can confirm characteristic features of a fatty liver (e.g., bright liver on ultrasound). These findings are nonspecific, however, and the ultimate diagnosis of NAFLD or NASH requires liver biopsy.

The principal treatments are dietary changes and weight loss, but some medications can also be helpful in selected patients (Chapter 155).

Porphyrias

The porphyrias (Chapter 217) are characterized by defects in the synthesis of heme, which is necessary for incorporation into numerous hemoproteins such as hemoglobin, myoglobin, catalase, and cytochromes. The porphyrias can present both acutely and chronically, with the acute disorders causing recurring bouts of abdominal pain, and the chronic disorders being characterized by skin lesions.

The most commonly encountered porphyria is porphyria cutanea tarda, which is characterized by vesicular-type lesions that appear on sun-exposed areas of the skin, such as the backs of the hands (see Fig. 447-11 in Chapter 447), tips of the ears, or over the cheekbones. About 40% of patients with porphyria cutanea tarda have mutations in *HFE* (Chapter 219), and about 50% have chronic hepatitis C (Chapter 151).

Liver disease associated with the porphyrias typically presents as an asymptomatic elevation of liver enzymes. After appropriate testing to confirm porphyria (Chapter 217), *HFE* mutation analysis, iron studies, and hepatitis C testing should be performed in all patients who present with porphyria cutanea tarda. Excess alcohol use is also associated with porphyria cutanea tarda, so patients should be counseled to decrease or eliminate alcohol use. Iron reduction therapy, using therapeutic phlebotomy, is the cornerstone of treatment for porphyria cutanea tarda, even in the absence of iron overload (Chapter 219). Concomitant chronic hepatitis C should be treated as well (Chapter 151). Skin lesions reverse in the majority of patients. Acute intermittent porphyria (Chapter 217), which is much less common, presents with abdominal pain in the absence of typical findings on physical examination. Intravenous hematin is the treatment of choice.

Lipid Storage Diseases

Lipid storage diseases that involve the liver include Gaucher's disease (Chapter 215) and Niemann-Pick disease (Chapter 215). Other rare disorders include abetalipoproteinemia, Fabry's disease (Chapter 215), Tangier disease (Chapter 213), and types 1 and 5 hyperlipoproteinemia (Chapter 213). On physical examination, the liver is enlarged owing to both fat deposition and increased hepatic glycogen deposition. Liver enzymes may be elevated and diagnosis requires liver biopsy in the appropriate clinical setting. Treatment is supportive, with enzyme infusions as indicated.

Amyloidosis

In patients with systemic amyloidosis (Chapter 194), the liver is commonly involved, but this involvement is sometimes identified only in the premorbid state or documented at autopsy. Characteristic pathologic findings include positive staining with Congo red histochemical stain, where an apple-green birefringence is noted under polarizing light. Liver enzymes may be mildly elevated, but this finding is nonspecific. Treatment is as for the systemic disease.

LIVER DISEASE IN PREGNANCY

In a pregnant patient with liver enzyme abnormalities, it is important to distinguish between liver diseases that are unique to pregnancy and those

TABLE 153-2 LIVER DISEASES UNIQUE TO PREGNANCY

DISEASE	TRIMESTER OF ONSET	SYMPTOMS	LABORATORY ABNORMALITIES	RECURRENCE WITH FUTURE PREGNANCIES
Hyperemesis gravidarum	1	Nausea, vomiting	Mild to moderate elevation in ALT/AST, occasionally hyperbilirubinemia	
Cholestasis	2, 3	Pruritus, jaundice	Bile acids >8 μM, elevated ALT/AST and bilirubin in more severe cases	Common
Acute fatty liver	3	Nausea, vomiting, abdominal pain	Elevated ALT/AST (100-1000 U/L), bilirubin >5 mg/dL, prolonged prothrombin time*	Rare
HELLP syndrome	2, 3, or postpartum	Abdominal pain, nausea, vomiting	Elevated ALT/AST (60-1500 U/L), platelets <100,000/mm^3, LDH >600 U/L, hemolytic anemia	3-25%

*Useful diagnostic distinction from HELLP syndrome, in which the prothrombin time, partial thromboplastin time, and fibrinogen are usually normal.
ALT = alanine aminotransferase; AST = aspartate aminotransferase; HELLP = hemolysis, elevated liver enzymes, and low platelet count; LDH = lactate dehydrogenase.

that occur commonly in pregnancy (Table 153-2). In normal pregnancy, levels of alkaline phosphatase, bile acids, globulins, fibrinogen, and triglycerides may be increased, whereas levels of albumin, antithrombin 3, protein S, and γ-glutamyltransferase may be reduced.

Hyperemesis Gravidarum

Hyperemesis gravidarum is a syndrome of unknown cause in which patients have fairly intractable nausea and vomiting. It generally occurs in the first trimester, usually before 10 weeks of pregnancy. Risk factors include young age, obesity, and nulliparity. Aminotransferases levels may be increased up to 200 U/L, and bilirubin may be elevated up to 4 mg/dL. No specific abnormalities are found on liver biopsy, but some patients have mild steatosis or mild cholestasis. Treatment is symptomatic with antiemetics.

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy presents with generalized pruritus. Most cases are associated with a mutation in the multiple drug resistance-3 gene. Ten percent to 25% of patients have visible jaundice, and laboratory abnormalities generally include hyperbilirubinemia less than 6 mg/dL. The alkaline phosphatase level may be elevated, and aminotransferase levels may be 2 to 10 times the upper limit of normal. Serum bile acids are also markedly increased at 2 to 100 times the upper limit of normal. If liver biopsy is performed, a bland cholestasis is identified. Ultrasonography is normal.

Treatment includes ursodeoxycholic acid or cholestyramine to bind bile salts. Phenobarbital has also been used. The syndrome resolves after delivery but is likely to recur with subsequent pregnancies.

Preeclampsia and HELLP Syndrome

Preeclampsia (Chapter 247), seen in as many as 7 to 10% of pregnancies, usually occurs in the third trimester or late in the second trimester. The triad of findings consists of hypertension, proteinuria, and edema. Some patients have severe hypertension, profound proteinuria, and seizures. Liver enzymes can be markedly elevated, and levels of lactate dehydrogenase and bilirubin can be increased by hemolysis. The prothrombin time is usually normal, but some patients may have thrombocytopenia. The *HELLP* syndrome (hemolysis, elevated liver enzymes, and low platelet count) is seen in about 10% of patients with preeclampsia and is considered a severe manifestation of eclampsia. Hepatic infarction is rare, but hepatic rupture can be catastrophic.

The diagnosis is generally made clinically, and a liver biopsy is usually not necessary. Treatment is by delivery.

Acute Fatty Liver Disease in Pregnancy

Acute fatty liver disease occurs in about 1 in 900 to 6000 pregnancies. Abnormalities in mitrochondrial function and adenosine triphosphate (ATP) synthesis have been described, and about 20% of cases have a deficiency in long-chain 3-hydroxyacyl-CoA dehydrogenase, with an abnormality in the beta oxidation of fatty acids. Acute fatty liver is characteristically seen in the third trimester. Patients can have profound hepatic dysfunction, but liver enzymes are usually not markedly elevated and are characteristically less than 10 times the upper limit of normal. The prothrombin time may be prolonged, and the bilirubin level is elevated. Some patients have disseminated intravascular coagulation, and some may have hypoglycemia.

Clinical features are nonspecific, and the clinical course ranges from mild complications to more severe problems. Diagnosis is by ultrasound showing steatosis and liver biopsy showing microvesicular steatosis. Treatment requires urgent delivery.

Other Hepatobiliary Conditions in Pregnancy

Other hepatic conditions that can occur in pregnancy including gallstones (Chapter 158) and Budd-Chiari syndrome (Chapter 145). Acute herpes hepatitis, caused by herpesvirus type 2, occurs in the second and third trimesters and is associated with fever, chills, malaise, and nausea. Liver enzymes may be markedly elevated, and the prothrombin time may be prolonged. Liver biopsy shows typical viral inclusions. Treatment is with antiviral therapy (Chapter 368).

TOTAL PARENTERAL NUTRITION–INDUCED LIVER DISEASE

As many as 30 to 40% of patients who receive total parenteral nutrition (Chapter 224) develop abnormal liver enzyme levels. These abnormalities range from mild elevations of aminotransferase levels, owing to hepatic steatosis, to cholestatic liver disease with elevated alkaline phosphatase levels. Minor adjustments in the formula usually resolve the abnormalities. Some patients with cholestatic abnormalities may benefit from ursodeoxycholic acid.

BACTERIAL, PARASITIC, FUNGAL, AND GRANULOMATOUS LIVER DISEASES

K. RAJENDER REDDY

INFECTIONS OF THE LIVER

Infections of the liver can be due to a variety of pathogens, including bacteria, fungi, amebae, protozoa, helminthes, spirochetes, and rickettsial infections. The manifestations of these infections are protean; some are generic to all infections, whereas others are specific to particular infections. The epidemiology can vary and depend on the geographic region of the world. In endemic areas, *Entamoeba histolytica* is a key consideration in the differential diagnosis of a liver abscess (Table 154-1).

TABLE 154-1 FEATURES OF BACTERIAL AND AMEBIC ABSCESSES

	DEMOGRAPHICS	RISK FACTORS	SYMPTOMS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Bacterial liver abscess	50-70 years old Male = female	Recent bacterial infection, biliary obstruction, diabetes mellitus	Fevers, chills, malaise, anorexia, diarrhea, cough, pleuritic chest pain, RUQ pain	Leukocytosis, anemia, elevated alkaline phosphatase and bilirubin, low albumin, positive blood cultures (50%)	Multifocal (50%), usually right lobe, irregular margins	Aspirate (70-80% positive)	Percutaneous drainage and antibiotics
Amebic liver abscess	18-50 years old Male > female	Alcohol intake, HLA-DR3, oral and anal sex, contaminated enema apparatus, travel to or living in an endemic area	Fever, RUQ pain, hepatic tenderness, anorexia, weight loss, uncommon to have colitis	Leukocytosis, no eosinophilia, mild anemia, elevated alkaline phosphatase, elevated ESR, positive serology	Single abscess (80%), usually right lobe, wall enhancement seen on CT scan with IV contrast	Aspirate (trophozoites rarely seen) can rule out superimposed bacterial infection, positive serology and risk factors	Metronidazole and iodoquinol

CT = computed tomography; ESR = erythrocyte sedimentation rate; IV = intravenous; RUQ = right upper quadrant.

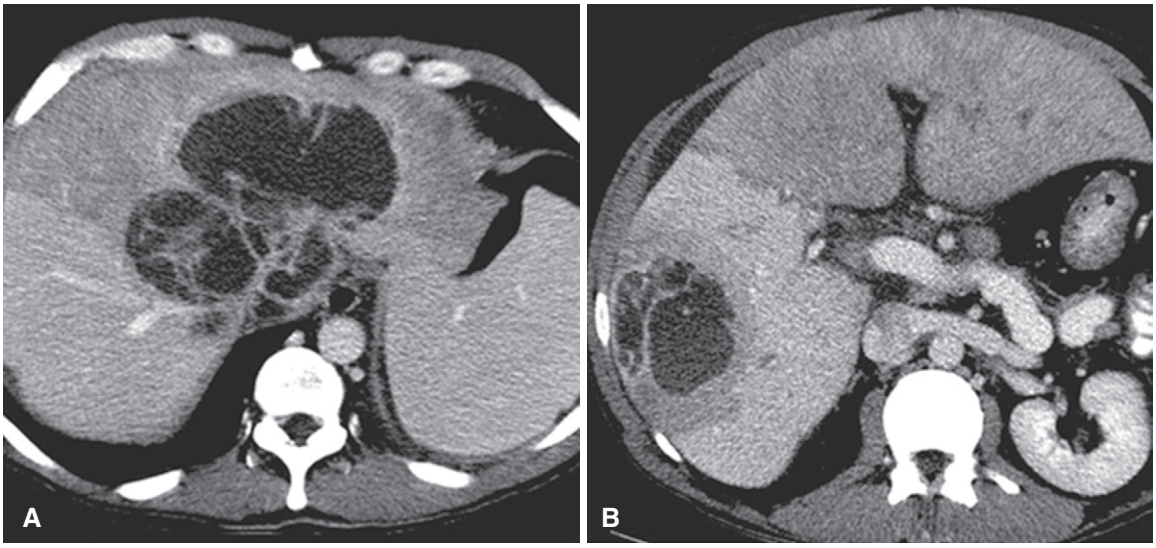

FIGURE 154-1. A and B, Computed tomographic scans of a pyogenic liver abscess. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

Pyogenic Liver Abscess

DEFINITION

Pyogenic liver abscess is a focal collection of purulent bacterial material and necroinflammatory debris. It can be solitary or multiple and can be caused by one or more aerobic and anaerobic bacteria (Fig. 154-1).

EPIDEMIOLOGY

Pyogenic liver abscess has an estimated global incidence of approximately 1.1 to 2.3 per 100,000 person-years, whereas in the United States the incidence is reported to be approximately 3.6 per 100,000 and has been rising. Biliary obstruction, caused by a malignancy or benign disease, accounts for 50 to 60% of pyogenic liver abscesses, whereas portal pyemia, owing to appendicitis or other intra-abdominal infections, accounts for about 20% of cases.

PATHOBIOLOGY

Bacteria can enter the liver through the portal system from infections in areas drained by the mesenteric system into the portal system, such as appendicitis (Chapter 144). Other mechanisms for pyogenic liver abscess include bacterial cholangitis owing to benign or malignant obstruction, and infection of the liver from a systemic bacteremia, such as an infection of the oral cavity. Pyogenic liver abscess can also be caused by blunt or penetrating trauma, including such unusual causes as the ingestion of a toothpick or fish bone that can cause an intestinal perforation, fistula to the liver, and subsequent abscess formation. Liver abscesses can occur in a transplanted graft owing to vascular compromise caused by hepatic artery thrombosis and ischemic bile duct strictures.

Multiple organisms can cause pyogenic liver abscess. The most common organism, *Klebsiella pneumoniae,* often is associated with biliary tract disease. Other aerobes include *Escherichia coli,* group D streptococci, β-hemolytic streptococci, and *Staphylococcus aureus.* Anaerobic infection is often seen with colonic disease. Less common causes of liver abscesses include actinomyces, *Nocardia asteroides, Yersinia pseudotuberculosis* and *Yersinia enterocolitica, Listeria monocytogenes, Campylobacter jejuni, Legionella pneumophila, Mycobacterium tuberculosis, Salmonella typhi* or *Salmonella paratyphi, Candida albicans,* and *Bartonella henselae*. Most often the organism recovered from an abscess cavity is single, but multiple organisms can be isolated in as many as one third of patients. No bacteria may be isolated from the abscess because of prior antibiotic therapy or the failure to perform proper anaerobic cultures.

CLINICAL MANIFESTATIONS

The signs and symptoms associated with a liver abscess typically include fever, right upper quadrant abdominal pain, chills, nausea, vomiting, weight loss, and jaundice. The presentation can be acute or indolent. An associated bacteremia is seen in approximately 50% of the patients, but frank sepsis is rare.

DIAGNOSIS

Appropriate diagnosis requires a high degree of clinical suspicion, and diagnosis is sometimes delayed. Usually, however, the diagnosis is made promptly with the wide availability of the various radiologic modalities. The two common causes of liver abscesses are pyogenic and amebic abscess, and it is important to make a distinction because the prognosis

and management differ. Amebic abscess can become secondarily infected with bacteria.

The diagnosis of an abscess is based on a constellation of clinical, bacteriologic, and radiologic features. Ultrasonography and computed tomography (CT) are the most common radiologic modalities to diagnose an abscess cavity reliably, as either single or multiple lesions, but CT is the preferred test, with sensitivity above 90%. Any concurrent biliary obstruction also can be diagnosed by these imaging studies. Approximately 50% of patients have multiple abscesses. On CT, the lesion is seen as a fluid collection with irregular borders and wall edema. One drawback to this imaging modality is that no specific features differentiate a pyogenic abscess from other infectious causes (i.e., amebic or fungal). Another drawback is that a very early stage abscess may not be well formed and may have characteristics more suggestive of a solid mass. Distinguishing an abscess from a tumor (Chapter 202) or a simple cyst can be difficult on noninvasive imaging if there is bleeding into a cyst, calcification, necrosis, or bleeding into a tumor. The presence of smaller (<2 cm) peripheral lesions that surround a central lesion argues strongly against a hepatic neoplasm. Calcification suggests bleeding into a tumor, but it also can be seen in the wall of an echinococcal cyst. Nonspecific radiologic features, including elevation of the right hemidiaphragm, right lower lung lobe atelectasis, and right pleural effusion, are seen in up to 30% of patients with pyogenic liver abscesses. Magnetic resonance imaging (MRI) and tagged white blood cell scans add little to the diagnosis of a liver abscess.

Microbial cultures are essential. In addition to blood cultures, the abscess cavity should be aspirated percutaneously, with either ultrasound or CT guidance, and the aspirate should be cultured for aerobic and anaerobic organisms as well as for amebae if there is any suspicion of an amebic abscess. Blood cultures are positive in only approximately 50% of cases. In approximately 15 to 20% of cases, multiple organisms are identified in the abscess cavity, but 20 to 30% of cases may have negative cultures despite appropriate culture techniques.

TREATMENT

Rx

Immediate broad-spectrum antibiotic coverage, as well as the prompt identification and treatment of the source of the infection, are essential for successful outcomes. Once the etiologic bacteria is identified, the antibiotic regimen can be tailored appropriately based on prevailing bacterial resistance patterns. Monotherapy with a β-lactam or β-lactamase inhibitor such as ampicillin-sulbactam (3 g intravenously every 6 hours), piperacillin-tazobactam (4.5 g intravenously every 6 hours), or ticarcillin-clavulanate (3.1 g intravenously every 6 hours) can be used, or a third-generation cephalosporin such as ceftriaxone (1 to 2 g intravenously daily) *plus* metronidazole (500 mg intravenously every 8 to 12 hours) can be used. Other potential regimens include a fluoroquinolone (e.g., ciprofloxacin, 400 mg intravenously every 12 hours, or levofloxacin, 500 or 750 mg intravenously daily) *plus* metronidazole (500 mg intravenously every 8 to 12 hours), or monotherapy with a carbapenem such as imipenem (500 mg intravenously every 6 hours), meropenem (1 g intravenously every 8 hours), or ertapenem (1 g intravenously daily).

The duration of therapy is partly based on the response to therapy. On an average, 4 to 6 weeks of antibiotic therapy appears reasonable, and the last 2 to 4 weeks of the antibiotic regimen can be administered orally. Abscesses that are hard to drain or are slow to demonstrate radiographic resolution require longer courses of therapy. Importantly, radiologic abnormalities resolve more slowly than clinical and biochemical features, so the latter should be used as an indicator for tailoring the therapeutic regimen.

Although antibiotics alone can sometimes successfully resolve small, multiple pyogenic abscesses, it also is critical to address the source of infection. Any underlying biliary source must be resolved, and any biliary obstruction must be relieved. More often, most patients will require drainage of the abscesses. The standard approach is placement of a drain for about 7 days. Alternatively, needle aspiration, repeated as needed when the abscess is large enough to drain percutaneously, provides equivalent results, except in abscesses larger than 10 cm in diameter. Surgical drainage seldom is the first option, except in patients who also have a surgically correctable precipitating lesion, such as appendicitis or biliary obstruction. More often, a biliary obstruction is treated with endoscopic retrograde cholangiopancreatography (ERCP) or transhepatic cholangiography with biliary drainage. For pyogenic abscesses in transplanted livers, management and proper biliary drainage may be difficult to achieve because of the diffuse nature of the biliary strictures.

PROGNOSIS

Abscesses smaller than 10 cm can take up to 16 weeks to resolve, whereas abscesses larger than 10 cm may take, on an average, another 6 weeks to resolve. Mortality from pyogenic liver abscess is associated with older age and with comorbidities such as cirrhosis, diabetes, chronic renal failure, and malignancy. Jaundice is an ominous sign. In developed countries, the mortality rate ranges from 2 to 12%. Patients with bacteremia have a four-fold higher risk for death.

Nonabscess Hepatic Bacterial Infections

Bacterial infections of the liver can also cause more diffuse infections without frank abscess formation. Implicated organisms include *L. monocytogenes* (Chapter 301), *Y. enterocolitica* (Chapter 320), *S. typhi* and *S. paratyphi* (Chapter 316), legionella (Chapter 322), ehrlichia (Chapter 335), and gonococci (Chapter 307). There are no specific features associated with these infections, and these organisms do not necessarily cause abscesses. Patients with chronic liver disease are especially at risk for listerial infection. Patients with active enteric yersinia infection can have secondary liver involvement with or without liver abscesses. Disseminated gonococcal infections (Chapter 307) can cause a perihepatitis (Fitz-Hugh-Curtis syndrome), which can present with right upper quadrant pain and tenderness.

Systemic bacteremia can cause a variety of hepatobiliary abnormalities, which may range from elevated aminotransferase and alkaline phosphatase levels (Chapter 149) to the cholestasis of sepsis with the development of jaundice. Common organisms that can disrupt normal liver function after entering the blood stream include *E. coli*, *Klebsiella* species, *Streptococcus pneumoniae*, and *S. aureus*, especially from pneumonias, urinary tract infections, or soft tissue infections. The hepatic biochemical abnormalities associated with bacteremia may be related to factors such as hemodynamic instability and liver hypoperfusion, as well as to the infection per se. Associated renal failure, a blood transfusion–derived bilirubin load, and drugs may complicate the picture. The course of cholestasis may be prolonged for several days to a few weeks, but it typically resolves with resolution of the systemic infection. There is no specific treatment for the cholestasis related to a systemic infection, but it is important to rule out drug-induced cholestasis that may evolve as a consequence of one or more of the antibiotics.

Fungal Diseases of the Liver

Except for hepatosplenic candidiasis with granuloma formation, clinically significant fungal diseases of the liver are unusual. Other fungal infections also commonly manifest as hepatic granulomas but usually are not accompanied by the high fever that is characteristic of hepatosplenic candidiasis.

HEPATOSPLENIC CANDIDIASIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Hepatosplenic candidiasis typically is caused by *C. albicans*, but other *Candida* species, including *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and *C. krusei*, have occasionally been reported. It occurs as part of disseminated candidiasis (Chapter 346), almost exclusively in patients with acute leukemia, but rarely in patients with lymphoma, aplastic anemia, and sarcoma. Up to 7% of patients with acute leukemia may develop hepatosplenic candidiasis, and it is more common with acute lymphoblastic leukemia than acute myeloid leukemia. Recently, however, the incidence of hepatosplenic candidiasis has decreased by a factor of four owing to the widespread use of prophylactic antifungal agents early in the disease. Hepatosplenic candidiasis presumably results from translocation of *Candida* species from the gastrointestinal tract into the blood stream as a result of prolonged neutropenia and a breach in mucosal integrity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatosplenic candidiasis presents with persistent and high spiking fevers in a patient who was previously neutropenic and has now returned to a normal neutrophil count. The fever may be accompanied by right upper quadrant pain, nausea, vomiting, and anorexia.

Patients typically have elevated levels of alkaline phosphatase and less commonly of aminotransferases, bilirubin, and leukocytes. CT, which is the imaging modality of choice, classically shows multiple areas of lucency representing microabscesses in the liver, spleen, and kidneys. If the CT scan is nondiagnostic but clinical suspicion remains high, an MRI should be performed.

TREATMENT AND PROGNOSIS

Rx

The mainstay of therapy is with antifungal therapy for a long duration of treatment. In clinically stable patients, oral fluconazole can be used. In acutely ill patients, a lipid formulation of amphotericin B (3 to 5 mg/kg intravenously daily) is recommended. If the lipid formulation of amphotericin B is not used, other options are caspofungin (70 mg loading dose, then 50 mg intravenously daily), anidulafungin (200 mg loading dose, then 100 mg intravenously daily), or micafungin (100 mg intravenously daily). After 1 to 2 weeks, oral fluconazole (400 mg daily) should be started. Treatment should continue until lesions resolve on follow-up CT scans, typically within 6 months of treatment. In patients who are receiving chemotherapy or stem cell transplantation, however, the high risk for recurrent hepatosplenic candidiasis typically warrants continued prophylactic fluconazole (400 mg orally, daily) to prevent relapse until native immunity is restored.

A definitive diagnosis is usually made on liver biopsy specimens that show multiple granulomas, and, with special stains, yeast and hyphal forms. However, biopsy often will not show evidence of infection, especially in patients who have received prior antifungal therapy. Although biopsy is the only means to establish a definitive diagnosis, it is not often required because other clinical, laboratory, and radiographic manifestations are almost always sufficient for diagnosis.

PROGNOSIS

With prolonged treatment with antifungals, there has been good success at treating hepatosplenic candidiasis.

Other Fungal Diseases

Other fungal infections of the liver are quite rare. Fungal cultures are always necessary to establish a definitive diagnosis.

Coccidioides immitis (Chapter 341) is often asymptomatic but may lead to fungal hepatitis characterized by an increased alkaline phosphatase level and the development of hepatic granulomas. Hepatic *Cryptococcus neoformans* infections (Chapter 344) are rare but are seen in patients with AIDS, who typically develop hepatomegaly. In the much more rare non-HIV-infected patient, disseminated cryptococcosis can result in focal granulomatous hepatitis, which may clinically mimic viral hepatitis, or can present as obstructive jaundice secondary to sclerosing cholangitis. *Histoplasma capsulatum* (Chapter 340) infects individuals who inhale the fungus, but most cases are subclinical. In symptomatic hepatic histoplasmosis, two thirds of patients present with hepatomegaly, with some showing splenic enlargement as well. Histologically, histoplasmosis can cause multiple granulomas diffusely distributed throughout the liver, although a more common finding is portal lymphohistiocytic infiltrate. *Paracoccidioides brasiliensis* (Chapter 343) most commonly infects adult males, and autopsy series have shown hepatic involvement in up to 50% of patients who die from this infection. Some individuals may present with hepatomegaly or jaundice, although the latter is found in less than 6% of patients. Aminotransferase levels are often elevated in the early stages of the disease, with changes in alkaline phosphatase or bilirubin levels tending to occur in the later stages. Biopsy may reveal lesions ranging from small granulomas to diffuse fibrosis and infiltration of yeast forms, often with bile duct involvement.

PARASITIC, PROTOZOAL, AND HELMINTHIC INFECTIONS OF THE LIVER

Amebic Liver Abscess

EPIDEMIOLOGY

Entamoeba histolytica (Chapter 360) is found throughout the world where the barriers between human feces and food and water are inadequate. After malaria, it is the second leading cause of death from parasitic diseases worldwide, accounting for an estimated 40,000 to 100,000 deaths annually. In the United States, most cases of amebiasis arise in immigrants from endemic areas and people living in states that border Mexico. Travelers to endemic areas are also at risk; ingestion of amebic cysts and colonization of the gastrointestinal tract can occur years before the development of a liver abscess. Amebic liver abscesses mainly affect men between the ages of 18 and 50 years but are also more common in postmenopausal women, thereby suggesting a hormonal protective effect. Other risk factors include alcohol intake, HLA-DR3, oral and anal sex, and contaminated enema apparatuses.

TABLE 154-2 PARASITIC INFECTIONS INVOLVING THE LIVER

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS AND ENDEMIC AREAS	MAJOR HEPATIC MANIFESTATIONS
MAJOR PROTOZOA				
Entamoeba histolytica	Ingested cysts develop into invasive trophozoites that colonize the colon and occasionally spread to the liver by the portal blood	Mexico, regions of Central and South America, India, and regions of Africa	Male gender, alcohol intake, HLA-DR3, oral and anal sex, and contaminated enema apparatuses	Amebic liver abscesses develop as a tissue response to trophozoite invasion with acute and chronic manifestations (see text)
OTHER PROTOZOA				
Cryptosporidium species and microsporidia	Ingested cysts develop into trophozoites in intestinal mucosa	Worldwide distribution	AIDS	Biliary tract infection with obstruction and cholangitis
Toxoplasma gondii	Ingestion of oocysts in contaminated soil or water or in infected meat; systemic spread of tachyzoites in the circulation	Worldwide distribution	Consumption of undercooked meat, contact with soil, and travel outside the United States, Europe, or Canada	Immunocompetent: asymptomatic or hepatomegaly and mild LFT elevations Immunocompromised: occasional overt hepatitis
Leishmania species	Sand fly bite transmits promastigotes; proliferation in the reticuloendothelial system	Worldwide distribution	Children <10 yr and immunocompromised adults Contact with sand flies	Hepatosplenomegaly months to years after infection
Plasmodium species	Mosquito (*Anopheles*) bite transmits sporozoites	Multiple regions throughout the world	Exposure to anopheline mosquito bites	Proliferation in hepatocytes causes hepatomegaly, enzyme elevations, and jaundice
Babesia microti	Tick bite transmits the agent, which parasitizes erythrocytes	Europe	Asplenia is a risk for fatal hepatic failure, especially bovine babesiosis	Mild liver enzyme elevations

PATHOBIOLOGY

E. histolytica has a simple life cycle consisting of the cyst (infectious form) and trophozoite (the motile stage associated with disease); it infects only humans and some nonhuman primates. Cysts are ingested and mature into trophozoites in the intestinal lumen. The development of amebic colitis is not essential for liver abscess formation. *E. histolytica* trophozoites penetrate through the mucosa and submucosal tissues and enter the portal circulation. *E. histolytica* blocks intrahepatic portal venules. When the trophozoites reach the liver, they create their unique abscesses, which are well-circumscribed regions of dead hepatocytes, liquefied cells, and cellular debris that are surrounded by a rim of connective tissue, a few inflammatory cells, and amebic trophozoites. The adjacent liver parenchyma is unaffected. Given the small numbers of amebae relative to the size of the abscess, it is suggested that *E. histolytica* can cause hepatocyte death without direct contact.

CLINICAL MANIFESTATIONS

Patients can present with amebic liver abscesses months to years after traveling to an endemic area, so a detailed travel history is essential for the diagnosis. The disease should be suspected in patients with an appropriate travel history, fever, right upper quadrant pain, and substantial hepatic tenderness. Jaundice is extremely uncommon. Symptoms are usually acute (<10 days in duration) but can be chronic, with anorexia and weight loss. Patients with acute disease tend to have multifocal disease, whereas patients with a more indolent course tend to have a solitary lesion. Laboratory data tend to demonstrate a leukocytosis without eosinophilia, mild anemia, an elevated alkaline phosphatase level, and high erythrocyte sedimentation rate.

DIAGNOSIS

Although some individuals with amebic liver abscesses have concurrent amebic colitis, most have no bowel symptoms; hence, stool microscopy for *E. histolytica* trophozoites and cysts are usually negative. The diagnosis relies on identification of a space-occupying lesion in the liver and a positive amebic serology. Both ultrasound and CT scan are very sensitive (Fig. 154-2), but neither provides absolute specificity for amebic liver abscesses. Serologic testing is highly sensitive (>94%) and specific (>95%). False-negative testing can be obtained within the first 7 to 10 days of infection, but repeat testing will usually be positive. Aspiration of the lesion may be necessary to exclude a primary or secondary bacterial infection.

TREATMENT AND PROGNOSIS

Rx

Metronidazole (500 to 750 mg orally three times daily or a 15-mg/kg loading dose followed by 7.5 mg/kg every 6 hours intravenously) usually provides evidence of clinical improvement within 72 to 96 hours but should be continued for 5 to 10 days. Nitroimidazole tinidazole at 2 g daily for 3 days is also effective. Drainage is not necessary,[3] except in patients who do not respond within 5 days. For cysts larger than 10 cm, catheter drainage is preferred over repeated needle aspiration.[4] The abscess usually shrinks by about 50% within a week, but the mean time to complete radiologic resolution is 3 to 9 months. Repeated imaging in a clinically improving patient may lead to unwarranted concern and unnecessary treatment.

Treatment must also address the removal of all of the cysts from the intestinal lumen in patients with evidence of intraluminal infection. A recommended treatment is iodoquinol (650 mg orally three times a day for 20 days) to prevent continued colonization and possible recurrence of the liver abscess. With prompt diagnosis and adequate medical treatment, the mortality rate from amebic abscess is 1 to 3%.

Other Protozoal Liver Diseases

In addition to *E. histolytica*, other protozoal diseases that affect the liver include *Cryptosporidium* species, *Toxoplasma gondii, Leishmania* species, *Plasmodium* species, and *Babesia microti* (Table 154-2).

HELMINTH INFECTIONS

Echinococcosis and Hydatid Cyst Disease

EPIDEMIOLOGY AND PATHOBIOLOGY

Human cystic echinococcosis is a zoonosis caused by the larval cestode *E. granulosus*. It is often referred to as hydatid cyst disease because of the watery cysts that characterize the infection.

SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Fever, RUQ pain, and substantial hepatic tenderness	Leukocytosis without eosinophilia, mild anemia, elevated serum AP, and high ESR	US, CT, and MRI can detect abscess but cannot always differentiate amebic from pyogenic. On CT or MRI, amebic abscess sometimes appears "cold" with bright rim.	Imaging, serology, stool antigen test (microscopic evaluation of stool has a poor yield)	Metronidazole, 500-750 mg PO tid × 5-10 days, or tinidazole, 2 g daily × 3 days; iodoquinol, 650 mg tid × 20 days, also needed to eradicate intestinal colonization
See Chapter 358	See Chapter 358	See Chapter 358	See Chapter 358	See Chapter 358
See Chapter 357	See Chapter 357	See Chapter 357	See Chapter 357	See Chapter 357

TABLE 154-2 PARASITIC INFECTIONS INVOLVING THE LIVER—cont'd

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS AND ENDEMIC AREAS	MAJOR HEPATIC MANIFESTATIONS
MAJOR HELMINTHS				
Schistosoma species	Cercaria in fresh water penetrate the skin, travel by the circulation to portal vein radicals	*S. mansoni* found in South America, Africa, and Middle East. *S. japonicum* found in Far East (mostly China and Philippines).	Contact with fresh water containing cercaria of schistosomes	Progressive presinusoidal blood flow obstruction, periportal fibrosis, portal hypertension, varices, ascites, splenomegaly
Echinococcus granulosus	Eggs of small (3-7 mm) tapeworms in stool of canid hosts; ingested eggs produce larval oncospheres that migrate to the liver and form cysts in sheep, humans, and other intermediate hosts	Worldwide distribution, found especially in sheep-raising areas (Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand)	Ingestion of food or water fecally contaminated with eggs and human contact with sheepdogs	Initial infection asymptomatic; liver cysts increase in diameter by 1-5 cm yearly and cause variable abdominal pain, hepatomegaly, and variable eosinophilia; occasional cyst rupture, secondary bacterial infection
Echinococcus multilocularis	Eggs of small tapeworms in stool of foxes; ingested eggs produce oncospheres in the liver of rodents, humans, and other intermediate hosts	Endemic in Northern hemisphere	Human exposure increasing with growing fox populations	Metacestodes colonize the liver as a tumor-like mass of small vesicles
Fasciola species	Leaf-shaped flukes up to 13 × 30 mm derived from ingested cysts; the fluke excysts in the duodenum, migrates directly across the bowel wall into the peritoneal cavity, and burrows directly into the liver (or occasionally out to the skin)	Worldwide distribution	Consumption of freshwater or aquatic plants contaminated by colonized livestock	Adult flukes live in the common and hepatic bile ducts causing obstruction and leading to thickening of the ducts, dilation, and fibrosis of the proximal biliary tree
Opisthorchis species and *Clonorchis sinensis*	Flukes of 8-25 mm derived from ingested cysts; the fluke excysts in the duodenum and migrates into the bile ducts	*Opisthorchis* sp: Southeast Asia, Central and Eastern Europe (particularly Siberia) *C. sinensis:* China, Japan, Vietnam, Korea	Consumption of raw, pickled, dried, smoked, or salted freshwater fish or crayfish originating from East Asia or, in the case of *Opisthorchis felineus,* Russia and Eastern Europe	*Acute:* typically asymptomatic *Chronic:* abdominal pain, fever, anorexia, tender hepatomegaly, sometimes eosinophilia *Late sequelae:* intermittent biliary obstruction, cholelithiasis, cholecystitis, cholangitis, secondary bacterial abscesses, cholangiocarcinoma
Toxocara species	Nematode infection disseminates to cause visceral larva migrans after ingestion of soil contaminated with dog or cat feces	Highest prevalence in southeastern United States	Consumption of food contaminated with soil containing eggs; distributed throughout the United States	Often an asymptomatic cause of eosinophilia (exclude *Trichinella* sp, *Strongyloides* sp, filaria, hookworm, schistosomiasis); hepatomegaly is common, but nonhepatic manifestations dominate the clinical picture
OTHER HELMINTHS				
Ascaris lumbricoides	Ingested eggs develop into larvae that migrate to the lungs and are coughed and swallowed; develop into roundworms 15-30 mm long in the small intestine	Global distribution with higher prevalence in Africa, South America, India, and the Far East; 20% of the world's population is colonized	Consumption of fecally contaminated food or water, particularly in young children	Colonization is typically asymptomatic with eosinophilia; biliary migration of worms can cause symptomatic biliary obstruction, cholangitis, cholecystitis, and secondary bacterial liver abscess
Capillaria hepatica	Ingested eggs develop into larvae in the intestinal mucosa; larvae migrate to the liver by portal blood flow and develop into short-lived roundworms	Human infection is rare	Consumption of food contaminated with rodent feces	Fever, eosinophilia, and hepatomegaly; subsequent foci of liver fibrosis, granulomas, and calcification in involved areas
Strongyloides stercoralis	Ingested eggs develop into 1.5- to 2.5-mm nematodes that invade the hepatic vasculature, lymphatics, and biliary tract	Tropical and subtropical areas, including southeastern United States and Southern and Eastern Europe	Consumption of food contaminated with soil containing eggs, infection with HTLV-1, and immunocompromised individuals	Hepatic disease in the setting of immunosuppression: jaundice, abdominal pain; eosinophilia is uncommon

AP = alkaline phosphatase; CT = computed tomography; ELISA = enzyme-linked immunosorbent assay; ERCP = endoscopic retrograde cholangiopancreatography; ESR = erythrocyte sedimentation rate; HTLV = human T-cell lymphotrophic virus; LFT = liver function test; MRI = magnetic resonance imaging; RUQ = right upper quadrant; US = ultrasonography.

SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Initial infection presents as itching. Later presentations include fever, diarrhea, chills, headaches, or hives. Hematemesis from ruptured gastroesophageal varices	Eosinophilia and splenomegaly; seroconversion occurs within 4 to 6 weeks	Extensive calcification with typical turtle-back appearance along portal tracts	Rectal biopsy, liver biopsy, microscopic examination of stool	Praziquantel (single dose, 40 mg/kg) with a second dose 6-12 weeks later if necessary
Enlarged hydatid cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass. Mild RUQ pain, urticaria, and episodes of pruritus	Positive Weinberg reaction (false negative in 38% of cases) or ELISA analysis; eosinophilia seen in ruptured cysts	On US or CT, cysts appear flaky, sometimes showing daughter cysts or peripheral focal calcification. Fluid is of variable density.	Imaging, Weinberg reaction, or ELISA	Albendazole, 400 mg 2× daily for 3-6 monthly cycles with 10-14 day intervals. Drainage of the cyst is essential. Surgical resection if the cyst communicates with the biliary tree.
See Chapter 362	See Chapter 362	See Chapter 362	See Chapter 362	See Chapter 362
Acute: fever, abdominal pain, eosinophilia *Chronic:* symptomatic biliary obstruction, variable eosinophilia	Serologic tests include hemagglutination, complement fixation, ELISA, and counterimmunoelectrophoresis. Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia are often seen.	CT is most useful: liver shows hypodense nodules or tortuous tracks; thickening of the liver capsule, subcapsular hematoma, and parenchymal calcification may also be seen	Serology, stool examination	Triclabendazole, 10 mg/kg once or twice
Chronic infection presents as dyspepsia, abdominal pain, diarrhea, nausea, vomiting, anorexia, weight loss, fevers, hepatomegaly, and urticaria. Acute presentation includes serum sickness, intrahepatic pigment stones, and facial edema. Other rare complications are cholangitis, pancreatitis, and obstructive jaundice.	Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia	US may detect flukes in biliary tree. CT shows small hypodense nodules.	Serology and stool examination	Praziquantel, 25 mg/kg q8h × 3 doses
See Chapter 365	See Chapter 365	See Chapter 365	See Chapter 365	See Chapter 365
Sensitized patients during pulmonary phase present with asthma-like symptoms, hemoptysis, chest pain, and cyanosis. Urticaria and other allergic reactions are sometimes seen. Patients in intestinal phase show cognitive and nutritional impairment with abdominal pain, hepatomegaly, cholangitis, and obstructive jaundice.	Leukocytosis with eosinophilia; hyperbilirubinemia occasionally seen	Movement of the worms within the biliary tree can sometimes be observed. A bull's-eye appearance can be seen on cross-sectional imaging.	Stool examination, imaging, and ERCP	Albendazole, 400 mg once
Persistent fever, eosinophilia, and hepatomegaly are most common. Splenomegaly, anorexia, nausea, vomiting, night sweats, and altered bowel habits are also seen.	Anemia, eosinophilia, moderately elevated liver enzymes, increased ESR, and hypergammaglobulinemia	US shows nonspecific hyperechoic areas in the portal spaces.	Stool and liver biopsy	Mebendazole, 200 mg bid × 20 days
Recurrent urticaria, abdominal pain, diarrhea, and cough; mild jaundice and hepatomegaly in the absence of splenomegaly	Eosinophilia and hypoalbuminemia Patients may have elevated liver enzymes.	Imaging studies not used in diagnosis	Serology and stool examination	Ivermectin, 200 µg/kg/day × 2 days, or albendazole, 400 mg/day × 7 days

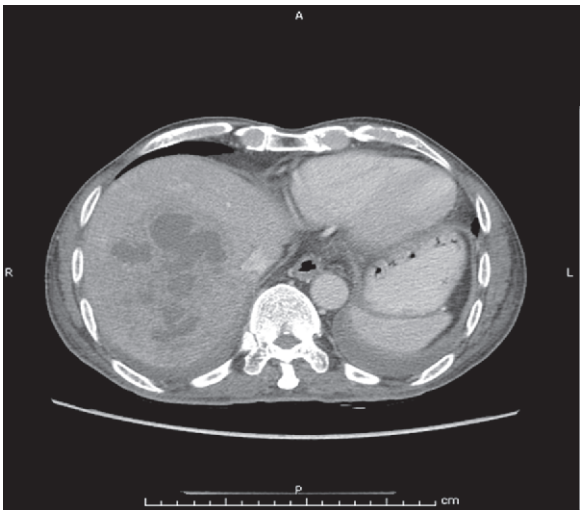

FIGURE 154-2. Computed tomographic scan of an amebic liver abscess. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

The disease remains endemic in sheep-raising areas of the world, including Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand. Dogs are the definitive hosts for *E. granulosus,* and sheep are the major intermediate hosts, although yaks, goats, and camels are other relevant intermediate hosts. Humans are only accidental hosts when they ingest food or water that is fecally contaminated with eggs. Human contact with sheepdogs that are in frequent contact with livestock is a major risk for infection.

The disease cycle begins when an adult tapeworm infects the intestinal tract of the definitive host (dogs usually). The adult tapeworm then produces eggs, which are expelled in the host's feces. Intermediate hosts become infected by ingesting the eggs of the parasite in fecally contaminated food. Inside the intermediate host, the eggs hatch and release tiny hooked embryos (called oncospheres), which travel in the blood stream and eventually lodge in the liver, lungs, or kidneys, where they develop into hydatid cysts. Inside these cysts grow thousands of tapeworm larvae, the next stage in the life cycle of the parasite.

CLINICAL MANIFESTATIONS

The initial infection is asymptomatic, but an enlarging hydatid liver cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass. Patients may describe symptoms of mild upper right quadrant pain, urticarial skin rash, and episodes of pruritus. If the cyst ruptures, serious complications can develop. Cysts that perforate into the peritoneum can lead to the development of extrahepatic cysts and may induce an allergic reaction with eosinophilia, pruritic urticaria, and systemic anaphylaxis. In most cases, however, cysts rupture into bile ducts, where they cause cholestatic jaundice, cholangitis, or biliary pain.

DIAGNOSIS

On ultrasound or CT scans (Fig. 154-3), the hydatid cysts are often large with a flaky appearance that is referred to as *hydatid sand*. CT imaging also may show multiple daughter cysts or a fluid density cyst with peripheral focal areas of calcification. Fluid is of variable density depending on the amount of proteinaceous debris.

Hydatid cysts of liver can be diagnosed by a serologic assay, the Weinberg reaction, but this test can have false-negative results in up to 38% of cases. An enzyme-linked immunosorbent assay (ELISA) may be more sensitive. Eosinophilia is not a feature unless the cyst ruptures; in fact, usually there are no changes in blood chemistries.

TREATMENT AND PROGNOSIS

Rx

Drug therapy includes albendazole, 400 mg twice a day for 3 to 6 monthly cycles separated by 10 to 14 day intervals, but treatment with albendazole alone is not effective, so drainage is essential to the effective treatment of hydatid cysts. In a randomized trial, percutaneous drainage consisting of puncture, aspiration, injection, and reaspiration of scolicidal solutions resulted in a similar rate of cyst disappearance as open surgical drainage but with fewer side effects, provided that patients received preprocedure and postprocedure albendazole therapy. Chlorhexidine, H_2O_2, 80% alcohol, and 0.5% cetrimide are the preferred scolicidal agents. If the cyst communicates with the biliary tree, however, injection of scolicidal agents carries an almost universal risk of secondary sclerosing cholangitis, and so it is contraindicated. In such cases, the cyst must be treated surgically, by either cystectomy or hepatic resection.

The prognosis is generally good, with complete cure expected after successful percutaneous or surgical treatment. However, spillage occurs in 2 to 25% of cases, depending on the location of the cyst and surgeon's experience, and the operative mortality rate varies from 0.5 to 4% for the same reasons.

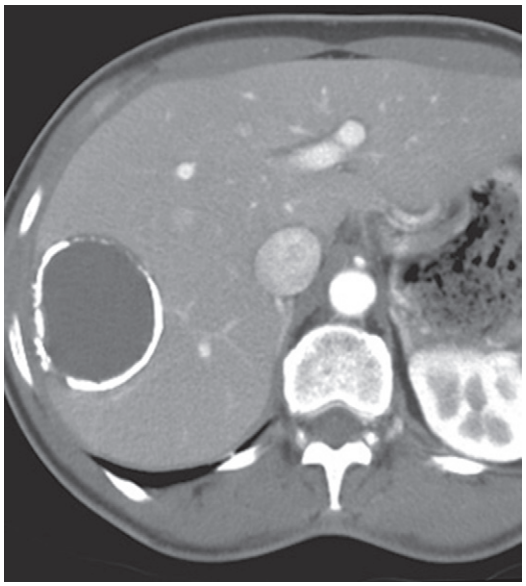

FIGURE 154-3. Computed tomographic scan of a hepatic echinococcal cyst.

Schistosomiasis

EPIDEMIOLOGY AND PATHOBIOLOGY

Schistosomiasis is an infection of trematodes. *Schistosoma* species (Chapter 363) cause periportal fibrosis and liver cirrhosis owing to deposition of eggs in the small portal venules. *Schistosoma mansoni* and *Schistosoma japonicum* lead to liver disease. Infection with *S. mansoni* is found in parts of South America, Africa, and the Middle East. Infection with *S. japonicum* is found in the Far East, mostly China and the Philippines. Although primary infection does not occur in the United States, 5% of the world's population may be infected, thereby making it a major international health concern and highly prevalent in immigrants.

Humans become infected after contact with water that contains the infective stage (cercaria) of schistosomes. After penetration of the skin, the larvae migrate to the lungs and then to the venules of the mesentery, urinary bladder, or ureters. They release eggs in the venules of the mesentery, and the eggs enter the liver through the portal vein, where they become lodged in the terminal branches of the portal venules. The lodged eggs cause a granulomatous inflammation, and the lesions heal by periportal fibrosis. *S. japonicum* is more virulent than *S. mansoni* because its infections produce ten times more eggs.

CLINICAL MANIFESTATIONS

Initial infection presents as itching that is caused by skin penetration by larvae. Several weeks later, patients may complain of fever, diarrhea, chills, headaches, or hives. At this time, patients will have eosinophilia. Over the next 5 to 15 years, periportal liver fibrosis develops and leads to presinusoidal portal hypertension, splenomegaly (Chapter 171), and gastroesophageal varices (Chapter 140). With *S. japonicum,* however, the progression can be much more rapid, with little interval between the acute and chronic disease. Hepatic function is generally well preserved, and patients usually present with hematemesis from ruptured gastroesophageal varices.

DIAGNOSIS

Schistosomal eggs typically have lateral or terminal spines and are easy to detect on microscopic examination of feces or on a rectal biopsy. Seroconversion occurs within 4 to 8 weeks of infection but cannot distinguish active

infection from a history of exposure. Imaging may show extensive calcification with the typical turtle-back appearance along the portal tracts reflecting the clustered, calcified eggs along the portal triads.

TREATMENT AND PROGNOSIS

Rx

Praziquantel (a single dose of 40 mg/kg) is effective in 70 to 100% of cases, but a second dose can be given 6 to 12 weeks later, particularly in patients with eosinophilia, high antibody titers, or persistent symptoms. Treatment of portal hypertension may be necessary (Chapter 156). The mortality rate is 0.05% for severe *S. mansoni* infection and 1.8% for severe *S. japonicum* infection. Bleeding from esophageal varices is the most serious complication. Chronic infection can lead to hepatocellular carcinoma.

GRANULOMATOUS DISEASES OF THE LIVER

Granulomas, which are found in up to 15% of liver biopsies, can be an incidental finding or may represent a wide array of liver diseases (Table 154-3). A granuloma is an accumulation of epithelioid cells, including transformed macrophages, mononuclear cells, and other inflammatory cells. Granulomas may have associated necrosis (caseating) as in tuberculosis (Chapter 332) or may be non-necrotizing (noncaseating) as in sarcoidosis (Chapter 95). In Q fever (Chapter 335), fibrin-ring granulomas are characterized by a vacuole encircled by a ring of fibrinoid necrosis and surrounded by lymphocytes and histiocytes.

An incidental granuloma requires minimal further evaluation. Tuberculosis should be excluded (Chapter 332). Sarcoidosis also should be considered because it is the most common cause of granulomas in the United States. An antimitochondrial antibody should be drawn to rule out primary biliary cirrhosis. The use of potentially causative drugs should be stopped (see Table 154-3).

Sarcoidosis

Sarcoidosis, which is the most frequently identified cause of hepatic granuloma in the United States, affects all racial and ethnic groups and occurs at all ages. In patients with sarcoidosis, the liver is the third most commonly involved organ, after the lymph nodes and lung; about 50 to 80% of patients with sarcoidosis have granulomas in their livers. The classic granuloma is found mainly in the portal triads, with a cluster of large epithelioid cells and often with multinucleated giant cells.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatic involvement of sarcoidosis is often subclinical, and only a minority of patients present with pruritus, fever, abdominal pain, hepatomegaly, cholestatic jaundice, or portal hypertension. In some patients, the granulomatous injury and destruction of the interlobular bile ducts eventually causes ductopenia and a histologic picture similar to primary biliary cirrhosis (Chapter 158). In other patients, damage to the large bile ducts may lead to a syndrome that mimics primary sclerosing cholangitis (Chapter 158). Other patients may present with focal liver lesions suggestive of malignant neoplasm.

Patients typically have a marked elevation of the serum alkaline phosphatase level. Angiotensin-converting enzyme (ACE) levels also are characteristically elevated but may not be helpful in differentiating sarcoidosis from other chronic liver diseases, such as primary biliary cirrhosis, in which it also may be elevated. The presence of noncaseating granulomas in a patient with clinically suspected sarcoidosis generally establishes the diagnosis. However, granulomas do not correlate with liver function tests or duration of disease.

TREATMENT AND PROGNOSIS

Rx

In general, hepatic sarcoidosis does not need to be treated except in patients with other indications for treatment (Chapter 95). Corticosteroids improve liver function tests but do not alleviate portal hypertension, and serial biopsies often show little improvement. Sarcoidosis that leads to portal hypertension and fibrosis may ultimately require liver transplantation (Chapter 157), and sarcoidosis may recur in the new organ.

Other Granulomatous Liver Diseases

In addition to sarcoidosis, another major cause of granulomatous liver disease is tuberculosis (Chapter 332). Military tuberculosis, caused by *Mycobacterium tuberculosis*, commonly results in hepatic granulomas, and patients present with hepatomegaly or abnormal liver function tests, or both. A biopsy revealing caseating granulomas along with a positive purified protein derivative test and active pulmonary tuberculosis can help in establishing a diagnosis. Other mycobacteria known to cause granulomatous liver disease include *M. avium-intracellulare*, *M. gevanese*, and *M. scrofulaceum* (Chapter 333).

Other causes of granulomatous liver disease include zoonotic infections such as cat-scratch disease (Chapter 323), Q fever (Chapter 335), and brucellosis (Chapter 318). Cat-scratch disease is caused by *B. henselae*, with cats serving as the main reservoir for the organism. The disease primarily affects children. Patients typically present with lymphadenopathy associated with persistent pyrexia of unknown origin, abdominal pain, and weight loss. *B. henselae* can be identified by a Warthin-Starry stain, or an imaging study may demonstrate scattered defects in the liver. Q fever is caused by the intracellular gram-negative rickettsial organism *Coxiella burnetii*. Most infections are

TABLE 154-3 CAUSES OF GRANULOMATOUS LIVER DISEASE

DIAGNOSIS	SPECIAL AND UNIQUE FEATURES
Sarcoidosis	Evidence of pulmonary sarcoidosis, granulomas found on biopsy specimens from other organs, elevated ACE level
Bacterial infections	
Mycobacteria tuberculosis	Caseating granulomas on biopsy, + PPD, active pulmonary tuberculosis
Other mycobacteria (*M. avium-intracellulare, M. lepra, M. mucogenicum, M. bovis*)	HIV, exposure history
Other bacteria (brucellosis, listeriosis, melioidosis, tularemia, yersiniosis, bartonellosis, Q fever, syphilis, psittacosis)	Fever, exposure history
Viral infections (cytomegalovirus, Epstein-Barr virus, hepatitis C, hepatitis B, hepatitis A)	Serology for acute or recent exposure
Fungal infections (histoplasmosis, coccidioidomycosis, blastomycosis, nocardiosis, candidiasis)	Fever, immunocompromised
Parasitic infections (schistosomiasis, *Ascaris lumbricoides* infection, toxoplasmosis, visceral leishmaniasis)	Travel to endemic regions, positive serologic testing
Primary biliary cirrhosis	Female sex, positive AMA, elevated IgM
Malignancies (Hodgkin's disease, non-Hodgkin's lymphoma, renal cell carcinoma)	Evidence of malignancy in kidney, lymph node, or bone marrow
Drug reactions (allopurinol, chlorpropamide, phenylbutazone, sulfonamides, carbamazepine, glyburide, quinidine, quinine, diltiazem, hydralazine, rosiglitazone, phenytoin, methyldopa, procainamide, amoxicillin–clavulanic acid, mebendazole, mesalamine, acetaminophen, pyrazinamide, halothane, isoniazid, norfloxacin)	Exposure history
Toxins (beryllium, copper sulfate, Thorotrast)	Previous exposure history
Miscellaneous (talc, Crohn's disease, Wegener's granulomatosis, after jejunoileal bypass, mineral oil lipogranulomas, hepatic allograft rejection, chronic granulomatous disease)	History of IV drug use, history of liver transplantation, diarrhea

ACE = angiotensin-converting enzyme; AMA = antimitochondrial antibody; HIV = human immunodeficiency virus; IV = intravenous; PPD = purified protein derivative.

asymptomatic, but patients may have self-limited influenza-like symptoms, pneumonia, and hepatitis. A liver biopsy may demonstrate fibrin-ring granulomas (doughnut shaped) in the background of nonspecific reactive hepatitis and steatosis. Brucellosis, which is not common in the United States, is caused by at least four species of Brucella: *B. abortus*, *B. suis*, *B. melitensis*, and *B. canis*. The disease presents as recurrent high fevers, drenching sweats, malaise, arthralgia, fatigue, abdominal pain, anorexia, and headaches. Patients often have hepatomegaly and increases in serum levels of aminotransferases and alkaline phosphatase. The granulomas formed by this infection are typically smaller than those caused by sarcoidosis or tuberculosis, and a definitive diagnosis can be established through serologic testing.

It is important to keep in mind that hepatic granulomas are formed naturally as a consequence of the immune response, so they may be seen in many infections with hepatic involvement (see Table 154-3). Examples of infections that can manifest as granulomatous liver disease include listeriosis, yersiniosis, candidiasis, histoplasmosis, coccidioidomycosis, and schistosomiasis. Viral infections (e.g., cytomegalovirus and hepatitis A, B, and C), primary biliary cirrhosis, malignancies, and certain drug reactions have all been etiologically linked to granulomatous liver disease.

ALCOHOLIC AND NONALCOHOLIC STEATOHEPATITIS

NAGA P. CHALASANI

Alcoholic liver disease and nonalcoholic fatty liver disease (NAFLD), which represent two of the most common forms of liver disease, can lead to cirrhosis, liver failure, and death. Although these two conditions have different risk factors and natural histories, in both conditions (Table 155-1) the hepatocytes are characterized by macrovesicular steatosis, which is the accumulation of triglycerides as one large cytoplasmic globule that displaces the nucleus. In microvesicular steatosis, cytoplasmic accumulation of fat occurs as multiple small globules with a central nucleus.

ALCOHOLIC LIVER DISEASE

DEFINITION

Excessive alcoholic consumption (Chapter 32) causes alcoholic liver disease and can significantly worsen other liver disorders such as viral hepatitis (Chapter 151) and hemochromatosis (Chapter 219). Although most individuals who consume alcohol do not consume it excessively and do not develop any physical or social consequences, some alcoholics consume sufficient alcohol and, presumably owing to other predisposing factors, develop alcoholic liver disease. Alcoholic liver disease is a spectrum of chronic liver diseases, ranging from alcoholic fatty liver to alcoholic hepatitis and cirrhosis.

Alcoholic fatty liver disease will develop in nearly 90% of individuals who consume alcohol heavily (on average, >6 drinks per day), and some individuals develop the more severe conditions of alcoholic hepatitis and alcoholic cirrhosis. Nearly 50% of the patients with alcoholic hepatitis have preexisting cirrhosis (Chapter 156), and individuals who do not yet have cirrhosis are at high risk for developing it, especially if they continue to consume alcohol.

EPIDEMIOLOGY

The true prevalence of alcoholic liver disease is not known, but nearly 1% of North American adults are believed to have alcoholic liver disease. Even this figure is considered an underestimation because milder forms of alcoholic liver disease are asymptomatic and often unrecognized. It has been estimated that alcoholic liver disease accounts for 40% of deaths from cirrhosis and 28% of all deaths from liver disease. It is the second most common indication for liver transplantation in the United States once abstinence from alcohol has been established.

PATHOBIOLOGY

The mechanisms underlying alcoholic liver injury can be broadly categorized into those caused by the effects of alcohol directly on hepatocytes and those caused by the effects mediated by Kupffer cells. The hepatocyte mechanisms include the altered redox state induced by alcohol and aldehyde dehydrogenase reactions, the oxidative stress and lipid peroxidation caused by the induction of CYP2E1 enzymes and the mitochondrial electron transfer system, and the effects of alcohol on the nuclear transcription factors (AMP kinase and SREBP-1c), protein adduct formation, and altered methionine and folate metabolism with resulting endoplasmic reticulum stress. Chronic alcohol consumption increases gut permeability, and the resulting portal endotoxemia activates Kupffer cells. Activated Kupffer cells release a number of proinflammatory mediators, including tumor necrosis factor-α (TNF-α), transforming growth factor-β1 (TGF-β1), interleukins 1, 6, 8, and 10, and platelet-derived growth factor (PDGF). TNF-α has plethora of biologic effects and causes hepatocyte apoptosis, whereas TGF-β1 and PDGF play important roles in stellate cell activation, collagen production, and hepatic fibrosis.

Among the known risk factors for developing alcoholic liver disease (Table 155-2), the amount of alcohol consumed is the single most important. For

TABLE 155-1 COMMON CAUSES OF MACROVESICULAR AND MICROVESICULAR STEATOSIS

MACROVESICULAR STEATOSIS	MICROVESICULAR STEATOSIS
Obesity, type 2 diabetes, metabolic syndrome, and dyslipidemia (nonalcoholic fatty liver disease)	Reye's syndrome
Excessive alcohol consumption	Medications (valproate, antiretroviral medicines, intravenous tetracycline)
Hepatitis C (genotype 3)	Heat stroke
Wilson's disease	Acute fatty liver of pregnancy
Lipodystrophy	HELLP syndrome
Starvation	Inborn errors of metabolism (lecithin-cholesterol acyltransferase deficiency, cholesterol ester storage disease, Wolman's disease)
Jejunoileal bypass	
Parenteral nutrition	
Abetalipoproteinemia	
Medications (amiodarone, methotrexate, tamoxifen, corticosteroids, antipsychotics)	

HELLP = *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets.

TABLE 155-2 RISK FACTORS FOR ALCOHOLIC LIVER DISEASE AND NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)

ALCOHOLIC LIVER DISEASE	NAFLD
MAJOR	**MAJOR**
Amount and duration of alcohol consumption	Obesity
Female gender	Type 2 diabetes
Genetic factors	Dyslipidemia
Protein-calorie malnutrition	Metabolic syndrome
MINOR	**MINOR**
Type of beverage	Polycystic ovary syndrome
Binge drinking	Hypothyroidism
Obesity	Sleep apnea
African-American and Hispanic ethnicity	Hypopituitarism

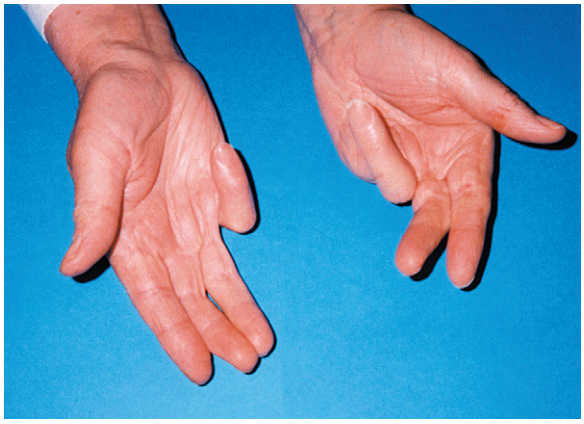

FIGURE 155-1. Dupuytren's contracture. (From Gudmundsson KG, Jonsson T, Arngrimsson R. Guillame Dupuytren and finger contractures. Lancet. 2003;362:165-168.)

unclear reasons, only 30 to 35% of individuals with heavy and long-term drinking develop alcoholic hepatitis, and less than 20% develop cirrhosis. Women are at higher risk; for example, the risk of alcoholic cirrhosis increases after 10 years of alcohol consumption at quantities of more than 60 to 80 g/day in men, whereas in women, it can develop at quantities of only more than 20 g/day. Moreover, the peak incidence of alcoholic liver disease in women is approximately a decade earlier than in men. The type of alcoholic beverage consumed may not be as critical, but "spirits" and beer may be more hepatotoxic than wine. African-American and Hispanic ethnic groups may be predisposed to more significant alcoholic liver injury. Both obesity and protein-calorie malnutrition, in which micronutrients and antioxidant capacity are diminished, also are important predispositions.

Polymorphisms in genes associated with alcohol metabolism (alcohol and aldehyde dehydrogenases and cytochrome P-450 enzymes) and dysregulated cytokine production (e.g., TNF-α) may also influence genetic susceptibility. In patients with other forms of chronic liver disease (e.g., viral hepatitis B or C), concomitant alcohol consumption significantly aggravates liver injury.

CLINICAL MANIFESTATIONS

Patients with alcoholic liver disease may have signs and symptoms from underlying alcoholism as well as those caused by liver disease. Stigmata of chronic alcoholism include palmar erythema (see Fig. 148-2 in Chapter 148), spider nevi, bilateral gynecomastia, testicular atrophy, bilateral parotid enlargement, and Dupuytren's contractures (Fig. 155-1). The clinical features of liver disease will depend on the stage of alcoholic liver disease, that is, whether a patient has alcoholic fatty liver or more advanced liver disease such as alcoholic hepatitis and cirrhosis.

Patients with alcoholic fatty liver disease are generally asymptomatic, but some patients may have anorexia, fatigue, right upper quadrant discomfort, and tender hepatomegaly. These patients may also have biochemical evidence of alcoholism and alcoholic liver disease with macrocytosis as well as elevated levels of aspartate aminotransferase (AST) and γ-glutamyl transpeptidase (GGT). Patients with alcoholic fatty liver typically do not have jaundice, ascites, or splenomegaly.

Patients with alcoholic hepatitis may have a more dramatic presentation with severe malaise, fatigue, anorexia, fever, evidence of protein-calorie malnutrition, and features of decompensated liver disease, including jaundice, coagulopathy, ascites, and encephalopathy. Physical examination invariably shows at least some features of chronic alcoholism, and jaundice (see Fig. 148-1 in Chapter 148), ascites (see Fig. 148-5 in Chapter 148), and splenomegaly are common. The laboratory examination is typically abnormal. Common hematologic abnormalities include leukocytosis with neutrophil predominance, macrocytic anemia (Chapter 167), thrombocytopenia (Chapter 175), and a prolonged prothrombin time. Liver biochemistries (Chapter 149) are abnormal with an elevated AST and ratio of AST to alanine transferase (ALT), alkaline phosphatase, GGT, and total bilirubin, but decreased levels of serum albumin. The AST rarely exceeds 300 IU/L. Serum electrolyte abnormalities including hypokalemia (Chapter 119), hypomagnesemia (Chapter 121), hypocalcemia (Chapter 253), and hypophosphatemia (Chapter 121) are frequent. Patients with alcoholic cirrhosis have the same clinical features that are common to other types of cirrhosis (Chapter 156), but also with striking features of underlying chronic alcoholism.

DIAGNOSIS

The diagnosis of alcoholic liver disease strongly depends on the history of excessive alcohol consumption and the presence of liver disease. Although laboratory abnormalities are not specific for alcoholic liver disease, they can be quite suggestive in the context of excessive alcohol consumption. An AST/ALT ratio of more than 2 is typical in alcoholic liver disease, and ALT values greater than 150 to 200 IU/L are very rare in alcoholic liver disease. Serology testing for co-existing chronic viral hepatitis (Chapter 151) is critical. Diagnostic dilemmas arise when a patient denies excessive alcohol consumption in the face of clinical features that are suggestive of alcoholic liver disease. Interviewing family members regarding specific alcohol consumption may be helpful in the accurate ascertainment of alcohol consumption. Elevated blood levels of carbohydrate-deficient transferrin, which is a form of transferrin with fewer than the four sialic acid chains present in normal transferrin, can identify recent heavy alcohol consumption. Hepatic imaging by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) will show changes consistent with hepatic steatosis or more advanced forms of liver disease, such as alcoholic hepatitis and cirrhosis. Imaging is also important to exclude other forms of liver disease, including malignancy and biliary obstruction. Imaging findings specific for alcoholic liver disease include an enlarged caudate lobe, greater visualization of the right posterior hepatic notch, and focal fat sparing or geographic fat distribution.

Because specific treatment for alcoholic hepatitis may be harmful in patients with other liver diseases, it is very important to exclude other predominant or coexisting liver diseases, including chronic viral hepatitis (Chapter 151) and drug-induced liver injury, especially from acetaminophen (Chapter 152), by history, blood tests, and biopsy if needed. Hyperferritinemia generally reflects an acute phase reactant, rather than an iron overload disorder, so it usually will return to normal when the acute liver injury resolves.

Liver biopsy is the key to precisely characterizing the nature of alcoholic liver disease and determining whether a patient has fatty liver or more advanced alcoholic hepatitis. Histologic features of alcoholic fatty liver include macrovesicular steatosis that is predominantly zone 3 in nature. In alcoholic hepatitis, the biopsy is more striking and reveals macrovesicular steatosis, lobular neutrophilic infiltration, Mallory's hyaline, balloon degeneration of the hepatocytes, and perivenular fibrosis. In general, patients with alcoholic hepatitis also have histologic evidence of chronic liver injury in the form of more advanced fibrosis (periportal or bridging fibrosis, or cirrhosis).

TREATMENT

Rx

Total abstinence, which is the most important treatment measure, is mandatory for the improvement of the clinical and histologic features of alcoholic liver disease. Its benefits are unequivocal, even in patients with severe decompensation. However, long-term abstinence is difficult to achieve, so a multidisciplinary approach with counseling and medications that promote abstinence should be considered. Disulfiram is not commonly used owing to its poor tolerability and hepatotoxicity. Opioid antagonists, such as naltrexone (50 mg/day for up to 6 months or even longer), nalmefene (20 mg/day as maintenance), and acamprosate (333 mg tablets, 2 tablets three times each day for 1 year) can help promote abstinence when used as part of a multidisciplinary approach (Chapter 32).

Alcoholic fatty liver disease requires no specific treatment other than abstinence. Patients with alcoholic hepatitis, however, have increased short- and long-term mortality and should be considered for therapeutic interventions in addition to mandatory abstinence. If a patient's liver biopsy is consistent with alcoholic hepatitis and there is no evidence of other inflammatory liver diseases, such as hepatitis C (Chapter 151), corticosteroids and pentoxifylline (400 mg three times daily for 28 days) are of some benefit. Prednisolone (40 mg per day for 4 weeks) should be given to carefully selected patients who have a score of greater than 32 on Maddrey's discriminant function (4.6 × [patient's prothrombin time—control prothrombin time] + total bilirubin level) and encephalopathy, but do not have gastrointestinal bleeding or systemic infection. Recent studies suggested that a Model for End-Stage Liver Disease (MELD) score (see Table 156-2 in Chapter 156) higher than 21 can substitute for Maddrey's score for guiding the use of prednisolone. Two other anti-TNF-α agents, infliximab and etanercept, are not effective and have significant side effects. All patients with alcoholic hepatitis and alcoholic cirrhosis should be assessed and treated for protein-calorie malnutrition and micronutrient deficiency. Hospitalized patients with severe decompensation should be considered for enteral nutrition (Chapter 223).

Complications such as ascites, spontaneous bacterial peritonitis, encephalopathy, variceal bleeding, hepatorenal syndrome, osteoporosis, and hepatopulmonary syndrome may occur in patients with decompensated alcoholic cirrhosis and must be managed carefully (Chapter 156). Liver transplantation is a reasonable option in patients with decompensated alcoholic cirrhosis, but 6 months of abstinence and strong social support are generally required for eligibility (Chapter 157). Patients with alcoholic cirrhosis are at risk for hepatocellular carcinoma (Chapter 202) and should be screened with semiannual liver imaging and serum α-fetoprotein levels. They are also at risk for extrahepatic malignancy, notably head and neck, lung, and esophageal cancer. For Dupuytren's contracture, injection of collagenase clostridium histolyticum can reduce the severity and improve the range of motion significantly.■

PROGNOSIS

Alcoholic fatty liver is generally reversible with total abstinence for a few months. Alcoholic hepatitis carries high mortality, with nearly 40% of patients dying within 6 months after its presentation.

NONALCOHOLIC FATTY LIVER DISEASE

DEFINITIONS

Histologically, NAFLD resembles alcoholic liver disease, but it occurs in individuals without significant alcohol consumption. Average alcohol consumption greater than two drinks per day in men and greater than one drink per day in women generally is not consistent with a diagnosis of NAFLD. In addition, the definition of NAFLD excludes patients with a history of exposure to steatogenic medications such as amiodarone, methotrexate, and tamoxifen.

NAFLD encompasses a spectrum of abnormal liver histology, ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis. In simple steatosis, liver histology reveals macrovesicular steatosis without ballooning degeneration of hepatocytes or liver fibrosis. NASH, which is a more advanced form of NAFLD, is histologically characterized by macrovesicular steatosis, ballooning degeneration of the hepatocytes, and sinusoidal fibrosis.

EPIDEMIOLOGY

NAFLD is one of the most common causes of elevated liver enzymes and chronic liver disease in the Western world. Its incidence in adults and children is rising rapidly owing to the ongoing epidemics of obesity (Chapter 227), type 2 diabetes mellitus (Chapter 237), and metabolic syndrome. Its prevalence is quite high in certain patient populations; for example, nearly 80% of type 2 diabetic patients and 90% of morbidly obese individuals have imaging evidence of NAFLD. Nearly one third of U.S. adults are estimated to have NAFLD, and up to 5% of U.S. adults may have NASH. These percentages compare reasonably well with other data suggesting that the prevalence of cirrhosis from NAFLD is about 2%. Hispanics and whites are at higher risk for NAFLD, whereas its prevalence is intriguingly quite low in African Americans.

PATHOBIOLOGY

The major risk factors for NAFLD include obesity, type 2 diabetes mellitus, metabolic syndrome, and dyslipidemia (see Table 155-2). Other comorbidities associated with NAFLD include polycystic ovary syndrome (Chapter 243), hypothyroidism (Chapter 233), hypopituitarism (Chapter 231), and sleep apnea (Chapter 100).

Two fundamental defects in NAFLD are insulin resistance/hyperinsulinemia and excessive levels of nonesterified fatty liver within the hepatocytes. An excessive influx of nonesterified fatty acids into the hepatocytes results in macrovesicular steatosis, which is predominantly centrilobular in location.

Additionally, patients with NAFLD have increased de novo intrahepatic lipogenesis. Although patients with NAFLD robustly esterify free fatty acids in neutral triglycerides, free fatty acids within the hepatocytes are considered the primary mediators of cell injury (lipotoxicity). In the background of hepatic steatosis, factors that promote cell injury, inflammation, and fibrosis include oxidative stress, endoplasmic reticulum stress, apoptosis, adipocytokines, and stellate cell activation. The sources of oxidative stress include mitochondria and microsomes. Adipocytokines that play an important role in the pathogenesis of NAFLD include adiponectin and TNF-α. It is unclear why some patients with NAFLD exhibit NASH, whereas other patients with a comparable risk factor profile have only simple steatosis. There is a consistent and significant relationship of *PNPLA3* genetic polymorphisms with the severity of steatosis and other histologic features of NAFLD. However, the genetic factors that play a role in NASH and NAFLD have not been fully elucidated.

CLINICAL MANIFESTATIONS

NAFLD is often asymptomatic but may rarely cause fatigue and right upper quadrant pain. Physical examination may reveal hepatomegaly, palmar erythema (see Fig. 148-2 in Chapter 148), and spider nevi. If liver disease is advanced, the features of liver failure, such as ascites, encephalopathy, and abdominal collateral vessels, are present. Simple steatosis is benign with a minimal risk of cirrhosis, whereas NASH is progressive and can lead to cirrhosis (Chapter 156) and liver failure (Chapter 157). In up to 20% of patients with NASH, liver histology will worsen and cirrhosis will develop over a 10- to 15-year period. Severe obesity, advancing age, and diabetes are believed to be risk factors for disease progression. Disease progression during the early phase can be identified only with a repeat liver biopsy, but in later stages, the signs and symptoms of portal hypertension (e.g., abdominal collateral vessels and low platelet count) indicate the development of cirrhosis. Patients with NASH-induced cirrhosis are at risk of developing hepatocellular carcinoma (Chapter 202). Patients with NAFLD have several metabolic risks that predispose them to atherosclerosis, and coronary artery disease is the single most common cause of death in patients with NAFLD.

DIAGNOSIS

NAFLD is generally suspected when aminotransferase levels are asymptomatically elevated in an individual with metabolic risk factors (obesity and diabetes) or when liver imaging (ultrasound, CT, or MRI) obtained for another reason shows fatty infiltration (Fig. 155-2). The diagnosis of NAFLD requires that there is no history of previous or ongoing significant alcohol consumption, no exposure to steatogenic medications, and no evidence of other causes of liver disease, such as viral hepatitis B or C. Elevated levels of aminotransferases, although common, are not required for the diagnosis of NAFLD. In contrast to alcoholic liver disease, ALT levels are higher than AST levels, but they rarely exceed 250 IU/L. In general, AST and ALT levels do not have diagnostic or prognostic significance. Mild hyperferritinemia is common and should not be confused with hereditary hemochromatosis (Chapter 219). Similarly, low-grade autoantibody (antinuclear antibody, anti–smooth muscle antibody) positivity is not uncommon and should not be confused with autoimmune liver disease (Chapter 151). Because steatosis is common in patients with Wilson's disease (Chapter 218), serum ceruloplasmin should be obtained as part of the diagnostic evaluation.

Fatty liver on ultrasonogram has a positive predictive value of only 77% and a negative predictive value of only 67% when compared with liver biopsy. Abdominal MRI is more accurate, but its high cost limits its usefulness in routine practice. Because none of these three tests can differentiate simple steatosis from NASH nor identify cirrhosis until hepatic fibrosis has caused overt portal hypertension, liver biopsy is required to establish the presence of NASH or cirrhosis. Common indications for a percutaneous liver biopsy

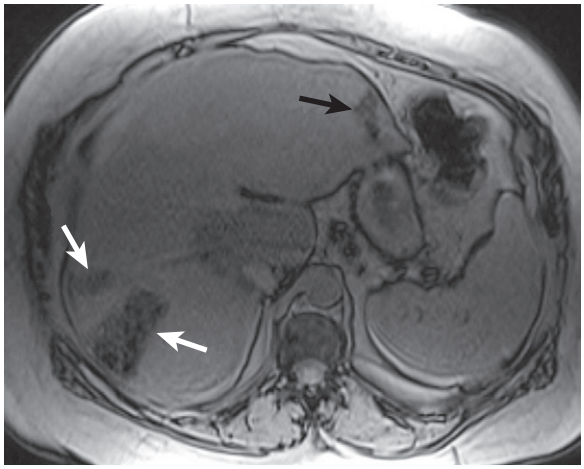

FIGURE 155-2. Magnetic resonance image of chronic liver disease due to nonalcoholic fatty liver disease. (Courtesy of Professor Kumar Sandrasegaran, Indiana University School of Medicine, Indianapolis, Ind.)

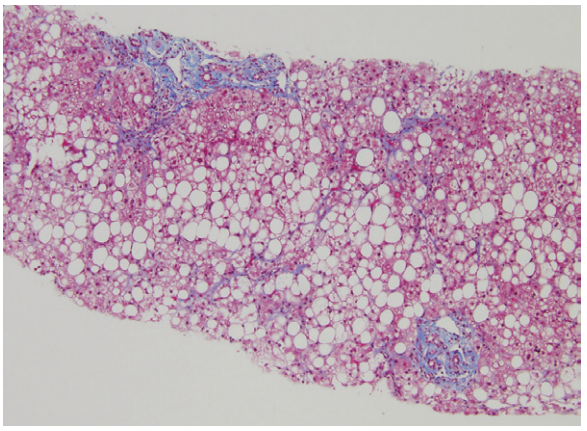

FIGURE 155-3. Liver biopsy showing nonalcoholic steatohepatitis, with increased fat and with early cirrhosis. (Courtesy of the NASH Clinical Research Network.)

in patients with NAFLD include persistently high aminotransferase levels, inability to exclude a competing or a coexisting cause (e.g., iron overload or autoimmune liver disease), or clinical suspicion of severe liver disease. In patients with NASH, liver histology shows steatosis, inflammation, ballooning, and fibrosis (Fig. 155-3).

TREATMENT

Rx

Lifestyle modification with dietary restriction and regular exercise is the first choice of treatment for NAFLD. It is generally recommended that patients with NAFLD lose 10% of their body weight in a gradual fashion, but this goal is difficult to achieve. If resources are available, a multidisciplinary approach with behavioral therapy, dietary advice, and monitoring by a professional nutritionist and an exercise expert is more successful than a prescriptive approach.[1]

Statins (e.g., atorvastatin 20 mg daily) with or without vitamins C and E can improve liver test results and reduce subsequent NAFLD.[5,6] In a large trial, 800 IU of vitamin E administered daily for 2 years significantly improved liver histology.[7] Thiazolidinedione insulin sensitizers (pioglitazone and rosiglitazone) improve steatosis, inflammation, and ballooning, but may not improve fibrosis.[8] Unfortunately, the weight gain that is common with thiazolidinediones may offset the histologic benefits that they offer. In morbidly obese individuals with NASH and other significant metabolic comorbidities, foregut bariatric surgery can lead to significant improvement in hepatic histology, but the physician must exclude the presence of portal hypertension before offering this type of surgery.[9] Patients with NAFLD often have dyslipidemia that puts them at excessive risk for coronary artery disease; their dyslipidemia (Chapter 213) should be treated aggressively with statins and other lipid-lowering agents, which can be safely administered to patients with NAFLD and NASH. Carefully selected patients with decompensated cirrhosis owing to NASH can be treated with liver transplantation (Chapter 157), but recurrence during the post-transplantation period is common.

PREVENTION

The measures to prevent NAFLD include maintaining optimal body weight, exercising regularly, and treating any associated metabolic comorbidities such as diabetes and dyslipidemia. Avoidance of saturated fat, high fructose intake, and alcohol consumption may reduce the development of NAFLD.

PROGNOSIS

Steatosis alone is generally benign, whereas steatohepatitis is often progressive. Otherwise, however, data are sparse regarding the risk and risk factors for the progression of NAFLD and NASH to cirrhosis and liver failure.

Because NAFLD often coexists with one or more components of the metabolic syndrome, its presence reflects guarded long-term overall prognosis. The long-term complications in patients with simple steatosis generally result from cardiovascular disease and atherosclerosis, not from liver failure.

Patients with NASH also are at risk for liver failure and liver cancer, in addition to their significantly increased risk of cardiovascular disease. For example, among patients with NASH on their initial biopsy, one third or more develop progressive fibrosis over a mean follow-up interval of about 5 years. Older age, diabetes, and ballooning and fibrosis on liver biopsy are important predictors of progression.

156 CIRRHOSIS AND ITS SEQUELAE

GUADALUPE GARCIA-TSAO

DEFINITION

Cirrhosis, which can be the final stage of any chronic liver disease, is a diffuse process characterized by fibrosis and conversion of normal architecture to structurally abnormal nodules (Fig. 156-1). These "regenerative" nodules lack normal lobular organization and are surrounded by fibrous tissue. The process involves the whole liver and is essentially irreversible. Although cirrhosis is histologically an "all or nothing" diagnosis, clinically it can be classified by its status as compensated or decompensated. Decompensated cirrhosis is defined by the presence of ascites, variceal bleeding, encephalopathy, or jaundice, which are complications that result from the main consequences of cirrhosis: portal hypertension and liver insufficiency.

EPIDEMIOLOGY

Because many patients with cirrhosis are asymptomatic until decompensation occurs, it is very difficult to assess the real prevalence and incidence of cirrhosis in the general population. The prevalence of chronic liver disease or cirrhosis worldwide is estimated to be 100 (range, 25 to 400) per 100,000 subjects, but it varies widely by country and by region.

Cirrhosis is an important cause of morbidity and mortality worldwide and in the United States. According to the World Health Organization, about 800,000 people die of cirrhosis annually. In the United States, cirrhosis accounts for about 27,500 deaths each year, or a death rate of 9.3 per 100,000, making it the 12th leading cause of death overall. Importantly, chronic liver disease and cirrhosis are the seventh leading cause of death in the United States in individuals between 25 and 64 years of age. Because chronic liver disease affects people in their most productive years of life, it has a significant impact on the economy as a result of premature death, illness, and disability.

Any chronic liver disease can lead to cirrhosis (Table 156-1). Chronic viral hepatitis C and alcoholic liver disease are the most common causes of

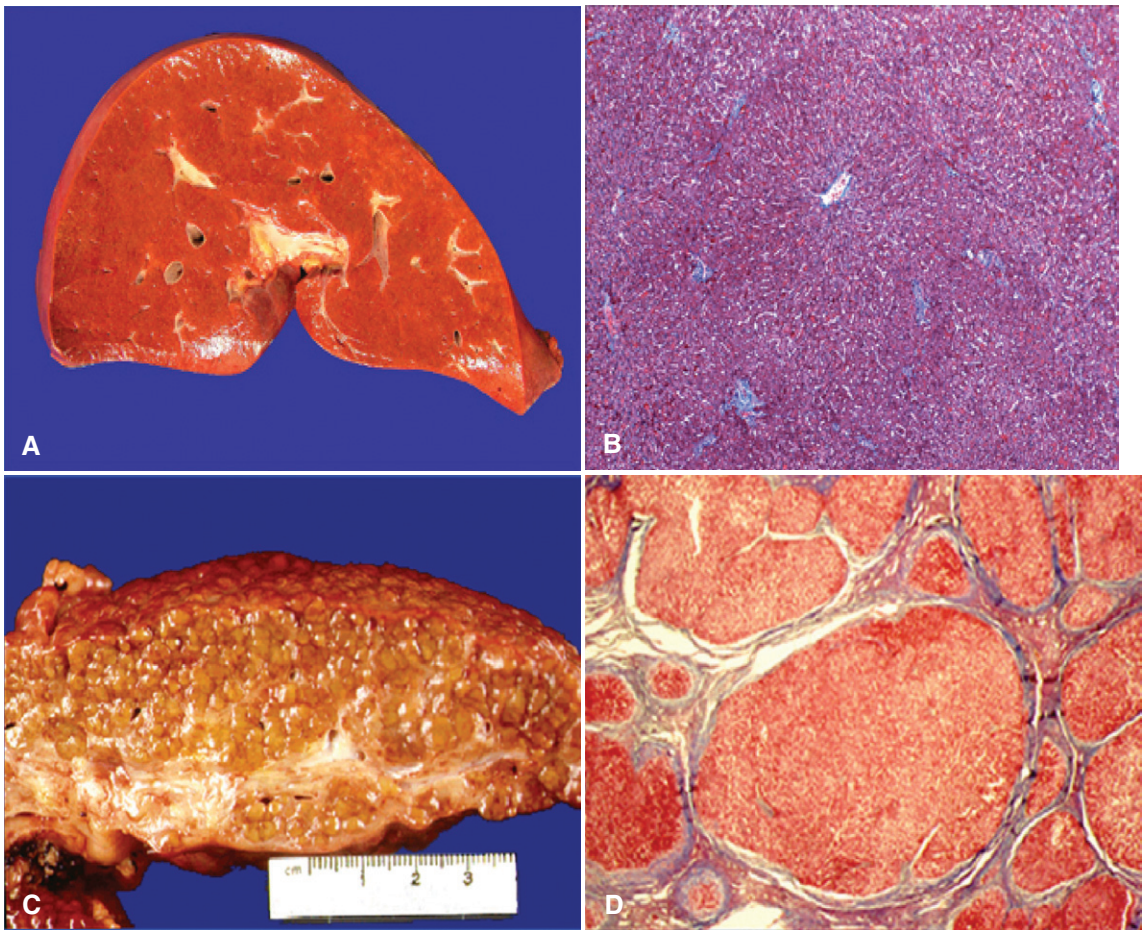

FIGURE 156-1. Gross and microscopic images of a normal and cirrhotic liver. A, Gross image of a normal liver with a smooth surface and homogeneous texture. **B,** Microscopically, liver sinusoids are organized, and vascular structures are normally distributed. **C,** Gross image of a cirrhotic liver. The liver has an orange-tawny color with an irregular surface and a nodular texture. **D,** Microscopically, the architecture is disorganized, and there are regenerative nodules surrounded by fibrous tissue.

TABLE 156-1 CAUSES OF CIRRHOSIS

MAIN FACTORS CAUSING CIRRHOSIS
Chronic hepatitis C
Alcoholic liver disease
Nonalcoholic fatty liver disease
Chronic hepatitis B
OTHER CAUSES OF CIRRHOSIS (<2% OF ALL CASES)
Cholestatic and autoimmune liver diseases
Primary biliary cirrhosis
Primary sclerosing cholangitis
Autoimmune hepatitis
Intrahepatic or extrahepatic biliary obstruction
Mechanical obstruction
Biliary atresia
Cystic fibrosis
Metabolic disorders
Hemochromatosis
Wilson's disease
α_1-Antitrypsin deficiency
Glycogen storage diseases
Abetalipoproteinemia
Porphyria
Hepatic venous outflow obstruction
Budd-Chiari syndrome
Veno-occlusive disease
Right-sided heart failure
Drugs and toxins
Intestinal bypass
Indian childhood cirrhosis

cirrhosis, followed by nonalcoholic fatty liver disease and chronic hepatitis B (Chapters 151 and 155). However, the many other causes of cirrhosis include cholestatic and autoimmune liver diseases such as primary biliary cirrhosis, primary sclerosing cholangitis (Chapter 158), autoimmune hepatitis (Chapter 151), and metabolic diseases such as hemochromatosis, Wilson's disease, and α_1-antitrypsin deficiency (Chapter 153). When all the causes have been investigated and excluded, cirrhosis is considered "cryptogenic." Many cases of cryptogenic cirrhosis are now thought to be due to nonalcoholic fatty liver disease (Chapter 155).

It is important to mention that although the entity termed *primary biliary cirrhosis* assumes the presence of cirrhosis, this term is actually misleading. Primary biliary cirrhosis (Chapter 158) is an immune-mediated cholestatic chronic liver disease that is characterized by progressive destruction of intrahepatic bile ducts and progresses over time from an initial stage in which fibrosis is minimal (stage 1) to a final stage in which there is well-established cirrhosis (stage 4).

PATHOBIOLOGY

Liver Fibrosis/Cirrhosis

The key pathogenic feature underlying liver fibrosis and cirrhosis is activation of hepatic stellate cells. Hepatic stellate cells, which are known as *Ito cells* or *perisinusoidal cells*, are located in the space of Disse between hepatocytes and sinusoidal endothelial cells. Normally, hepatic stellate cells are quiescent and serve as the main storage site for retinoids (vitamin A). In response to injury, hepatic stellate cells become activated, as a result of which they lose their vitamin A deposits, proliferate, develop a prominent rough endoplasmic reticulum, and secrete extracellular matrix (collagen types I and III, sulfated proteoglycans, and glycoproteins). Additionally, they become contractile hepatic myofibroblasts.

Unlike other capillaries, normal hepatic sinusoids lack a basement membrane. The sinusoidal endothelial cells themselves contain large fenestrae (100 to 200 nm in diameter) that allow the passage of large molecules with molecular weights up to 250,000. Collagen deposition in the space of Disse,

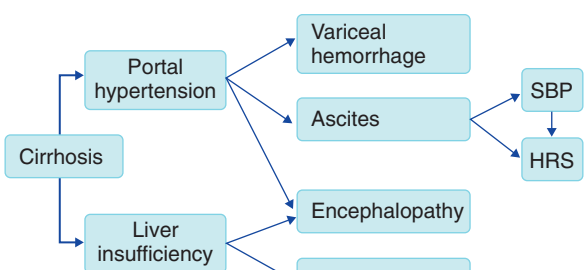

FIGURE 156-2. Complications of cirrhosis result from portal hypertension or liver insufficiency. Varices and variceal hemorrhage are a direct consequence of portal hypertension. Ascites results from sinusoidal portal hypertension and can be complicated by infection (spontaneous bacterial peritonitis [SBP]) or renal dysfunction (hepatorenal syndrome [HRS]). Hepatic encephalopathy results from portosystemic shunting (i.e., portal hypertension) and liver insufficiency. Jaundice results solely from liver insufficiency.

as occurs in cirrhosis, leads to defenestration of the sinusoidal endothelial cells ("capillarization" of the sinusoids), thereby altering exchange between plasma and hepatocytes and resulting in a decreased sinusoidal diameter that is further exacerbated by the contraction of stellate cells.

Complications of Cirrhosis

The two main consequences of cirrhosis are portal hypertension, with the accompanying hyperdynamic circulatory state, and liver insufficiency (Fig. 156-2). The development of varices and ascites is a direct consequence of portal hypertension and the hyperdynamic circulatory state, whereas jaundice occurs as a result of an inability of the liver to excrete bilirubin (i.e., liver insufficiency). Encephalopathy is the result of both portal hypertension and liver insufficiency. Ascites, in turn, can become complicated by infection, which is called *spontaneous bacterial peritonitis,* and by functional renal failure, which is called *hepatorenal syndrome.*

Portal Hypertension and the Hyperdynamic Circulatory State

In cirrhosis, portal hypertension results from both an increase in resistance to portal flow and an increase in portal venous inflow. The initial mechanism is increased sinusoidal vascular resistance secondary to (1) deposition of fibrous tissue and subsequent compression by regenerative nodules (fixed component) and (2) active vasoconstriction (functional component), which is amenable to the action of vasodilators such as nitroprusside and is caused by a deficiency in intrahepatic nitric oxide (NO), as well as enhanced activity of vasoconstrictors.

Early in the portal hypertensive process, the spleen grows and sequesters platelets and other formed blood cells, thereby leading to hypersplenism. In addition, vessels that normally drain into the portal system, such as the coronary vein, reverse their flow and shunt blood away from the portal system to the systemic circulation. These portosystemic collaterals are insufficient to decompress the portal venous system and offer additional resistance to portal flow. As collaterals develop, an increase in portal blood inflow maintains the portal hypertensive state as a result of splanchnic vasodilation, which in turn is secondary to increased production of NO. Thus, the paradox in portal hypertension is that a deficiency of NO in the intrahepatic vasculature leads to vasoconstriction and increased resistance, whereas overproduction of NO in the extrahepatic circulation leads to vasodilation and increased flow.

In addition to splanchnic vasodilation, there is systemic vasodilation, which by causing a decreased *effective* arterial blood volume, leads to activation of neurohumoral systems (renin-angiotensin-aldosterone system), retention of sodium, expansion of plasma volume, and development of a hyperdynamic circulatory state. This hyperdynamic circulatory state maintains portal hypertension, thereby leading to the formation and growth of varices, and plays an important role in the development of all other complications of cirrhosis.

Varices and Variceal Hemorrhage

The complication of cirrhosis that results most directly from portal hypertension is the development of portal-systemic collaterals, the most relevant of which are those that form through dilation of the coronary and gastric veins and constitute gastroesophageal varices. The initial formation of esophageal collaterals depends on a threshold portal pressure, clinically established by a hepatic venous pressure gradient of 10 to 12 mm Hg, below which varices do not develop.

Development of a hyperdynamic circulatory state leads to further dilation and growth of varices and eventually to their rupture and variceal hemorrhage, one of the most dreaded complications of portal hypertension. Tension in a varix determines variceal rupture and is directly proportional to variceal diameter and intravariceal pressure and inversely proportional to variceal wall thickness.

Ascites and Hepatorenal Syndrome

Ascites in cirrhosis is secondary to sinusoidal hypertension and retention of sodium. Cirrhosis leads to sinusoidal hypertension by blocking hepatic venous outflow both anatomically by fibrosis and regenerative nodules and functionally by increased postsinusoidal vascular tone. Similar to the formation of esophageal varices, a threshold hepatic venous pressure gradient of 12 mm Hg is needed for the formation of ascites. In addition, retention of sodium replenishes the intravascular volume and allows the continuous formation of ascites. Retention of sodium results from vasodilation that is mostly due to an increase in NO production because NO inhibition in experimental animals increases urinary sodium excretion, lowers plasma aldosterone levels, and reduces ascites. With progression of cirrhosis and portal hypertension, vasodilation is more pronounced, thereby leading to further activation of the renin-angiotensin-aldosterone and sympathetic nervous systems and resulting in further sodium retention (refractory ascites), water retention (hyponatremia), and renal vasoconstriction (hepatorenal syndrome).

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis, an infection of ascitic fluid, occurs in the absence of perforation of a hollow viscus or an intra-abdominal inflammatory focus such as an abscess, acute pancreatitis, or cholecystitis. Bacterial translocation, or the migration of bacteria from the intestinal lumen to mesenteric lymph nodes and other extraintestinal sites, is the main mechanism implicated in spontaneous bacterial peritonitis. Impaired local and systemic immune defenses are a major element in promoting bacterial translocation and, together with shunting of blood away from the hepatic Kupffer cells through portosystemic collaterals, allow a transient bacteremia to become more prolonged, thereby colonizing ascitic fluid. Spontaneous bacterial peritonitis occurs in patients with reduced ascites defense mechanisms, such as a low complement level in ascitic fluid. Another factor that promotes bacterial translocation in cirrhosis is bacterial overgrowth attributed to a decrease in small bowel motility and intestinal transit time. Infections, particularly from gram-negative bacteria, can precipitate renal dysfunction through worsening of the hyperdynamic circulatory state.

Encephalopathy

Ammonia, a toxin normally removed by the liver, plays a key role in the pathogenesis of hepatic encephalopathy. In cirrhosis, ammonia accumulates in the systemic circulation because of shunting of blood through portosystemic collaterals and decreased liver metabolism (i.e., liver insufficiency). The presence of large amounts of ammonia in the brain damages supporting brain cells or astrocytes and leads to structural changes characteristic of hepatic encephalopathy (Alzheimer's type II astrocytosis). Ammonia results in upregulation of astrocytic peripheral-type benzodiazepine receptors, the most potent stimulants of neurosteroid production. Neurosteroids are the major modulators of γ-aminobutyric acid, which results in cortical depression and hepatic encephalopathy. Other toxins, such as manganese, also accumulate in the brain, particularly the globus pallidus, where they lead to impaired motor function. Other yet-to-be-elucidated toxins may also be involved in the pathogenesis of encephalopathy.

Jaundice

Jaundice (Chapter 149) in cirrhosis is a reflection of the inability of the liver to excrete bilirubin and is therefore the result of liver insufficiency. However, in cholestatic diseases leading to cirrhosis (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, vanishing bile duct syndrome), jaundice is more likely due to biliary damage than liver insufficiency. Other indicators of liver insufficiency, such as the prothrombin time or the presence of encephalopathy, help determine the most likely contributor to hyperbilirubinemia (Chapter 149).

Cardiopulmonary Complications

The hyperdynamic circulatory state eventually results in high-output heart failure with decreased peripheral utilization of oxygen, a complication that

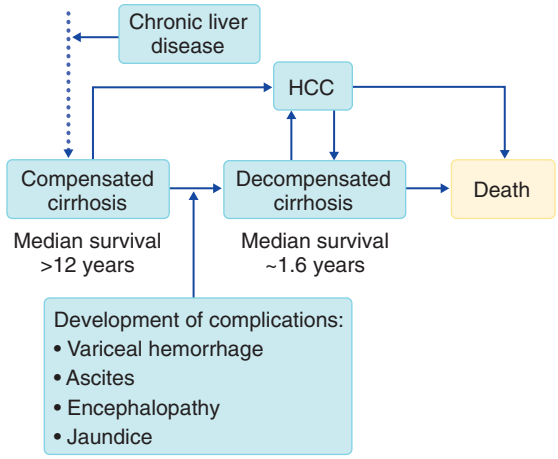

FIGURE 156-3. Natural history of cirrhosis. Any chronic liver disease will lead to cirrhosis. Initially, cirrhosis will be compensated (median survival, >12 years), but once complications (ascites, variceal hemorrhage, encephalopathy, jaundice) develop, it becomes decompensated (median survival, 1.6 years). Hepatocellular carcinoma (HCC) can develop at any stage and precipitate decompensation and death.

TABLE 156-2 THE TWO MOST COMMONLY USED SCORING SYSTEMS IN CIRRHOSIS

1. CHILD-TURCOTTE-PUGH (CTP) SCORE (RANGE, 5-15)

	Points Ascribed		
PARAMETERS	**1**	**2**	**3**
Ascites	None	Grade 1-2 (or easy to treat)	Grade 3-4 (or refractory)
Hepatic encephalopathy	None	Grade 1-2 (or induced by a precipitant)	Grade 3-4 (or spontaneous)
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds > control) or INR	<4 <1.7	4-6 1.7-2.3	>6 >2.3

CTP classification: Child A: score of 5-6; Child B: score of 7-9; Child C: score of 10-15

2. MODEL OF END-STAGE LIVER DISEASE (MELD) SCORE (RANGE, 6-40)

$[0.957 \times \text{LN (creatinine in mg/dL)} + 0.378 \times \text{LN (bilirubin in mg/dL)} + 1.12 \times \text{LN (INR)} + 0.643] \times 10$

INR = international normalized ratio; LN = natural logarithm.

has been referred to as *cirrhotic cardiomyopathy.* Vasodilation at the level of the pulmonary circulation leads to arterial hypoxemia, the hallmark of hepatopulmonary syndrome. Normal pulmonary capillaries are 8 μm in diameter, and red blood cells (slightly less than 8 μm) pass through them one cell at a time, thereby facilitating oxygenation. In hepatopulmonary syndrome, the pulmonary capillaries are dilated up to 500 μm, so passage of red cells through the pulmonary capillaries may be many cells thick. As a result, a large number of red cells are not oxygenated, which causes the equivalent of a right-to-left shunt.

Conversely, portopulmonary hypertension occurs when the pulmonary bed is exposed to vasoconstrictive substances that may be produced in the splanchnic circulation and bypass metabolism by the liver; the initial result is reversible pulmonary hypertension. However, because these factors result in endothelial proliferation, vasoconstriction, in situ thrombosis, and obliteration of vessels, irreversible pulmonary hypertension ensues.

CLINICAL MANIFESTATIONS

The clinical manifestations of cirrhosis range widely, depending on the stage of cirrhosis, from an asymptomatic patient with no signs of chronic liver disease to a patient who is confused and jaundiced and has severe muscle wasting and ascites. The natural history of cirrhosis is characterized by an initial phase, termed *compensated* cirrhosis, followed by a rapidly progressive phase marked by the development of complications of portal hypertension or liver dysfunction (or both), termed *decompensated* cirrhosis (Fig. 156-3). In the compensated phase, portal pressure may be normal or below the threshold level identified for the development of varices or ascites. As the disease progresses, portal pressure increases and liver function decreases, thereby resulting in the development of ascites, portal hypertensive gastrointestinal (GI) bleeding, encephalopathy, and jaundice. The development of any of these complications marks the transition from a compensated to a decompensated phase. Progression to death may be accelerated by the development of other complications such as recurrent GI bleeding, renal impairment (refractory ascites, hepatorenal syndrome), hepatopulmonary syndrome, and sepsis (spontaneous bacterial peritonitis). The development of hepatocellular carcinoma (Chapter 202) may accelerate the course of the disease at any stage (see Fig. 156-3). Transition from a compensated to a decompensated stage occurs at a rate of approximately 5 to 7% per year. The median time to decompensation, or the time at which half the patients with compensated cirrhosis will become decompensated, is about 6 years.

Compensated Cirrhosis

In this stage, cirrhosis is mostly asymptomatic and is diagnosed either during the evaluation of chronic liver disease or fortuitously during routine physical examination, biochemical testing, imaging for other reasons, endoscopy showing gastroesophageal varices, or abdominal surgery in which a nodular liver is detected. Nonspecific fatigue, decreased libido, or sleep disturbances may be the only complaints. About 40% of patients with compensated cirrhosis have esophageal varices. Nonbleeding gastroesophageal varices are asymptomatic, and their presence (without bleeding) does not denote decompensation.

Decompensated Cirrhosis

At this stage, there are signs of decompensation: ascites, variceal hemorrhage, jaundice, hepatic encephalopathy, or any combination of these findings. Ascites, which is the most frequent sign of decompensation, is present in 80% of patients with decompensated cirrhosis.

Variceal Hemorrhage

Gastroesophageal varices are present in approximately 50% of patients with newly diagnosed cirrhosis. The prevalence of varices correlates with the severity of liver disease and ranges from 40% in Child A cirrhotic patients (Table 156-2) to 85% in Child C cirrhotic patients.

Both the development of varices and the growth of small varices occur at a rate of 7 to 8% per year. The incidence of a first variceal hemorrhage in patients with small varices is about 5% per year, whereas medium and large varices bleed at a rate of approximately 15% per year. Large varices, severe liver disease, and red wale markings on varices are independent predictors of variceal hemorrhage. Bleeding from gastroesophageal varices can be manifested as overt hematemesis or melena, or both (Chapter 137).

Ascites and Hepatorenal Syndrome

Ascites is the most common cause of decompensation in cirrhosis and occurs at a rate of 7 to 10% per year. The most frequent symptoms associated with ascites are increased abdominal girth, which is often described by the patient as tightness of the belt or garments around the waist, and recent weight gain. When present in small to moderate amounts, ascites can be identified on examination by bulging flanks, flank dullness, and shifting dullness (Chapter 148).

Hepatorenal syndrome is a type of prerenal kidney injury that occurs in patients with cirrhosis and ascites. It is divided into two types based on clinical characteristics and prognosis. Type 1 hepatorenal syndrome is rapidly progressive *acute* kidney injury in which the rise in serum creatinine occurs within a 2-week period. Type 2 hepatorenal syndrome is more slowly progressive and associated with ascites that is refractory to diuretics. Patients with hepatorenal syndrome usually have tense ascites that responds poorly to diuretics, but no specific symptoms or signs typify this entity.

Spontaneous Bacterial Peritonitis

About one third of cirrhotic patients are admitted for or acquire bacterial infections during hospitalization, the most common being spontaneous bacterial peritonitis. The two most important predictors of the development of bacterial infection are the severity of liver disease and admission for GI hemorrhage. The most frequent clinical manifestations of spontaneous bacterial peritonitis are fever, jaundice, and abdominal pain. On physical examination,

there is typically abdominal tenderness, with or without rebound tenderness, or ileus (or both). However, patients with spontaneous bacterial peritonitis may have just encephalopathy, acute kidney injury or evidence of shock. Up to one third of patients may be entirely asymptomatic.

Hepatic Encephalopathy

Hepatic encephalopathy, which is the neuropsychiatric manifestation of cirrhosis, occurs at a rate of approximately 2 to 3% per year. Hepatic encephalopathy associated with cirrhosis is of gradual onset and rarely fatal. Clinically, it is characterized by alterations in consciousness and behavior ranging from inversion of the sleep-wake pattern and forgetfulness (stage 1); to confusion, bizarre behavior, and disorientation (stage 2); to lethargy and profound disorientation (stage 3); to coma (stage 4). On physical examination, early stages may demonstrate only a distal tremor, but the hallmark of hepatic encephalopathy is the presence of asterixis (Chapter 157). Additionally, patients with hepatic encephalopathy may have sweet-smelling breath, a characteristic termed *fetor hepaticus*.

Pulmonary Complications

Hepatopulmonary syndrome is associated with exertional dyspnea, which can lead to extreme debilitation. Clubbing of the fingers, cyanosis, and vascular spiders may be seen on physical examination. Hepatopulmonary syndrome is present in approximately 5 to 10% of patients awaiting liver transplantation.

Portopulmonary hypertension is manifested as exertional dyspnea, syncope, and chest pain. On examination, an accentuated second sound and right ventricular heave are prominent (Chapter 68).

DIAGNOSIS

The diagnosis of cirrhosis should be considered in any patient with chronic liver disease. In asymptomatic patients with *compensated cirrhosis*, typical signs of cirrhosis may not be present, and the diagnosis may often require histologic confirmation by liver biopsy, which is the "gold standard" for the diagnosis of cirrhosis. In patients with symptoms or signs of chronic liver disease, however, the presence of cirrhosis can frequently be confirmed noninvasively by imaging studies without the need for liver biopsy.

Physical Examination

On physical examination, stigmata of cirrhosis consist of muscle atrophy, mainly involving the bitemporal muscle regions and the thenar and hypothenar eminences; spider angiomas, mostly on the trunk, face, and upper limbs; and palmar erythema involving the thenar and the hypothenar eminences and the tips of the fingers. Although muscular atrophy is a marker of liver insufficiency, spider angiomas and palmar erythema are markers of vasodilation and a hyperdynamic circulation. Males may have hair loss on the chest and abdomen, gynecomastia, and testicular atrophy. Petechiae and ecchymoses may be present as a result of thrombocytopenia or a prolonged prothrombin time. Dupuytren's contracture, which is a thickening of the palmar fascia, occurs mostly in alcoholic cirrhosis. A pathognomonic feature of cirrhosis is the finding on abdominal examination of a small right liver lobe, with a span of less than 7 cm on percussion, and a palpable left lobe that is nodular with increased consistency. Splenomegaly may also be present and is indicative of portal hypertension. Collateral circulation on the abdominal wall (caput medusae) may also develop as a consequence of portal hypertension. Absence of any of the aforementioned physical findings does not exclude cirrhosis.

Laboratory Tests

Laboratory test results suggestive of cirrhosis include even subtle abnormalities in serum levels of albumin or bilirubin or elevation of the international normalized ratio. The most sensitive and specific laboratory finding suggestive of cirrhosis in the setting of chronic liver disease is a low platelet count ($<150{,}000/mm^3$), which occurs as a result of portal hypertension and hypersplenism. Other serum markers that are often abnormal include levels of aspartate aminotransferase, γ-glutamyl transpeptidase, hyaluronic acid, α_2-macroglobulin, haptoglobin, tissue metalloproteinase inhibitor I, and apolipoprotein A. Although attempts have been made to use combinations of such markers to predict the presence of cirrhosis, none has sufficient sensitivity and specificity to be useful clinically.

Imaging Studies

Confirmatory imaging tests include computed tomography, ultrasound, and magnetic resonance imaging. Findings consistent with cirrhosis include a nodular contour of the liver, a small liver with or without hypertrophy of the left or caudate lobe, splenomegaly, and in particular, identification of intra-abdominal collateral vessels indicative of portal hypertension (Fig. 156-4). Transient elastography, a new noninvasive technique based on ultrasound wave propagation, measures liver stiffness and appears to be useful in the diagnosis of cirrhosis. Typical findings on any of these imaging studies, together with a compatible clinical picture, are indicative of the presence of cirrhosis. A liver biopsy then would not be required unless the degree of inflammation or other features require investigation.

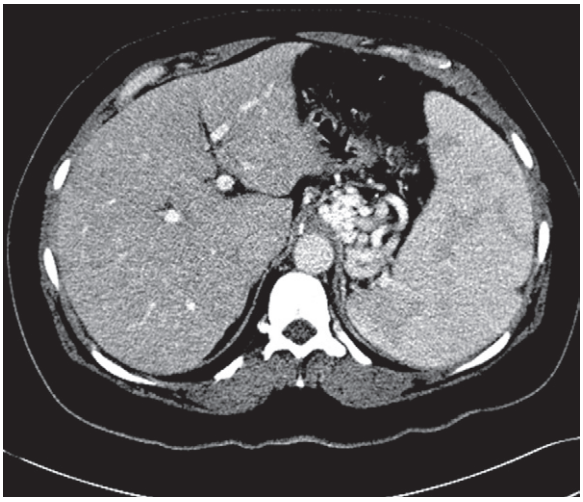

FIGURE 156-4. Computed tomography in a patient with compensated cirrhosis. The liver parenchyma is heterogeneous, there is splenomegaly, and, importantly, there are portosystemic collaterals.

In *decompensated cirrhosis*, detection of ascites, variceal bleeding, or encephalopathy in the setting of chronic liver disease essentially establishes the diagnosis of cirrhosis, so a liver biopsy is not necessary to establish the diagnosis. Patients with decompensated cirrhosis often exhibit malnutrition, more severe muscle wasting, more numerous vascular spiders, and hypotension and tachycardia as a result of the hyperdynamic circulatory state.

Portal Pressure Measurements

Direct measurements of portal pressure involve catheterization of the portal vein, are cumbersome, and may be associated with complications. Hepatic vein catheterization with measurement of wedged and free pressure is the simplest, safest, most reproducible, and most widely used method to indirectly measure portal pressure. Portal pressure measurements are expressed as the hepatic venous pressure gradient: the gradient between wedged hepatic venous pressure, which is a measure of sinusoidal pressure, and free hepatic or inferior vena cava pressure, which is used as an internal zero reference point. In a patient with clinical evidence of portal hypertension (e.g., varices), the hepatic venous pressure gradient is useful in the differential diagnosis of the cause of portal hypertension: it will be normal (3 to 5 mm Hg) in prehepatic causes of portal hypertension, such as portal vein thrombosis (Chapter 145), and in intrahepatic but presinusoidal causes, such as schistosomiasis (Chapter 363), but will be abnormal (≥6 mm Hg) in sinusoidal causes of portal hypertension, such as cirrhosis, and in postsinusoidal causes, such as veno-occlusive disease. A hepatic venous pressure gradient of 10 mm Hg or greater ("clinically significant" portal hypertension) predicts the development of complications of portal hypertension, and its reduction on pharmacologic therapy predicts a favorable outcome in patients with cirrhosis.

Complications of Cirrhosis

Varices and Variceal Hemorrhage

Upper GI endoscopy (Chapters 136) remains the main method for diagnosing varices and variceal hemorrhage. Varices are classified as small (straight, minimally elevated veins above the esophageal mucosal surface), medium (tortuous veins occupying less than one third of the esophageal lumen), or large (occupying more than one third of the esophageal lumen). The diagnosis of variceal hemorrhage is made when diagnostic esophagogastroduodenoscopy shows one of the following: active bleeding from a varix, a "white nipple" overlying a varix, clots overlying a varix, or varices with no other potential source of bleeding.

TABLE 156-3 USING THE SERUM-ASCITES ALBUMIN GRADIENT AND THE ASCITES TOTAL PROTEIN LEVEL TO DIAGNOSE THE CAUSE OF ASCITES

CONDITION	SERUM-ASCITES ALBUMIN GRADIENT*	ASCITES TOTAL PROTEIN LEVEL†
Cirrhosis	High	Low
Malignant ascites	Low	High
Cardiac ascites	High	High

*High is greater than 1.1 g/dL; low is less than 1.1 g/dL.
†High is greater than 2.5 g/dL; low is less than 2.5 g/dL.

Ascites

The most common cause of ascites is cirrhosis, which accounts for 80% of cases. Peritoneal malignancy (e.g., peritoneal metastases from GI tumors or ovarian cancer), heart failure (Chapter 58), and peritoneal tuberculosis (Chapter 332) together account for another 15% of cases. The initial, most cost-effective, and least invasive method to confirm the presence of ascites is abdominal ultrasonography.

Diagnostic paracentesis is a safe procedure that should be performed in every patient with new-onset ascites, even in those with coagulopathy. Ultrasound guidance should be used in patients in whom percussion cannot locate the ascites or in whom a first paracentesis attempt does not yield fluid. The fluid in a patient with new-onset ascites should always be evaluated for albumin (with simultaneous estimation of serum albumin), total protein, polymorphonuclear (PMN) blood cell count, bacteriologic cultures, and cytology. The PMN cell count and bacteriologic culture are useful to exclude infection (either spontaneous or secondary bacterial peritonitis), and cytologic evaluation is needed if peritoneal carcinomatosis is suspected. Depending on the clinical setting, additional tests can be performed on the fluid: glucose and lactate dehydrogenase levels (if secondary bacterial peritonitis is suspected), smear and culture for acid-fast bacilli (if peritoneal tuberculosis is suspected), and an amylase level (if pancreatic ascites is suspected).

The serum-ascites albumin gradient and ascites protein levels are useful in the differential diagnosis of ascites (Table 156-3). The serum-ascites albumin gradient correlates with sinusoidal pressure and will therefore be elevated (>1.1 g/dL) in patients in whom the source of ascites is the hepatic sinusoid (e.g., cirrhosis or cardiac ascites). Protein levels in ascitic fluid are an indirect marker of the integrity of the hepatic sinusoids: normal sinusoids are permeable structures that "leak" protein, whereas sinusoids in cirrhosis are "capillarized" and do not leak as much protein. The three main causes of ascites—cirrhosis, peritoneal malignancy or tuberculosis, and heart failure—can easily be distinguished by combining the results of both the serum-ascites albumin gradient and ascites total protein content. Cirrhotic ascites typically has a high serum-ascites albumin gradient and low protein, cardiac ascites has a high serum-ascites albumin gradient and high protein, and ascites secondary to peritoneal malignancy typically has a low serum-ascites albumin gradient and high protein.

Hepatorenal Syndrome

Hepatorenal syndrome represents the extreme of the spectrum of abnormalities that lead to cirrhotic ascites and is characterized by maximal peripheral vasodilation as well as maximal activation of hormones that cause the retention of sodium and water and intense vasoconstriction of renal arteries. Ascites unresponsive to diuretics is universal, and dilutional hyponatremia is almost always present.

Hepatorenal syndrome, which is a diagnosis of exclusion, should be made only after discontinuing diuretics, expanding intravascular volume with albumin, and excluding or treating any condition that leads to worsening of the hemodynamic status of the cirrhotic patient. The differential diagnosis includes conditions that worsen vasodilation, such as sepsis, the use of vasodilators, and large-volume paracentesis not accompanied by albumin infusion; conditions that decrease effective arterial blood volume, such as gastrointestinal hemorrhage, overdiuresis or diarrhea (often induced by overdoses of lactulose); conditions that induce renal vasoconstriction, such as nonsteroidal anti-inflammatory drugs; and nephrotoxic insults, such as from aminoglycosides.

Spontaneous Bacterial Peritonitis

A high index of suspicion and early diagnosis are key in the management of spontaneous bacterial peritonitis. Diagnostic paracentesis should be performed in any patient with symptoms or signs of spontaneous bacterial peritonitis, including unexplained encephalopathy and renal dysfunction. Because spontaneous bacterial peritonitis is often asymptomatic and frequently community acquired, diagnostic paracentesis should be performed when any cirrhotic patient is admitted to the hospital, regardless of the cause for admission.

The diagnosis of spontaneous bacterial peritonitis is established by an ascitic fluid PMN count greater than 250/mm^3. Bacteria can be isolated from ascitic fluid in only 40 to 50% of cases, even with sensitive methods such as inoculation directly into a blood culture bottle. Spontaneous bacterial peritonitis is mostly a monobacterial infection, usually with gram-negative enteric organisms. Anaerobes and fungi very rarely cause spontaneous bacterial peritonitis; their presence, as well as a polymicrobial infection, should raise suspicion of secondary bacterial peritonitis.

Hepatic Encephalopathy

The diagnosis of hepatic encephalopathy is clinical and based on the history and physical examination showing alterations in consciousness and behavior, as well as the presence of asterixis. Ammonia levels are unreliable, and there is poor correlation between the stage of hepatic encephalopathy and ammonia blood levels. Therefore, measurements of ammonia are not useful. Psychometric tests and an electroencephalogram are typically used in research but are not useful for clinical diagnosis. Minimal hepatic encephalopathy, formerly called *subclinical* hepatic encephalopathy, which occurs in about 30 to 70% of patients who have cirrhosis without overt hepatic encephalopathy, is detected by psychometric and neuropsychological testing of attention (e.g., number connection test, digit symbol test) and psychomotor function (e.g., grooved pegboard) alone. However, screening of cirrhotic patients for asymptomatic hepatic encephalopathy is not recommended because diagnostic tests are not standardized and the benefits of treatment are unknown.

Hepatopulmonary Syndrome and Portopulmonary Hypertension

The diagnostic criteria for hepatopulmonary syndrome are arterial hypoxemia with a Pao_2 of less than 80 mm Hg or an alveolar arterial oxygen gradient of greater than 15 mm Hg, along with evidence of pulmonary vascular shunting on contrast echocardiography (Chapter 55) or a ^{99m}Tc-labeled macroaggregated albumin scan demonstrating abnormal shunting of radioactivity to the brain. Portopulmonary hypertension is diagnosed by the presence of mean pulmonary arterial pressure higher than 25 mm Hg on right heart catheterization, provided that pulmonary capillary wedge pressure is less than 15 mm Hg.

TREATMENT

Treatment of cirrhosis should ideally be aimed at interrupting or reversing fibrosis. However, antifibrotic drugs have not been shown to reverse fibrosis consistently or improve outcomes in cirrhotic patients. Treatment of compensated cirrhosis is currently directed at preventing the development of decompensation by (1) treating the underlying liver disease (e.g., antiviral therapy for hepatitis C or B) to reduce fibrosis and prevent decompensation; (2) avoiding factors that could worsen liver disease, such as alcohol and hepatotoxic drugs; and (3) screening for varices (to prevent variceal hemorrhage) and for hepatocellular carcinoma (to treat at an early stage) (Fig. 156-5). Treatment of decompensated cirrhosis focuses on specific decompensating events and the option of liver transplantation.

Varices and Variceal Bleeding

Reducing portal pressure decreases the risk for the development of varices and variceal hemorrhage, as well as the risk for ascites and death. Nonselective β-adrenergic blockers (propranolol, nadolol) reduce portal pressure by producing splanchnic vasoconstriction and decreasing portal venous inflow. In patients with cirrhosis and medium or large varices that have never bled, nonselective β-blockers significantly reduce the risk for first variceal hemorrhage.[1] Propranolol is initiated at a dose of 20 mg orally twice a day, whereas nadolol is initiated at a dose of 20 mg orally every day. The dose should be titrated to produce a resting heart rate of about 50 to 55 beats per minute. Endoscopic variceal ligation (Fig. 136-3 in Chapter 136), a therapy that aims to obliterate varices by placing rubber rings on variceal columns, is as useful as nonselective β-blockers to prevent a first variceal hemorrhage.[2] Because ligation is a local therapy that has no effect on portal pressure and that can lead to hemorrhage from ligation-induced ulcers, a rational approach is to start therapy with β-blockers and to use ligation in patients who cannot tolerate or have contraindications to β-blockers.

In patients with no varices, nonselective β-blockers do not prevent the development of varices and are associated with more side effects.[3] In

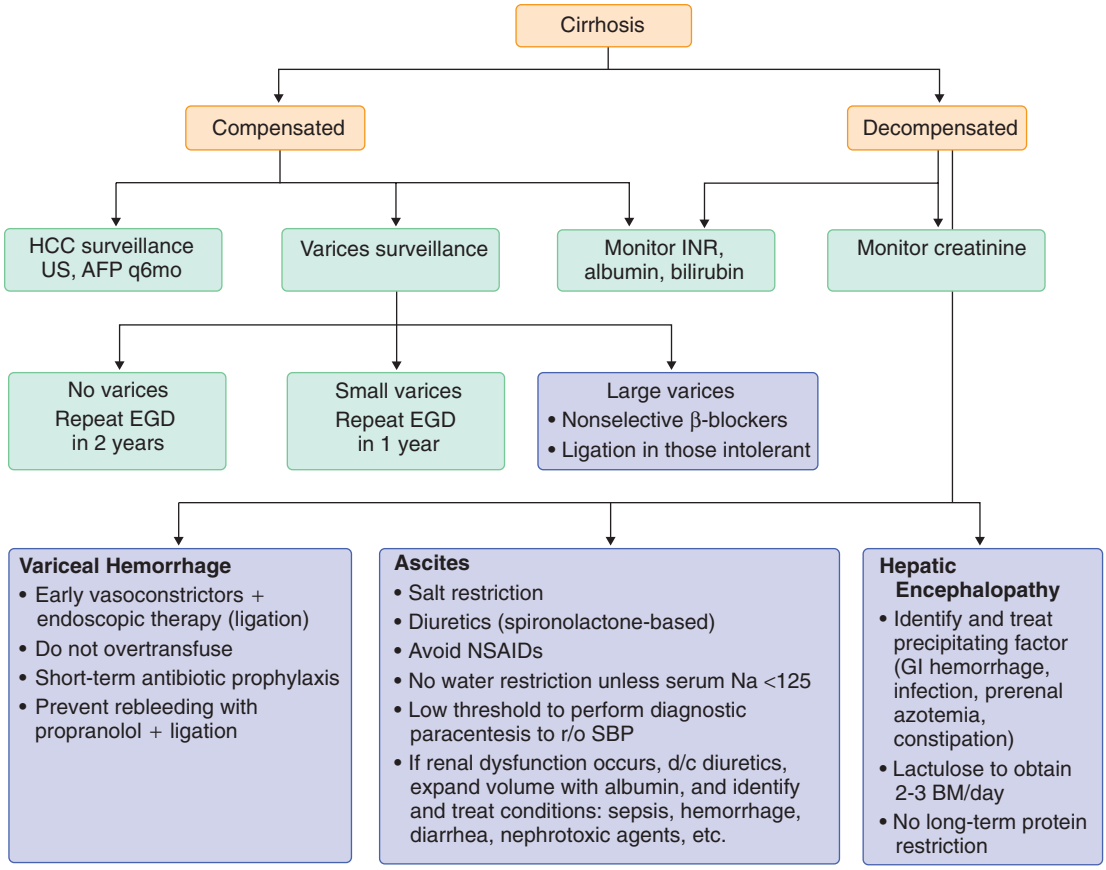

FIGURE 156-5. Summary of the management of compensated and decompensated cirrhosis. AFP = α-fetoprotein; BM = bowel movement; d/c = discontinue; EGD = esophagogastroduodenoscopy; GI = gastrointestinal; HCC = hepatocellular carcinoma; INR = international normalized ratio; Na = sodium; NSAIDs = nonsteroidal anti-inflammatory drugs; r/o = rule out; SBP = spontaneous bacterial peritonitis; US = ultrasound.

patients with small varices, data are insufficient to recommend therapy with nonselective β-blockers. Endoscopy should be repeated every 2 to 3 years in patients with no varices, every 1 to 2 years in patients with small varices, and sooner in patients with decompensated disease so that effective therapy can be instituted before the varices grow in size and bleed.

Patients with cirrhosis and variceal hemorrhage require resuscitation in an intensive care unit. However, overtransfusion should be avoided because it can precipitate rebleeding. Hemoglobin values should be maintained at about 7-8 g/dL. Prophylactic antibiotics should be used in this setting not only to prevent bacterial infections but also to decrease rebleeding[8] and death. The recommended antibiotic is oral norfloxacin at a dose of 400 mg twice daily for 5 to 7 days, although intravenous ceftriaxone at a dose of 1 g/day for 5 to 7 days is preferable in patients with advanced liver disease (malnutrition, ascites, encephalopathy, and jaundice) or in those already on norfloxacin prophylaxis.[8]

The most effective specific therapy for the control of active variceal hemorrhage is the combination of a vasoconstrictor with endoscopic therapy.[8] Safe vasoconstrictors include terlipressin, somatostatin, and the somatostatin analogues octreotide and vapreotide; they can be initiated at admission to the hospital and continued for 2 to 5 days. The vasoconstrictor currently available in the United States is octreotide, which is used as a 50-μg intravenous bolus followed by an infusion at 50 μg/hour.

After control of hemorrhage, the 1-year recurrence of hemorrhage without treatment is very high at about 60%. Therefore, therapy to prevent rebleeding should be instituted before the patient is discharged. The lowest rebleeding rates (about 10%) are observed in patients who achieve a significant reduction in the hepatic venous pressure gradient with pharmacologic therapy (β-blockers, at the same dose recommended for prevention of first hemorrhage, with or without isosorbide mononitrate at stepwise dosing starting at 20 mg/day orally and increased as tolerated up to 40 mg twice a day); however, because hepatic venous pressure gradient measurements are not widely used, the next best results (rebleeding rates of about 22%) are obtained with the combination of nonselective β-blockers (propranolol or nadolol), with or without isosorbide mononitrate, and endoscopic variceal ligation.[9] The dose of β-blockers should be the maximal dose tolerated, and endoscopic variceal ligation should be repeated every 2 to 4 weeks until the varices are obliterated.

Shunt therapy, either surgical or through radiologic placement of a transjugular intrahepatic portosystemic shunt (TIPS), should be used in patients whose variceal bleeding has persisted or recurred despite combined pharmacologic and endoscopic therapy. Both types of shunts are equally effective,[8] and the choice will depend on local expertise. Although uncovered TIPS stents frequently occlude, newer polytetrafluoroethylene-covered stents are associated with lower occlusion rates and lower rates of hepatic encephalopathy.[8]

Ascites

Salt restriction and diuretics constitute the mainstay of management of ascites. Dietary sodium intake should be restricted to 2 g/day. A more restrictive diet is not recommended and may compromise nutritional status. Fluid restriction is not required unless the serum sodium concentration is below 130 mEq/L.

Spironolactone, which is more effective than loop diuretics, should be started at a dose of 100 mg/day (once a day in the morning). The dose should be adjusted every 3 to 4 days to a maximal effective dose of 400 mg/day. Furosemide, at an escalated dose from 40 to 160 mg/day, can be started concurrently with spironolactone if weight loss is inadequate or if hyperkalemia develops on spironolactone alone. The goal is weight loss of 1 kg in the first week and 2 kg/week subsequently. However, diuretics should be reduced if the rate of weight loss is greater than 0.5 kg/day in patients without peripheral edema or more than 1 kg/day in patients with peripheral edema. Side effects of diuretic therapy include electrolyte abnormalities, renal dysfunction, encephalopathy, and painful gynecomastia (with spironolactone).

In the 10 to 20% of patients with ascites who are refractory to diuretics, large-volume paracentesis, aimed at removing all or most of the fluid, plus albumin at a dose of 6 to 8 g intravenously per liter of ascites removed, particularly when more than 5 L is removed at once, is a reasonable approach. The frequency of large-volume paracentesis is dictated by the rapidity at which the ascites reaccumulates. TIPS with uncovered stents is more effective than large-volume paracentesis plus albumin in preventing recurrent ascites but is associated with a higher rate of encephalopathy without a significant improvement in survival.[10] In patients requiring frequent large-volume paracentesis (more than twice per month), polytetrafluoroethylene-covered TIPS stents should be considered. A peritoneovenous shunt, using a subcutaneously placed silicone tube that transfers ascites from the peritoneal cavity to the systemic circulation, can be used in patients who are not candidates for TIPS or liver transplantation.

Hepatorenal Syndrome

Because hepatorenal syndrome is a functional kidney injury that results from hemodynamic abnormalities secondary to end-stage liver disease and severe portal hypertension, the mainstay of therapy is liver

transplantation (Chapter 157). Therapies that have been used to "bridge" a patient to transplantation include vasoconstrictors (terlipressin, noradrenaline, octreotide plus midodrine) plus albumin, TIPS, and extracorporeal albumin dialysis, which is an experimental hemofiltration dialysis method that uses an albumin dialysate. The largest experience is with the use of terlipressin, which at a dose 0.5 to 2.0 mg intravenously every 4 to 6 hours leads to a higher reversal rate of hepatorenal syndrome compared with placebo.[11] Because terlipressin is not yet available in the United States, the most used combination is octreotide (100 to 200 µg subcutaneously three times a day) plus midodrine (7.5 to 12.5 mg orally three times a day), with the dose adjusted to obtain an increase of at least 15 mm Hg in mean arterial pressure. Improvements may become clinically noticeable at day 7.

Spontaneous Bacterial Peritonitis

Empirical antibiotic therapy with an intravenous third-generation cephalosporin (e.g., cefotaxime, 2 g intravenously every 12 hours, or ceftriaxone, 1 to 2 g intravenously every 24 hours) or amoxicillin-clavulanic acid (1 g/0.5 g intravenously every 8 hours) should be initiated as soon as the diagnosis is established and before culture results are available; the minimal duration of therapy should be 5 days. Aminoglycosides should be avoided because of the high incidence of renal toxicity in cirrhotic patients. Repeat diagnostic paracentesis should be performed 2 days after starting antibiotics, by which time the number of PMN neutrophils in ascitic fluid should have decreased by more than 25% from baseline. Lack of response should prompt further investigations to exclude secondary peritonitis. The renal dysfunction associated with spontaneous bacterial peritonitis can be prevented by the intravenous administration of albumin, particularly in patients who have any evidence of renal dysfunction (blood urea nitrogen >30 mg/dL or creatinine >1 mg/dL, or both) or serum bilirubin greater than 4 mg/dL at the time of diagnosis. Albumin has been used at a dose of 1.5 g/kg of body weight at diagnosis, repeated on the third day at an intravenous dose of 1 g/kg of body weight. However, this dosing is empirical and should not exceed 100 g per dose.

The administration of nonabsorbable (or poorly absorbable) antibiotics can prevent the development of spontaneous bacterial peritonitis and other infections in cirrhosis by selectively eliminating gram-negative organisms in the gut. However, the widespread use of prophylactic norfloxacin is associated with a higher rate of infections by antibiotic-resistant organisms. Long-term antibiotic prophylaxis with oral norfloxacin at a dose of 400 mg/day is justified only in two groups: patients who have recovered from a previous episode of spontaneous bacterial peritonitis, and patients who have an ascites protein level of less than 1 g/L with advanced liver and circulatory dysfunction as evidenced by the presence of jaundice, hyponatremia, or renal dysfunction.[12,13]

Hepatic Encephalopathy

Treatment of hepatic encephalopathy involves identifying and treating the precipitating factor and reducing the ammonia level. Precipitating factors include infections, overdiuresis, GI bleeding, a high oral protein load, and constipation. Narcotics and sedatives contribute to hepatic encephalopathy by directly depressing brain function. TIPS is a common precipitant of hepatic encephalopathy, and shunt reduction or occlusion may be required. Agents aimed at decreasing ammonia production in the gut are lactulose (15 to 30 mL orally twice daily adjusted to obtain two to three soft bowel movements per day) or orally administered nonabsorbable antibiotics such as neomycin (500 mg to 1 g three times per day), metronidazole (250 mg two to four times per day), or rifaximin (550 mg two times per day).[14] L-Ornithine, L-aspartate, and benzoate may increase ammonia fixation in the liver. Switching dietary protein from an animal source to a vegetable source may be beneficial, but protein restriction is not necessary and should not be used long term.[15]

Pulmonary Complications

Hepatopulmonary syndrome rarely resolves spontaneously, and medical therapy is disappointing. TIPS is not generally recommended. The only viable treatment is liver transplantation (Chapter 157).

By comparison, portopulmonary hypertension is not an indication for liver transplantation. In fact, a mean pulmonary arterial pressure higher than 50 mm Hg is an absolute contraindication to liver transplantation.

Surgical Therapy

Liver Transplantation

Orthotopic liver transplantation (Chapter 157), which is the definitive therapy for cirrhosis, is indicated when the risk for dying from liver disease is greater than the risk for dying from transplantation, as determined by a Child-Pugh score of 7 or higher (see Table 156-2) or a Model for End-Stage Liver Disease (MELD) score of 15 or higher. MELD (see Table 157-4 in Chapter 157), which is a mathematical model that estimates the risk for 3-month mortality, is used to determine the priority for liver transplantation. The number of available deceased donor organs is lower than the number of patients awaiting liver transplantation; as a result, 15 to 20% of patients awaiting liver transplantation in the United States die before an organ becomes available.

PRIMARY PREVENTION

Treatment of the underlying liver disease, before the development of cirrhosis, is a primary prevention strategy. Because the major causes of cirrhosis are related to lifestyle choices such as injection drug use (Chapter 33), alcohol consumption (Chapter 32), and unprotected sex, primary prevention programs that focus on encouraging alcohol abstinence, reducing high-risk behavior for hepatitis virus infection, and vaccinating for hepatitis B are even better prevention strategies.

PROGNOSIS

The outcome of cirrhosis depends on the patient's stage. Patients with compensated cirrhosis die of liver disease only after transition to a decompensated stage. The 10-year survival rate of patients who remain in a compensated stage is approximately 90%, whereas their likelihood of decompensation is 50% at 10 years. Inception cohort studies of patients with compensated cirrhosis show a median survival of all patients, including those in whom decompensation develops over time, of about 10 years, whereas the median survival after decompensation is about 2 years.

Four clinical stages of cirrhosis have recently been identified, each with a different prognosis. In stage 1 patients without varices or ascites, the mortality rate is about 1% per year. Stage 2 patients, or those with varices but without ascites or bleeding, have a mortality rate of about 4% per year. Stage 3 patients have ascites with or without esophageal varices that have never bled; their mortality rate while remaining in this stage is 20% per year. Stage 4 patients, or those with portal hypertensive GI bleeding with or without ascites, have a 1-year mortality rate of 57%, with nearly half of these deaths occurring within 6 weeks after the initial episode of bleeding. Stages 1 and 2 correspond to compensated cirrhosis, whereas stages 3 and 4 are decompensated cirrhosis. Hepatocellular carcinoma develops at a fairly constant rate of 3% per year and is associated with a worse outcome at whatever stage it develops.

Predictors of survival are different in compensated and decompensated patients, with parameters of portal hypertension (varices, splenomegaly, platelet count, γ-globulin) assuming greater importance in compensated patients, whereas renal dysfunction, hemorrhage, and hepatocellular carcinoma are important predictive factors in patients with decompensated cirrhosis. In clinical practice, the Child-Pugh score is applicable to all cirrhotic patients, and the MELD score is used in decompensated patients to determine priority for liver transplantation.

157 HEPATIC FAILURE AND LIVER TRANSPLANTATION

EMMET B. KEEFFE

Liver transplantation is the treatment of choice for patients with severe liver failure, end-stage liver disease, and certain metabolic liver diseases for which no alternative therapies are available. More than 6000 liver transplantations are performed in the United States annually, with a waiting list that has grown to approximately 16,000 patients. With modern immunosuppressive drug regimens, technical advances, and improved perioperative care, the current 1-year survival rate after liver transplantation is 85 to 90% (Table 157-1). Many studies show that liver transplantation significantly improves the physical, cognitive, and psychological functioning of the recipient. In recent years, the disparity between a limited supply of cadaver donor organs and much greater need for liver transplantation has resulted in an unacceptable number of deaths of patients listed for transplantation and created a mandate to optimize the selection of patients and timing of transplantation.

INDICATIONS AND SELECTION CRITERIA FOR LIVER TRANSPLANTATION

The indications and contraindications for liver transplantation, the most appropriate candidates to receive a transplant, and the organ allocation scheme continue to evolve. The diseases for which liver transplantation is performed in adults include cirrhosis with end-stage liver disease (Chapter 156), acute liver failure, hepatic malignancies (particularly hepatocellular carcinoma; Chapter 202), and metabolic diseases in which the inborn error of metabolism resides in the hepatocytes (e.g., hemochromatosis, α_1-antitrypsin deficiency, Wilson's disease; Chapter 153). The most common indications for liver transplantation are chronic hepatitis C and alcoholic liver disease in adults (together accounting for approximately 50% of transplantations) and biliary atresia and α_1-antitrypsin deficiency in children.

General selection criteria that should be considered in the referral of patients for liver transplantation include the following: (1) the absence of alternative forms of therapy that may reverse liver failure and defer the need for liver transplantation, (2) the absence of any absolute contraindication to transplantation (discussed later), (3) expected compliance with longitudinal follow-up care, and (4) the ability to provide for the financial costs of liver transplantation and follow-up care, including medications that may be expensive. Insurance coverage for transplantation is typically determined before referral by a financial counselor at the transplantation center.

TABLE 157-1 KAPLAN-MEIER PATIENT SURVIVAL RATES FOR LIVER TRANSPLANTATION PERFORMED FROM 1997 TO 2004

	Kaplan-Meier Survival Rate (%)		
DIAGNOSIS	**1-YEAR**	**3-YEAR**	**5-YEAR**
Acute hepatic necrosis	81	72	69
Cholestatic cirrhosis	90	85	80
Noncholestatic cirrhosis	86	77	70
Other liver disease	81	72	63
Metabolic disease	89	84	81
Malignant neoplasm	86	68	54
Benign neoplasm	86	81	68

TABLE 157-2 BIOCHEMICAL AND CLINICAL INDICATIONS FOR LIVER TRANSPLANTATION IN CHRONIC LIVER DISEASE

CHOLESTATIC LIVER DISEASE
Bilirubin >10 mg/dL
Intractable pruritus
Progressive cholestatic bone disease
Recurrent bacterial cholangitis
HEPATOCELLULAR LIVER DISEASE
Serum albumin <3 g/dL
Prothrombin time >3 seconds above control
BOTH CHOLESTATIC AND HEPATOCELLULAR LIVER DISEASES
Recurrent or severe hepatic encephalopathy
Refractory ascites
Spontaneous bacterial peritonitis
Recurrent portal hypertensive bleeding
Severe chronic fatigue and weakness
Progressive malnutrition
Development of hepatorenal syndrome
Detection of small hepatocellular carcinoma

INR = International Normalized Ratio.

Referral for Liver Transplantation

Patients with chronic (Table 157-2) or acute (Table 157-3) liver disease should be referred when hepatic decompensation first develops or the presence of hepatocellular carcinoma is first detected. The greatest likelihood of survival and return to an excellent quality of life occurs in patients who undergo liver transplantation before the onset of multiorgan failure. Meticulous attention to medical management of the complications of cirrhosis, such as avoidance of excessive diuretic therapy or aminoglycosides to preserve renal function in patients with ascites or spontaneous bacterial peritonitis, is critical. Blood loss in patients with gastrointestinal bleeding should be replaced judiciously with blood products to avoid fluid overload and pulmonary edema.

For long-term management in patients with chronic liver disease who may ultimately become candidates for transplantation, nonsurgical interventions, such as transjugular intrahepatic portosystemic shunt (TIPS) for refractory portal hypertensive bleeding and endoscopic or radiologic approaches to dominant biliary strictures in patients with primary sclerosing cholangitis, are preferable to abdominal procedures that can cause adhesions. Patients with cirrhosis (Chapter 156) should undergo surveillance for hepatocellular carcinoma with ultrasound or computed tomography and α-fetoprotein

testing every 6 months to facilitate early diagnosis of lesions, when they are small and amenable to treatment with modalities such as resection or liver transplantation.

Chronic Liver Disease

Although the survival of patients with compensated cirrhosis is excellent (approximately 90% at 5 years), the development of decompensation with ascites, portal hypertensive bleeding, or encephalopathy implies a lower 5-year survival rate of about 20%. A patient with a Child-Turcotte-Pugh (see Table 156-2 in Chapter 156) score of 5 or 6 (Child's class A cirrhosis) without a history of portal hypertensive bleeding or spontaneous bacterial peritonitis is likely to remain stable for a considerable period of time and does not require listing for transplantation. Suggested criteria for listing should be clinical decompensation or biochemical deterioration of synthetic function that results in a Child's class B or C status, any complication of portal hypertension, or the development of a small hepatocellular carcinoma, although one randomized trial showed no benefit to listing patients with Child's class B alcoholic cirrhosis compared with standard care.■ Many centers are also using a Model for End-Stage Liver Disease (MELD; see Table 156-2 in Chapter 156) score of 10 to assist in the timing of evaluation for liver transplantation.

Liver transplantation for hepatocellular carcinoma (Chapter 202) is reserved for selected patients who have advanced cirrhosis, who do not have the hepatic reserve to undergo resection, and who have no evidence of extrahepatic tumor after thorough evaluation. Risks for recurrent hepatocellular carcinoma after transplantation include advanced disease (stage 3 or greater) as defined by lymph node involvement, gross vascular invasion by imaging studies, tumor burden (single lesion <5 cm, or two or more lesions >3 cm), or involvement of more than one lobe. In low-risk patients with stage 1 or 2 disease (single lesion of 5 cm, or two or three lesions of ≤3 cm), the actuarial survival rate is about 75% at 4 years, whereas the survival in patients with higher risk is about 50% at 4 years. Evolving data support expanding liver transplantation to patients with early stage 3 hepatocellular carcinoma, but use of these expanded criteria remains experimental.

Acute Liver Failure

Liver transplantation is a major advance in the management of severe acute liver failure. *Fulminant hepatic failure* refers to the presence of acute liver failure with superimposed hepatic encephalopathy developing within 2 to 8 weeks after the onset of illness in a patient without preexisting liver disease. *Subfulminant hepatic failure* (or *late-onset hepatic failure*) is applied to a syndrome that develops more slowly, after 2 to 8 weeks up to 3 to 6 months. The selection of patients with acute liver failure who are likely to die and therefore would benefit from liver transplantation is challenging but can be predicted by certain biochemical and clinical features, the most popular of which was established at King's College Hospital in London (see Table 157-3).

Aggressive supportive care is necessary in patients with fulminant hepatic failure to prevent and treat bleeding, infection, cerebral edema, renal failure, and respiratory failure. These complications are the main reasons that transplantation may not be possible and may also contribute to postoperative morbidity and mortality.

Potential alternative treatment strategies for fulminant hepatic failure include extracorporeal liver assist devices, hepatocyte transplantation, and heterotopic auxiliary liver transplantation, although all of these currently must be viewed as investigational. The goals of these therapies are to prevent irreversible brain damage, provide time for possible hepatic regeneration and recovery of acceptable function, and stabilize patients who do not recover until liver transplantation can be performed. Clinical experience with hepatic support devices, primarily using either porcine or human hepatocytes, is encouraging but limited to ongoing trials. Hepatocyte transplantation and heterotopic liver transplantation have a number of technical problems that limit their application.

Patients with fulminant hepatic failure should be treated in an intensive care unit, with the patient's head elevated at 20 to 30 degrees. Although lactulose is the cornerstone of treatment of chronic hepatic encephalopathy, it is less effective in patients with acute encephalopathy, and the role of antibiotics such as neomycin is unknown. However, a trial of lactulose, 30 mL two to four times daily, adjusted to achieve two to three loose bowel movements daily, is worthwhile, and the drug may need to be administrated by nasogastric tube or by rectal enema. Factors precipitating hepatic encephalopathy, such as gastrointestinal bleeding, hypokalemia, or sepsis, should be identified and treated.

Cerebral edema is manifest frequently by hypertension, bradycardia, and neurologic findings such as decerebrate posturing or abnormal pupillary reflexes. These findings may occur late; therefore, monitoring of intracranial pressure (ICP) with institution of therapy to maintain ICP at less than 20 mm Hg is preferred. ICP may be monitored with either a subdural or an epidural transducer, and the risk for hemorrhage as a complication of placement is outweighed by the benefit of monitoring and early intervention.

Initial treatment of increased ICP is with mannitol (0.5 to 1 g/kg by intravenous infusion over 5 minutes). Repeated doses of mannitol may be required to treat recurrent increases in ICP. Mannitol can be given only if the serum osmolality is less than 320 mOsm/L. Caution is advised in patients with renal failure, and mannitol may need to be administered in combination with hemodialysis or continuous arteriovenous hemofiltration. Other useful therapies include disturbing the patient as little as possible, controlling agitation, and administering moderate hyperventilation to a partial carbon dioxide pressure of 25 to 30 mm Hg. A persistent ICP greater than 40 mm Hg that is refractory to treatment precludes liver transplantation.

Listing for Liver Transplantation

Before final selection and listing for liver transplantation, prospective candidates with acute or chronic liver disease undergo a pretransplantation evaluation to define the current status of systemic diseases and to determine whether any absolute or relative contraindications are present. Routine evaluation includes blood bank and hematologic studies, complete liver and kidney chemistry profiles, viral serology assays (hepatitis A, B, and C viruses; human immunodeficiency virus [HIV]; cytomegalovirus [CMV]), chest radiography, and abdominal computed tomography or Doppler ultrasound studies of the hepatic vasculature. Additional routine tests include skin testing for tuberculosis, creatinine clearance, electrocardiogram, and, in the presence of lung disease, pulmonary function testing. Patients who are at risk for coronary artery disease undergo cardiology consultation and, if indicated, stress testing, cardiac catheterization, or both. Cancer screening, depending on age and gender, includes Papanicolaou smear, mammography, and colonoscopy. Consultations with a social worker, financial counselor, and psychiatrist are routinely performed at the transplantation center.

Patients are generally assigned to one of four categories by the liver transplantation center selection committee: (1) suitable and ready, with listing for transplantation; (2) suitable but too well, with placement on inactive status and continued follow-up with the referring physician; (3) potentially reversible relative contraindication, with treatment and recategorization at a later date; and (4) absolute contraindication, with denial of transplantation. Patients who are approved for liver transplantation are then listed for a donor organ with the United Network for Organ Sharing (UNOS), and final approval by the insurance carrier or third party payer is sought.

Allocation of Donor Organs

In the current UNOS system, patients with fulminant liver failure receive the first priority for available organs. The MELD score (see Table 156-2 in Chapter 156) was adopted by UNOS in 2002 as the severity measure to determine priority for transplantation and allocation of organs to patients with end-stage liver disease (Table 157-4). Recent data indicate that lower serum sodium levels also independently predict higher mortality over and beyond MELD scores alone, but serum sodium has not been included in the formula used to allocate organs.

Contraindications to Liver Transplantation

Absolute Contraindications

The list of absolute contraindications to transplantation is short: advanced cardiopulmonary disease, active untreated sepsis, extrahepatic malignancy, anatomic abnormality precluding transplantation, active alcohol or substance abuse, and documented poor compliance with medical care. In addition, patients should not undergo liver transplantation if they have compensated cirrhosis (Child's class A; Chapter 156) and no history of portal hypertensive bleeding. Patients are not candidates for liver transplantation if they have poor ventricular function or severe valvular heart disease. Coronary artery disease, if anatomically reversible by angioplasty or bypass surgery, is not a contraindication to listing if left ventricular function is adequate.

Nearly 50% of liver transplantation candidates have abnormal arterial oxygenation, but only patients with advanced chronic obstructive pulmonary disease or pulmonary fibrosis are precluded from liver transplantation. Previous tuberculosis is not a contraindication to liver transplantation. The

TABLE 157-4 RELATIONSHIP BETWEEN MELD SCORE AND 3-MONTH MORTALITY IN HOSPITALIZED CIRRHOTIC PATIENTS

MELD SCORE	NO. DEATHS/TOTAL NO. OF PATIENTS	MORTALITY RATE (%)
≤9	6/148	4
10-19	28/103	27
20-29	16/21	76
30-39	5/6	83
≥40	4/4	100

MELD = Model for End-Stage Liver Disease.
Adapted from Wiesner RH, McDiarmid SV, Kamath PS, et al. MELD and PELD: application of survival models to liver allocation. *Liver Transpl.* 2001;7:567-580.

benefits of treating latent tuberculosis before liver transplantation appear to outweigh the risks, providing justification for the strategy of performing a skin test and treating with isoniazid if positive. Active tuberculosis should be treated for at least 2 to 3 weeks and preferably for several months before liver transplantation and for up to 1 year afterward. Hepatopulmonary syndrome (Chapter 156), which is diagnosed on the basis of the triad of chronic liver disease with portal hypertension, intrapulmonary vascular dilation with right-to-left shunting, and arterial hypoxemia, may be reversed by liver transplantation. By contrast, portopulmonary hypertension is associated with high operative mortality; for example, patients with a mean pulmonary artery pressure of 50 mm Hg or greater have a postoperative mortality rate that approaches 100%. Conversely, patients with mean pulmonary artery pressures lower than 35 mm Hg do not have increased perioperative mortality.

Active untreated infection should be controlled before proceeding with liver transplantation. In the setting of spontaneous bacterial peritonitis, most programs defer transplantation until antibiotic treatment has been administered for 48 hours and resolution of infection is documented on repeat paracentesis. Sepsis and pneumonia remain absolute contraindications to liver transplantation. Serious chronic infections such as osteomyelitis, chronic fungal diseases, and abscesses preclude transplantation unless they can be treated effectively. Selected HIV-positive patients are currently undergoing liver transplantation in a few centers in the United States to determine whether the benefits outweigh the risks.

Liver transplantation is not performed in the presence of extrahepatic malignancy, except perhaps for patients with isolated liver metastases from slow-growing neuroendocrine tumors (Chapter 201), such as gastrinoma, insulinomas, glucagonomas, somatostatinomas, and carcinoid tumors. The results of liver transplantation are so poor with cholangiocarcinoma (Chapter 158) that most centers consider this diagnosis to be an absolute contraindication, although a few centers have demonstrated acceptable tumor-free survival rates when liver transplantation is combined with adjuvant chemotherapy and radiation in highly selected patients.

Most programs accept patients with alcoholic liver disease as candidates for liver transplantation only after proven alcohol abstinence for at least 6 months and completion of an inpatient or outpatient rehabilitation program. Isolated portal vein thrombosis, previously considered an absolute contraindication, is only a relative problem in light of novel reconstructive innovations, including thrombectomy or jump grafts.

Relative Contraindications

Patient selection should be based on an assessment of biologic age and absence of major systemic illnesses rather than an arbitrary chronologic age cutoff. Patients undergoing evaluation for liver transplantation may have hepatorenal syndrome, chronic renal failure, or reversible acute renal failure that may be related to intercurrent events such as spontaneous bacterial peritonitis, gastrointestinal bleeding, or excessive diuresis; however, these conditions are not contraindications to transplantation. Chronic renal failure secondary to intrinsic kidney disease is not a contraindication to liver transplantation but necessitates consideration for combined liver and kidney transplantation. Transient deterioration in renal function due to an acute injury usually is not a problem unless it is complicated by the development of hepatorenal syndrome, which is reversible only if urgent liver transplantation can be performed.

THE TRANSPLANTATION PROCEDURE

Donors and recipients are matched according to blood type and body size. In general, organs are transplanted into recipients in keeping with standard ABO compatibility rules. Most surgeons believe that a satisfactory size match exists if the donor's and recipient's body weights are within 20% of one another. The donor organ is harvested according to standard protocols to ensure that the physiologic condition of the donor is close to normal when the organ is removed and to limit warm ischemia time. The cold ischemia time while the organ is in a preservation solution is also kept as short as possible—the usual goal is less than 12 hours—to minimize the risk for delayed graft function or nonfunction.

The recipient undergoes bilateral subcostal incision with upper midline extension. The standard hepatectomy includes removal of both the vena cava and the liver, often with use of a pump-driven venovenous bypass to return the inferior vena cava and portal venous flow to the heart through the axillary vein. A popular alternative method is to preserve the retrohepatic vena cava during hepatectomy. After hepatectomy, the donor liver is put in place, with repair of the inferior vena cava if it was interrupted, portal reperfusion, hepatic arterial reconstruction, and, finally, duct-to-duct reconstruction of the common bile duct. A Roux-en-Y choledochojejunostomy is used when a duct-to-duct anastomosis is not suitable, such as in patients who have primary sclerosing cholangitis, in whom the diseased common bile duct is removed in its entirety.

Evolving Approaches to Liver Transplantation

The growing discrepancy between the number of available organs and the need for transplantation has led to increasing application of novel approaches to liver replacement, including deceased donor split-liver transplantation and adult living donor liver transplantation. Xenotransplantation and hepatocyte transplantation are investigational.

Split-liver transplantation allows two liver transplants from a single deceased donor liver, usually a right lobe implanted into an adult recipient and left lobe or left lateral segment implanted into a pediatric recipient. This technique has the potential to provide grafts to most listed pediatric patients and to decrease substantially the waiting time for adult patients.

Living donor liver transplantation uses the left lateral segment for adult-to-child donation, with a very low risk to the adult donor, who usually is a parent. Good results also have been achieved in recent years with elective adult-to-adult living donor liver transplantation grafting the right lobe (segments 5 to 8), which represents 60 to 65% of the liver, into the recipient. Advantages of living donor liver transplantation include thorough donor screening, optimization of the timing of transplantation, and minimal cold ischemia time. This operation has also been applied to urgent cases with good outcomes. Patients with small hepatocellular carcinomas and those with primary sclerosing cholangitis at risk for cholangiocarcinoma are excellent candidates for a timely living donor liver transplantation. Unfortunately, adult-to-adult living donor liver transplantation is just a partial solution to the donor shortage for adult liver transplantation because only about 15% of potential donors are satisfactory candidates after complete evaluation, and most liver transplantation centers do not routinely pursue this option. The morbidity and mortality rates for the donor average 15 to 30% and 0.3 to 0.5%, respectively, making the operation formidable and necessitating careful informed consent from the donor.

POST-TRANSPLANTATION MANAGEMENT

Allograft dysfunction is the most important complication after liver transplantation. Liver biopsy is critical in differentiating the various causes of dysfunction because many of them share similar but nonspecific clinical and biochemical presentations. Diagnostic evaluations may also include a cholangiogram and duplex ultrasound of the vessels supplying the liver.

Standard Medical Therapies

In general, all patients receive corticosteroids in large intravenous doses during the operation. Steroid doses are rapidly reduced over 5 days and can be discontinued by 3 to 12 months after transplantation in many patients, depending on the underlying disease and the presence or absence of rejection. Either cyclosporine or tacrolimus is initiated at the time of liver transplantation and is used long-term in most patients to prevent acute and chronic allograft rejection. Immunosuppression can be prednisone and a calcineurin agent (cyclosporine or tacrolimus) with early withdrawal of

corticosteroids (from 14 days to 3 months after transplantation) followed by use of a calcineurin agent alone. Alternatively, a three-drug regimen (daclizumab, mycophenolate mofetil, and tacrolimus) may reduce rejection and avoid steroid side effects.[2] In patients with renal dysfunction, calcineurin-sparing regimens using mycophenolate mofetil with lower doses of a calcineurin agent or sirolimus alone are used. Calcineurin-sparing regimens reduce the incidence of late renal failure, which approaches 15 to 20% by 20 years after transplantation. Immunosuppressive drugs are typically titrated to therapeutic or slightly subtherapeutic blood levels, but different drug strategies are used in different centers. Other routine medications after liver transplantation include those used for preemptive prevention of viral and fungal infection (see later discussion).

Early Complications after Liver Transplantation

Problems that may occur in the first few days after liver transplantation include hepatic artery thrombosis, portal vein thrombosis, primary graft nonfunction, and hyperacute rejection. Hepatic artery thrombosis, which occurs in about 2 to 8% of adults and in 3 to 20% of children who undergo liver transplantation, is more common among patients who receive sirolimus. Hepatic artery thrombosis typically manifests early after transplantation as fulminant liver failure; occasionally, it occurs 1 to 2 months after transplantation and manifests with stenosis or intimal hyperplasia with eventual rearterialization from collaterals. Early hepatic artery thrombosis is first treated by immediate revascularization through thrombectomy or use of a surgical conduit, but it often requires urgent retransplantation. Hepatic artery stenosis without thrombosis is usually associated with multiple ischemic biliary strictures and manifests somewhat later. Retransplantation is indicated if biliary sepsis or graft failure develops.

Portal vein thrombosis complicates only 1 to 3% of liver transplantation cases. Early acute portal vein thrombosis leads to fulminant liver failure and requires immediate revascularization or urgent retransplantation. Conversely, late portal vein thrombosis manifests as portal hypertension.

Primary graft nonfunction, or delayed ischemia-reperfusion injury, is the most common cause of graft loss within the early postoperative period after a technically successful liver transplantation. The clinical presentation resembles that of fulminant liver failure, with persistent or new hepatic encephalopathy and elevated serum aminotransferase levels (>2500 IU/L).

Initial poor graft function is characteristic of a marginally functioning graft that typically recovers adequate function days to weeks after transplantation. This syndrome has a milder clinical presentation than primary nonfunction, and serum aminotransferases are usually less than 2500 IU/L. Treatment is largely supportive, and most grafts eventually recover.

Acute and Chronic Allograft Rejection

The most common cause of allograft dysfunction after the first postoperative week is acute cellular rejection, which occurs overall in one half to two thirds of cases and is seen within 5 to 30 days of transplantation. The incidence of acute rejection with the use of low-dose prednisone, tacrolimus, and mycophenolate mofetil is 25 to 30%. An acute rejection episode occurring beyond 6 weeks after transplantation should raise suspicion for a subtherapeutic immunosuppressive regimen or for noncompliance with the medical regimen. The patient is usually asymptomatic and presents with increases in serum bilirubin, alkaline phosphatase, and γ-glutamyltransferase in the early post-transplantation course and with predominant elevations in the serum aminotransferases if acute rejection occurs several weeks after transplantation. However, recipients may also present with fever, malaise, abdominal pain, or portal hypertensive changes such as ascites. Histologic examination reveals a mixed portal or periportal inflammatory infiltrate (with neutrophils, eosinophils, plasma cells, and lymphocytes) leading to destructive suppurative cholangitis and endotheliitis. Treatment, which reverses 65 to 85% of episodes, consists of high-dose intravenous corticosteroids, usually 1 g of methylprednisolone, followed by oral prednisone with a rapid taper over 7 days.

Chronic ductopenic rejection now occurs in 2 to 3% of patients, most commonly between 6 weeks and 6 months after transplantation. Cholestatic enzymes, such as alkaline phosphatase and γ-glutamyltransferase, gradually increase for weeks to months before the onset of jaundice that signals the late stage of chronic ductopenic rejection. Histologic evaluation reveals sparse lymphocytic portal inflammation but progressive loss of interlobular and septal bile ducts in at least half of the portal tracts—a condition known as vanishing bile duct syndrome. Approximately 10 to 20% of retransplantations are done because of chronic ductopenic rejection.

Biliary Complications after Liver Transplantation

The biliary tree has very poor regenerative and reparative capacity when damaged and is the most common site for technical complications after transplantation. Biliary complications occur in 10 to 25% of all recipients, with more than two thirds of cases diagnosed within 1 month and 80% within 6 months after transplantation. Causes of biliary complications include technical factors, preservation injury, hepatic artery thrombosis, immunologic factors, and infection, particularly with CMV. Bile leaks and strictures are the most common presentations of biliary complications in the first 3 months after surgery.

Choledochocholedochostomy and choledochojejunostomy are the two methods of primary biliary reconstruction in liver transplantation. The more commonly performed choledochocholedochostomy, or duct-to-duct anastomosis, preserves the sphincter of Oddi and endoscopic access to the biliary tree after transplantation. Choledochojejunostomy, or Roux-en-Y anastomosis, is used for retransplantation, for transplantation of small liver grafts, and in patients with intrinsic disease of the extrahepatic bile ducts, such as primary sclerosing cholangitis.

Bile leakage occurs in up to 25% of all recipients and can be diagnosed by cholangiogram or biliary scintigraphy if the leak is sufficiently large. Patients may present with fever, abdominal pain, peritonitis, hypotension, or sepsis with biloma. For patients who suffer from bile leak after T-tube removal, endoscopic placement of a nasobiliary drain or internal plastic stent allows the leakage to heal as the bile flows preferentially through the ampulla. Surgical creation or revision of choledochojejunostomy should be performed only after failure of endoscopic or radiologic interventions.

Anastomotic biliary stricture, which affects 4 to 10% of all recipients, occurs within the first 6 months after transplantation. Clinical presentation is typical of cholangitis but may be asymptomatic, with only elevation of cholestatic enzymes (predominantly alkaline phosphatase and γ-glutamyltransferase). Balloon dilation or stenting endoscopically or radiologically should be attempted before resorting to surgery. Nonanastomotic biliary strictures, affecting up to 20% of all recipients, occur within the first 4 months after transplantation. The biliary strictures are usually multiple and may be associated with extrahepatic and intrahepatic bile leaks. Management of these strictures depends on their number, location, and severity, as well as liver function. Diffuse strictures in the setting of bile leakage and biloma indicate the need for retransplantation. Focal intrahepatic strictures may benefit from repeated sessions of balloon dilation and stenting performed endoscopically or radiologically.

Infections

Most infections occur within the first 2 months after transplantation, whereas recipients are receiving a high-dose induction immunosuppressive regimen. Bacteria and fungi cause more than 90% of infections during this period. Pneumonia, urinary infection, intra-abdominal and hepatic abscesses, peritonitis, wound infection, and line sepsis are the most common infections. *Candida albicans* is the most common infecting fungal agent in the immediate post-transplantation period. Other frequently seen fungi include *Aspergillus fumigatus* and non-*albicans Candida* species. Despite its nephrotoxicity, amphotericin B is the treatment of choice for invasive fungal infections. Oral fluconazole, 100 mg daily, prevents most fungal infections and is the standard antifungal prophylaxis used for the first 6 weeks after transplantation.

The routine use of trimethoprim-sulfamethoxazole prophylaxis, one single-strength tablet (80/400) daily or one double-strength tablet three times weekly for 3 to 12 months, has made infection with *Pneumocystis jirovecii* (formerly *P. carinii*) rare in liver transplant recipients. Inhalational pentamidine, 300 mg every 4 weeks, and oral dapsone, 50 to 100 mg daily, are alternative prophylactic regimens for patients who are allergic to sulfa. Prophylaxis is administered for 3 months to 1 year after transplantation but should be extended for an extra year if the patient received additional high-dose immunosuppressants (e.g., steroid boluses, muromonab-CD3, increased tacrolimus) during the first year after transplantation.

CMV infection and disease are less common than in the past but remain a risk after liver transplantation. Prophylaxis with acyclovir, ganciclovir, or valganciclovir is effective and reduces mortality[3]; oral valganciclovir (900 mg daily) is most commonly used for the first 3 months after transplantation. Prophylaxis with oral acyclovir (200 mg daily) or valganciclovir is also a useful preventive strategy against the reactivation of oral or genital herpes simplex virus in the first 3 months after transplantation. Reactivation of

varicella-zoster virus may manifest as localized dermatomal vesicles or, in patients who were seronegative before transplantation, as cutaneous and visceral dissemination; treatment is with high-dose acyclovir (800 mg four to five times daily for 5 to 7 days).

By 6 months after liver transplantation, recipients who have normal allograft function and are receiving standard doses of immunosuppressive drugs share the same risks as immunocompetent hosts for community-acquired infections and are not at increased risk for opportunistic infections. Conversely, recipients who have been receiving high-dose immunosuppressive drug regimens for antirejection therapy continue to be at high risk for life-threatening opportunistic infections.

Long-Term Follow-up

Long-term management after liver transplantation requires continuing communication and cooperation between the transplantation center and the primary care physician. Patients require careful routine medical management, screening for malignancy, and immunization updates and boosters.

Hypertension

Hypertension (Chapter 67) occurs in two thirds of all liver transplant recipients and is related to cyclosporine and tacrolimus, which cause vasoconstriction in the systemic and renal vasculature, and corticosteroids, which result in sodium retention, increased plasma volume, and weight gain. Management of hypertension in these patients follows a stepwise approach. Dietary sodium restriction, resumption of physical activity, and weight reduction are the first steps. Because of the pathophysiology of vasoconstriction, calcium-channel blockers are the drugs of first choice. The preferred calcium-channel blockers belong to the dihydropyridine class, such as nifedipine. Verapamil, diltiazem, and nicardipine are also effective, but they increase the drug levels of cyclosporine and tacrolimus. Second-line antihypertensive agents include diuretics, β-blockers, and α-adrenergic blockers. Angiotensin-converting enzyme inhibitors should be used with caution because they can aggravate hyperkalemia and, in rare instances, exacerbate leukopenia. Hypertension may improve with time as corticosteroids are discontinued and the dose of cyclosporine or tacrolimus is lowered.

Diabetes Mellitus

Diabetes mellitus (Chapter 237) develops in up to one third of liver recipients after transplantation, with most cases being insulin dependent. The pathogenesis is multifactorial, including genetic predisposition and use of tacrolimus, cyclosporine, and corticosteroids. Steroid tapering is the key to management of early post-transplantation hyperglycemia. Management is otherwise similar to that for the nontransplanted population.

Hyperlipidemia

Hyperlipidemia (Chapter 213) develops in approximately one fourth of all liver transplant recipients. The management of hyperlipidemia includes appropriate dietary restrictions of fat and carbohydrate, weight reduction, regular exercise, and smoking cessation. The preferred medication for patients with resistant hyperlipidemia is 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors.

Bone Mineral Density

Bone mineral density decreases during the first few months after transplantation but eventually regains its preoperative level. Fractures most frequently involve trabecular bones such as the vertebrae and the ribs. *Osteonecrosis* or *avascular necrosis* of the hips and, less often, the knees and the humerus bones, may occur. Contributing risk factors to bone disease include preexisting osteopenia, prolonged bed rest, malnutrition, corticosteroids, cyclosporine, tacrolimus, furosemide, and the original diagnosis of primary biliary cirrhosis or primary sclerosing cholangitis with associated metabolic osteodystrophy. Management includes regular exercise and pharmacologic therapies such as calcium supplementation, vitamin D derivatives, and bisphosphonates (Chapter 251).

Cancer

Skin cancer (Chapter 210) is the most common malignancy occurring in the setting of solid-organ transplantation and immunosuppression. Squamous cell carcinoma is more common than basal cell carcinoma or malignant melanoma in this population, and some recipients develop hundreds of squamous cell carcinomas. Patients should seek medical attention if they have a skin growth that bleeds or crusts, increases in size or thickness, or changes in color or texture. Sunscreen with a sun protection factor of at least 15 is recommended. Patients should undergo at least annual skin examinations depending on their previous history of skin cancers.

Colon cancer (Chapter 199) is a common de novo neoplasia after transplantation. Colonoscopic surveillance with multiple biopsies every 6 months for the first 2 years after transplantation, followed by annual examinations, has been recommended for high-risk patients with ulcerative colitis.

If not given before liver transplantation, hepatitis A, hepatitis B, and pneumococcal vaccines (Chapter 17) should be given. Other immunizations include influenza vaccine annually and tetanus toxoid booster every 5 years. Vaccines based on live or attenuated microorganisms should be avoided, including those for measles, mumps, rubella, chickenpox, polio, and bacille Calmette-Guérin (BCG).

DISEASES OF THE GALLBLADDER AND BILE DUCTS

NEZAM H. AFDHAL

THE BILIARY SYSTEM

Definition

The biliary tract consists of the intrahepatic biliary canaliculus; the small, medium, and large intrahepatic bile ducts; the common bile duct; the gallbladder; the cystic duct; and the ampulla of Vater. The primary functions of the biliary system are secretion and storage of bile salts that solubilize intestinal lipids, excretion of cholesterol to maintain cholesterol homeostasis, excretion of excess bilirubin, and excretion of organic ions, including drug metabolites.

CHOLESTASIS

PATHOBIOLOGY

Cholestasis is the systemic retention of biliary constituents as a result of failure of formation and flow of bile (Table 158-1). In the liver, hepatocytes are organized into cribriform, anastomosing plates along the sinusoids. At the apical pole, between adjacent hepatocytes, is the 1- to 2-μM biliary canaliculus or space. Each hepatocyte can have multiple canaliculi (up to three), which are characterized by microvilli that protrude into the canalicular lumen. Bile consists of water, electrolytes, and organic solutes (Table 158-2). It is continuously modified both by the cholangiocytes that line the bile ducts and by the gallbladder mucosa; therefore, gallbladder bile is markedly different from hepatic bile. The gallbladder mucosa absorbs water and concentrates bile, so the total lipid content of gallbladder bile is much higher than that of hepatic bile (10 vs. 3 g/dL, respectively).

TABLE 158-1 CAUSES OF CHOLESTASIS

EXTRAHEPATIC	INTRAHEPATIC
Choledocholithiasis	Viral hepatitis
Bile duct stricture	Alcoholic hepatitis
Cholangiocarcinoma	Drug induced
Pancreatic carcinoma	Ductopenia syndromes
Chronic pancreatitis	Primary biliary cirrhosis
Papillary stenosis	Benign recurrent intrahepatic cholestasis
Ampullary cancer	Byler's disease
Primary sclerosing cholangitis	Primary sclerosing cholangitis
Choledochal cysts	Alagille's syndrome
Parasites (e.g., *Ascaris, Clonorchis*)	Sarcoid
Acquired immunodeficiency syndrome (AIDS) cholangiopathy	Lymphoma
Biliary atresia	Postoperative
Portal lymphadenopathy	Total parenteral nutrition
Mirrizzi's syndrome	α_1-Antitrypsin deficiency

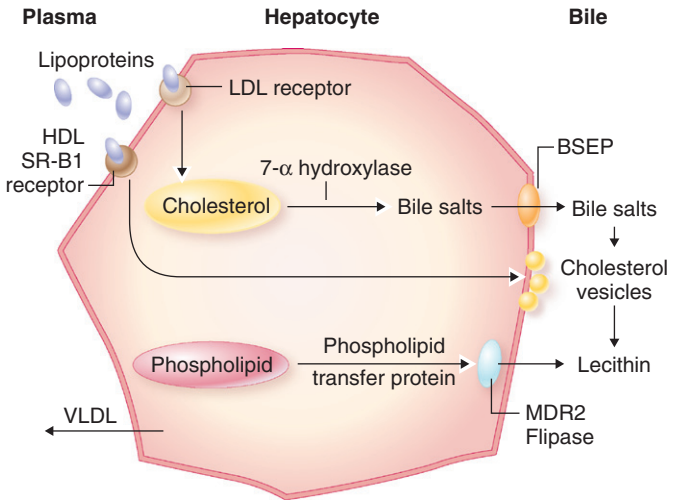

FIGURE 158-1. Schematic diagram of the metabolism of phospholipid and cholesterol by the hepatocyte. BSEP = bile salt export pump; HDL = high-density lipoprotein; LDL = low-density lipoprotein; MDR2 = multidrug resistant receptor 2 (a phospholipid lipase highly selective for phosphatidylcholine or lecithin); VLDL = very low density lipoprotein.

TRANSPORTER NAME	GENE CODE	SUBSTRATE	ASSOCIATED HEREDITARY DISEASE
FIC1	*ATP8B1*	?	PFIC type 1 (Byler's disease)
BSEP	*ABCB11*	Bile salts	PFIC type 2
MDR3	*ABCB4*	Phosphatidylcholine	PFIC type 3
MDR1	*ABCB1*	Amphipathic drugs	
MRP2 (cMOAT)	*ABCC2*	Anionic neutral drugs	Dubin-Johnson syndrome
ABCG5/ABCG8	*ABCG5/8*	Cholesterol	Sitosterolemia

ATP = adenosine triphosphate; BSEP = bile salt export pump; cMOAT = canalicular multispecific organic anion transporter; MDR = multidrug-resistant receptor; MRP2 = multidrug resistance-associated protein 2; PFIC = progressive familial intrahepatic cholestasis.

The major primary bile acids are cholic and chenodeoxycholic acid. The secondary bile acids, lithocholic and deoxycholic acids, which are derived from the intestinal breakdown of primary bile acids, are more hydrophobic, increase in cholestasis, and can be toxic to hepatocytes. Amidation with glycine or taurine results in the formation of bile salts that are preferentially secreted into bile. Bile salts are amphophilic detergent-like molecules synthesized from cholesterol via a pathway dependent on either 7α-hydroxylase or sterol 27-hydroxylase. Bile salt synthesis accounts for approximately 50% of the liver metabolism of cholesterol. Bile salts are secreted into the canalicular space by an energy-dependent bile salt export pump (Fig. 158-1). In the canalicular membrane, bile salts exist as simple (bile salt only) or mixed (with phosphatidylcholine and cholesterol) micelles and are transported into the gallbladder. A fatty meal results in contraction of the gallbladder, with expulsion of bile salts into the duodenum, where they form micelles with intraluminal fat. About 95% of bile acids are absorbed by a sodium-dependent bile acid transporter in the terminal ileum. The total bile acid pool is circulated four to six times per day, and the volume of biliary secretion is approximately 1 L/day. The major phospholipid in bile is phosphatidylcholine, also called lecithin. Phosphatidylcholine in bile is derived from newly synthesized hepatic phosphatidylcholine, which is then transported through the hepatocyte by a phosphatidylcholine transfer protein and delivered to the multidrug resistance receptor 3 (MDR3), a phosphatidylcholine-specific transporter for final secretion into bile (see Fig. 158-1). All biliary lipids, including cholesterol, are secreted in a controlled manner by adenosine triphosphate (ATP)–binding cassette transporters (Table 158-3).

CLINICAL MANIFESTATIONS

The clinical manifestations depend on the location and cause of the obstructive process and the degree to which an associated increase in pro-inflammatory cytokines decreases bile salt synthesis and secretion. Intrahepatic cholestasis is usually the result of either hepatocellular dysfunction or injury to the small and medium bile ducts secondary to viruses, alcohol, or drugs.

Bile salt retention can lead to an excess of hydrophobic bile salts, such as deoxycholate, which are hepatotoxic. These retained bile salts can overflow out of the liver and lead to increased levels of bile salts in the serum and skin; the clinical manifestation is pruritus. Excess cholesterol is deposited in all tissues, particularly as tendinous xanthomas and periorbital xanthelasmas, but clinically significant atherosclerosis is uncommon.

In cholestasis, concentrations of intestinal bile salts are inadequate to solubilize dietary lipids; the result is the excretion of excess nonabsorbed fat. Long-chain dietary fats also irritate the colonic mucosa. Steatorrhea is suggested by the presence of stainable fat in stool and confirmed by quantitative analysis of a stool collection.

Because malabsorption of the fat-soluble vitamins A, D, E, and K can result in deficiency syndromes, fat-soluble vitamins and essential fatty acids should be given as dietary supplements. The combination of osteomalacia and osteoporosis is a serious consequence of cholestasis and chronic liver disease.

DIAGNOSIS

In pure cholestasis, alkaline phosphatase and γ-glutamyltransferase levels are elevated significantly, whereas aminotransferase levels are normal or only mildly increased (Chapter 149). Bilirubin may be elevated but can be normal even in severe intrahepatic cholestasis until the very late stages of disease. Dilation of the intrahepatic ducts on ultrasonography (US) suggests extrahepatic obstructive cholestasis.

TREATMENT

Rx

Therapy should attempt to remove the cause of cholestasis, such as bypassing an obstructing pancreatic cancer (Chapter 200) with surgery or a stent. In the progressive cholestasis of intrahepatic biliary disease (e.g., primary biliary cirrhosis [PBC]), liver transplantation (Chapter 157) may be the only recourse.

Bile acid binders or sequestrants, such as cholestyramine, can lower the bile acid concentration but are associated with bloating and constipation (Table 158-4). Replacement of hydrophobic bile salts with hydrophilic bile salts, such as ursodeoxycholic acid (UDCA), treats all forms of intrahepatic cholestasis and the associated pruritus. The sensorineural pathway can also be blocked by using opioid antagonists such as naloxone and naltrexone, but care must be taken to avoid the risk for opioid withdrawal syndrome. Hepatic enzyme inducers such as phenobarbital and rifampicin have also been used successfully to treat pruritus. Rifampicin may induce drug-metabolizing transporters, resulting in increased excretion of pruritogens, but with a risk of hepatotoxicity. In some cases of intractable pruritus, marijuana or its synthetic form dronabinol (Marinol) has been useful in controlling symptoms. Finally, for situations such as the intractable pruritus of biliary cirrhosis, liver transplantation is the only option.

Supplementation with calcium, 1500 mg/day, plus vitamin D is essential. If bone density scans show osteopenia, therapy with bisphosphonates should be instituted (Chapter 251).

BILIARY TRACT DISEASES

Lesions of the intrahepatic and extrahepatic biliary tree, including the ampulla of Vater, are rare.

Biliary Atresia

Biliary atresia is a fibro-obliterative process that affects the perinatal bile ducts from the hilar bifurcation to the duodenum in 1 in every 13,000 live births in the United States. Associated genetic abnormalities in 25% of cases include polysplenia, anomalies of the portal vein and hepatic artery, abdominal situs inversus, intestinal malrotation, and cardiovascular and urinary tract anomalies. The clinical findings consist of jaundice with acholic stools persisting for 2 weeks after birth. The diagnosis can be suspected by endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) but is usually confirmed by laparotomy. Surgical correction by portoenterostomy should be performed within the first 60 days of life. About 80% of children grow normally through the first years of life, but subsequent stenosis of the anastomosis, with progressive biliary cirrhosis and liver failure, is common and is an indication for liver transplantation.

TABLE 158-4 CLINICAL FEATURES OF AND THERAPY FOR CHOLESTASIS

CLINICAL SYNDROME	TREATMENT
Pruritus	Bile salt binders (e.g., cholestyramine), ursodeoxycholic acid, rifampicin, naltrexone, carbinoids, phenobarbital
Hypercholesterolemia	Bile salt binders (e.g., cholestyramine) Statins—poor effect
Malabsorption	Medium-chain triglycerides, fat-soluble vitamins (A, D, E, K), essential fatty acids
Osteopenia	Calcium, vitamin D, bisphosphonates

Choledochal Cysts

Choledochal cysts are congenital ductal ectasias involving either a segment of the biliary tree or its entirety. The incidence is 1 per 13,000 live births in the United States, but it is 13 times higher in Japan and other parts of Asia. There is a four-fold greater prevalence in females, and choledochal cysts are associated with an abnormal pancreatic ductal junction and congenital hepatic fibrosis. The usual clinical manifestation is a right upper quadrant mass, jaundice, and pain. Acute pancreatitis, cholangitis, variceal hemorrhage, and cyst rupture are alternative findings. The diagnosis is usually made by imaging studies, including US, computed tomography (CT), MRCP, and ERCP. Therapy is generally surgical excision of the cyst with a Roux-en-Y hepaticojejunostomy because of the high (3 to 26%) incidence of malignant transformation of the cysts into cholangiocarcinoma. When there is extensive intrahepatic ductal dilation (Caroli's disease), recurrent cholangitis and intrahepatic stones are common, and liver transplantation is the optimal therapy.

Oriental Cholangiohepatitis

Recurrent cholangitis with hepatolithiasis is endemic in East Asia, especially in Taiwan, where the incidence is as high as 13% in areas where infection with *Ascaris lumbricoides* (Chapter 365) and *Clonorchis sinensis* (Chapter 364) is common. These worms cause local strictures and dilation of the intrahepatic biliary tree. Biliary stasis ensues, and the bile becomes infected with bacteria that are able to deconjugate bilirubin and cause brown stones to form. Recurrent cholangitis is the usual finding, but malignant transformation to cholangiocarcinoma can also occur. The diagnosis is made by US or CT. Treatment includes intravenous fluids and antibiotics. Endoscopic stone removal plus clearance of infected biliary segments is a primary option, but surgical resection of localized segments of the liver may be necessary.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is a chronic cholestatic condition characterized by segmental fibrosing inflammation of the intrahepatic and extrahepatic bile ducts.

EPIDEMIOLOGY

The prevalence of primary sclerosing cholangitis is 1 to 6 cases per 100,000 in the U.S. population, with a male-to-female ratio of 2.3 : 1. The mean age at diagnosis is 32 to 40 years, but children can be affected.

PATHOBIOLOGY

The cause remains unknown, but primary sclerosing cholangitis is thought to be a primary autoimmune disease. Genome-wide association studies implicate loci near human leukocyte antigen (HLA)-B on chromosome 6p21 and loci not related to HLA on chromosomes 13q31, 2q35, and 3p21. Even more sophisticated technologies will likely identify specific genes and molecular pathways in the future. The disease is progressive, with the obliteration of small, medium, and large bile ducts leading to three distinct clinical syndromes: (1) cholestasis with eventual biliary cirrhosis, (2) recurrent cholangitis and large duct strictures, and (3) cholangiocarcinoma. The multiple causes of secondary sclerosing cholangitis can be accompanied by symptoms and signs indistinguishable from those of the primary form (Table 158-5).

Primary sclerosing cholangitis is associated with both ulcerative colitis and Crohn's disease of the colon (Chapter 143). Between 70 and 90% of patients with primary sclerosing cholangitis have clinical or microscopic colitis, and between 1.3 and 13% of patients with colitis have primary sclerosing cholangitis. Inflammatory bowel disease usually precedes primary sclerosing cholangitis, but in some cases the colitis is asymptomatic and is discovered by subsequent colonoscopy and biopsy. There is also a crossover syndrome between primary sclerosing cholangitis and primary autoimmune hepatitis (Chapter 151).

CLINICAL MANIFESTATIONS

The most common laboratory finding is an elevated alkaline phosphatase level, which is present in 90% of patients, and mildly elevated aminotransferase levels. The bilirubin level is initially normal in 60% of patients but increases over time and is an important prognostic factor. Autoantibodies, including antinuclear antibodies and anti–smooth muscle antibodies, are seen in 22% of patients, but a positive antimitochondrial antibody (AMA) is rare and suggests PBC. Perinuclear antineutrophilic cytoplasmic antibody (pANCA) is positive in 90% of patients with primary sclerosing cholangitis

TABLE 158-5 DISEASES ASSOCIATED WITH SCLEROSING CHOLANGITIS

PRIMARY SCLEROSING CHOLANGITIS	SECONDARY SCLEROSING CHOLANGITIS
Ulcerative colitis	Choledocholithiasis
Crohn's colitis or ileocolitis	Infections in immunocompromised patients (*Cryptosporidium, Trichosporon*, cytomegalovirus, *Cryptococcus*, visceral protothecosis)
Type 1 autoimmune hepatitis	HTLV-1-associated myelopathy Ischemic injury to the hepatic artery or arterioles Trauma Neoplasia Toxic injury Floxuridine (hepatic artery injection) Formalin injection of echinococcal cysts Congenital abnormalities Celiac sprue

HTLV = human T-lymphotropic virus.

and colitis, but pANCA is nonspecific and is also found in ulcerative colitis and in autoimmune hepatitis without primary sclerosing cholangitis.

DIAGNOSIS

The diagnosis is based on pathologic and radiologic findings, and all patients should undergo both liver biopsy and cholangiography. Large duct disease, which is diagnosed most frequently by ERCP or MRCP, includes strictures, beading, and dilation (Fig. 158-2). Liver biopsy shows an obliterative cholangitis with inflammation and characteristic periductular "onion ring" fibrosis (Fig. 158-3). As the disease progresses, ductopenia and secondary biliary cirrhosis predominate. In stage I, inflammation is confined to the portal tracts; in stage II, there is hepatitis and portal fibrosis; in stage III, bridging fibrosis appears; and stage IV is characterized by biliary cirrhosis and regenerative nodules. Associated conditions include pancreatitis (15% of patients), perihepatic lymphadenopathy, and cholangiocarcinoma (27 to 41% of patients at autopsy or transplantation).

TREATMENT

Rx

No treatment slows disease progression. Medical therapy includes treatment of cholangitis and endoscopic therapy for large strictures via balloon dilation and stent insertion. Surgery is avoided, if possible, because it increases the risk for recurrent cholangitis. Immunosuppressive therapy is not effective. In randomized trials, UDCA (15 mg/kg/day) improved bilirubin, alkaline phosphatase, and albumin levels, but it provided no definite benefit in terms of survival or time to liver decompensation. Higher doses (>20 mg/kg) have often been used, but a randomized trial suggested that doses of 28 to 30 mg/kg are not beneficial and may actually increase morbidity when compared with placebo.■

Liver transplantation (Chapter 157), which is the only potentially curative therapy, provides an actuarial survival rate of 83% at 1 year and 73% at 5 years. All patients with primary sclerosing cholangitis who undergo transplantation should be screened periodically for colon carcinoma because they have chronic colitis (Chapter 143). Recurrent primary sclerosing cholangitis after transplantation is rare and difficult to distinguish from other causes of bile duct injury. If small (<1 cm), incidental cholangiocarcinomas are found at transplantation, survival is not affected, but larger cholangiocarcinomas (>2 cm) detected during the pretransplant evaluation by CT or magnetic resonance imaging are a contraindication to liver transplantation.

Patients with primary sclerosing cholangitis should be screened for possible cholangiocarcinoma by cholangiography of strictures every 6 to 12 months, with brushings and biopsies. If cholangiocarcinoma is detected, patients should be offered surgical resection or radiation therapy (Chapter 202).

PROGNOSIS

The natural history is variable. Some patients have severe recurrent cholangitis, whereas others progress to biliary cirrhosis. The median survival until death or transplantation is approximately 12 years, with a range of up to 21 years. Actuarial survival is greater for asymptomatic patients than for symptomatic ones (10-year survival rate of 80% vs. 50%).

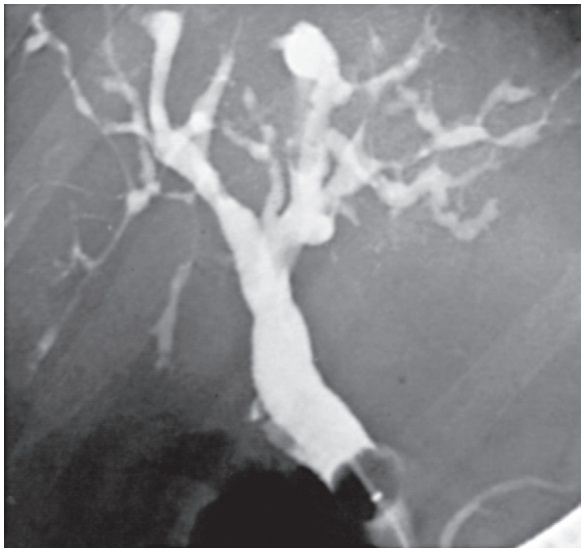

FIGURE 158-2. Endoscopic retrograde cholangiopancreatography for primary sclerosing cholangitis with contrast injected through a balloon catheter (seen in the lower common duct). The intrahepatic ducts are mainly affected and show diminished arborization (pruning); diffuse segmental strictures alternating with normal-caliber or mildly dilated duct segments (cholangiectases) have resulted in a beaded appearance. (From Mahadevan U, Bass NM. Sclerosing cholangitis and recurrent pyogenic cholangitis. In: Feldman M, Friedman LS, Sleisenger MH, eds. *Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management,* 7th ed. Philadelphia: Saunders; 2002:1137.)

Primary Biliary Cirrhosis

DEFINITION

PBC is a slowly progressive, obliterative autoimmune cholangiopathy involving the small and medium-sized bile ducts. It leads to ductopenia, progressive fibrosis, cholestasis, and liver failure.

EPIDEMIOLOGY

PBC is predominantly a disease of women (95% of cases) between the ages of 20 and 60 years. The age- and gender-adjusted prevalence has been estimated at 65 and 12 per 100,000 persons, respectively, for women and men. The incidence of the disease may be increasing, and a U.S. study estimated it at 2.7 per 100,000 person years, or 4.5 and 0.7 for women and men, respectively.

PATHOBIOLOGY

PBC is thought to be an autoimmune disorder, but the mechanism of progressive destruction of the small interlobular ducts is unknown. Genome-wide studies show an association with HLA, interleukin (IL) 12A, and IL-12RB2 variants, suggesting that IL-12 signaling might be important. Mouse models have pointed to the potential roles of IL-12Rα and transforming growth factor-βII receptor. The human disease is slowly progressive and can eventually lead to biliary cirrhosis with portal hypertension and liver

failure. The classic histologic finding is the presence of noncaseating granulomas associated with small bile ducts and an overall paucity of bile ducts in the portal tracts. The presence of significant bridging fibrosis or cirrhosis carries a worse prognosis.

CLINICAL MANIFESTATIONS

Almost 60% of patients with PBC are asymptomatic at diagnosis. The most common symptoms are fatigue (50%) and pruritus (30%). Fatigue is unrelated to the degree of underlying liver injury or cholestasis and can be extremely debilitating. Pruritus is often first noticed in pregnancy but persists after delivery, and many patients are initially referred for dermatologic evaluation.

In addition to the features of cholestasis, multiple clinical syndromes are associated with PBC and are suggestive of an autoimmune origin. Autoimmune thyroid dysfunction (Chapter 233), sicca syndrome (Chapter 276), Raynaud's phenomenon (Chapter 275), and celiac disease (Chapter 142) have all been associated with PBC. Metabolic bone disease can be particularly troublesome because of the long duration of cholestasis; bone density studies are mandatory every 2 years to guide and monitor therapy.

DIAGNOSIS

The most common biochemical abnormality is an elevation in serum alkaline phosphatase, which should be confirmed by an elevated γ-glutamyl transpeptidase and indicates cholestasis. The bilirubin level is not elevated until late in the course of the disease, and most of the elevation usually consists of conjugated bilirubin. US should be performed to image the biliary tree and confirm the absence of extrahepatic disease. AMA, which has a sensitivity and specificity higher than 95% when the titer is greater than 1 : 40, can be positive before there is any clinical or biochemical evidence of PBC. Total immunoglobulins are generally normal, but the immunoglobulin M fraction can be elevated. Liver biopsy is performed to stage the disease and occasionally to confirm the diagnosis, particularly in AMA-negative patients.

TREATMENT

Rx

UDCA therapy reduces intracellular hydrophobic bile acids and may have a cytoprotective effect on cell membranes. Although initial randomized trials showed a significant increase in survival after up to 4 years of UDCA therapy (12 to 15 mg/kg), as judged by the time to liver transplantation, a more recent meta-analysis of 16 trials showed no benefit in terms of reducing mortality or delaying liver transplantation.■ Serum bilirubin, alkaline phosphatase, and cholesterol levels improve with UDCA therapy, but treatment does not relieve the fatigue and has a variable effect on pruritus. Side effects are rare, the most common being diarrhea.

There is no definite benefit from steroids, colchicine, or azathioprine. Low-dose methotrexate (2.5 mg three times/week) has been tried, but data are insufficient to support its routine use at this time. PBC is a common indication for liver transplantation (Chapter 157), but there is considerable debate regarding the timing of transplantation.

PROGNOSIS

PBC is a progressive disease, with up to two thirds of asymptomatic patients becoming symptomatic in 2 to 4 years. Median survival is 9.3 years from diagnosis, and the most reliable determinants of prognosis are the serum bilirubin level and the Mayo risk score, a composite score that predicts clinical outcomes and is calculated as follows: R = 0.871 log(e) (bilirubin in mg/dL) + 2.53 log(e) (albumin in g/dL) + 0.039 (age in years) + 2.38 log(e) (prothrombin time in seconds) + 0.859 (edema score of 0, 0.5, or 1). Liver failure develops in 26% of patients by 10 years after diagnosis.

Vanishing Bile Duct Syndromes

Vanishing bile duct syndromes are characterized by a paucity of intrahepatic bile ducts and by eventual cholestasis and biliary cirrhosis. Causes include PBC, primary sclerosing cholangitis, autoimmune hepatitis (Chapter 151), graft-versus-host disease, chronic liver allograft rejection (Chapter 157), ischemia, intrahepatic chemotherapy, drug toxicity (e.g., ampicillin, amoxicillin, flucloxacillin, erythromycin, tetracycline, doxycycline, cotrimoxazole), human immunodeficiency virus (HIV) infection (Chapter 397), sarcoidosis (Chapter 95), idiopathic or paraneoplastic bile duct paucity, and histiocytosis. Almost all these conditions are accompanied by chronic cholestasis and elevated alkaline phosphatase levels. Treatment is for the complications of cholestasis, and UDCA (15 mg/kg) is given to increase bile flow. Most of these conditions are slowly progressive and result in biliary cirrhosis, which ultimately requires liver transplantation.

TABLE 158-6 RISK FACTORS FOR GALLSTONE DISEASE

Age
Female gender
Parity
Obesity
Rapid weight loss
Hypertriglyceridemia
Genetic (e.g., Pima Indians, Chileans)
Medications: estrogen, clofibrate, ceftriaxone, octreotide acetate (Sandostatin)
Terminal ileal resection
Gallbladder hypomotility: pregnancy, diabetes, after vagotomy
Somatostatinoma
Total parenteral nutrition
Spinal cord injury

GALLSTONE DISEASE

DEFINITION

There are three different types of gallstones: cholesterol gallstones, mixed gallstones, and pigment stones, which can be further divided into black and brown stones. Cholesterol and mixed stones account for 80% of gallstone disease in the United States. Cholesterol stones contain more than 70% cholesterol, whereas mixed stones also contain significant amounts of pigments such as bilirubin. Black pigment stones, which are generally associated with hemolytic diseases, contain calcium salts, bilirubin, and proteins. Brown pigment stones are more common in Asia, where they are associated with intrahepatic cholangitis and infection; in the United States, brown stones are seen after cholecystectomy, especially when they manifest as choledocholithiasis.

EPIDEMIOLOGY

Approximately 30 million people in the United States have gallstones, and the estimated annual cost of gallstone disease is $15 billion. In Europe, large ultrasound studies in subjects between 30 and 65 years of age have shown gallstones in 18.8% of women and 9.5% of men. In a study in which 1930 subjects were monitored for 10 years, the cumulative incidence of new stones was 4.6%.

Age is a major risk factor for gallstone disease (Table 158-6); less than 2% of cholecystectomies for gallstones are performed in children, usually because of hemolytic diseases. However, the increased prevalence of obesity in children may result in an earlier incidence of gallstone disease.

The age-adjusted female-to-male ratio for gallstone disease is 2.9 : 1 between the ages of 30 and 39 years, but it decreases to 1.2 : 1 between the ages of 50 and 59 years. Women with gallstone disease also appear to be more likely than men to undergo cholecystectomy. Pregnancy appears to be the major risk factor for gallstones in younger women, with a prevalence of 1.3% in nulliparous women versus 13% in multiparous women. Estrogen use is also associated with a higher risk for symptomatic gallstones and cholecystectomy: a relative risk of 2.1 to 3.7 versus no estrogen use. The mechanisms of increased risk include activation of estrogen α-receptor-mediated hepatic cholesterol secretion, a progesterone-induced reduction in gallbladder contraction, and a pregnancy-induced alteration in hydrophobic-hydrophilic bile salt balance.

Obesity increases the risk for gallstones as a result of enhanced cholesterol absorption, synthesis, and secretion. The risk is higher in women and in the morbidly obese, but rapid weight reduction by very low-calorie diets is also associated with gallstones. Diets high in polyunsaturated and monounsaturated fats may reduce the risk for gallstone disease.

PATHOBIOLOGY

Gallstone disease is predominantly an inability to maintain free cholesterol in solution in bile. As canalicular bile passes down the bile duct system, cholangiocytes maintain bile flow and volume by secreting chloride, bicarbonate, and water into bile. In cystic fibrosis (Chapter 89), defects in the cystic fibrosis transmembrane conductance regulator, which in the liver is found only on cholangiocytes, reduces choleresis and results in the

formation of mucous plugs, with subsequent focal biliary cirrhosis and gallstone disease.

The gallbladder, which acts as the final storage reservoir for bile, concentrates bile by removing water and thereby increasing the lipid concentration from 3 g/dL in hepatic bile to 10 g/dL in gallbladder bile. Bile salt concentrations can be as high as 300 mM and would digest the biliary epithelium if the gallbladder did not secrete mucin for protection. The gallbladder mucosa also secretes hydrogen ions to prevent calcium salt deposition and maintain a bile pH of about 6.5. A normal gallbladder ejects 10 to 20% of its contents in response to duodenal-gallbladder enteric nervous stimulation. Postprandially, duodenal lipids cause an approximately 70% contraction of the gallbladder, mediated by both the enteric nervous system and cholecystokinin. Impaired contractility is one of the critical steps in the pathogenesis of gallstones.

Genetics

Family history studies have shown that gallstones are twice as common in first-degree relatives of gallstone patients as in age- and sex-matched control subjects. In the United States, descendants of the original Amerindians have a markedly increased prevalence of gallstones, with the highest rates in female Pima Indians older than 25 years, who have a 75% prevalence of cholesterol gallstones. Amerindians in South America and Mexico also have a very high prevalence of gallstones, and these populations have the highest rate of complications of gallstone disease, such as gallbladder cancer, in the world. South Americans of Hispanic origin have much lower rates of gallstone disease.

No specific gallstone genes have been found in humans, but lithogenic genes, including the bile salt export pump gene, have been described in gallstone-susceptible mice. Human gallstone disease is probably a combination of complex multigene susceptibility and environmental factors.

Cholesterol Gallstones

Cholesterol gallstones contain 50 to 90% cholesterol and are the most common form of stones in countries where people consume a Western diet high in protein and fat. Cholesterol is an intensely hydrophobic molecule that can remain soluble in aqueous solution only as saturated micelles and vesicles in conjunction with bile salts and lecithin. Cholesterol in gallbladder bile is found in multiple phases; in the presence of cholesterol supersaturation, unstable cholesterol vesicles nucleate to form cholesterol crystals (Fig. 158-4). Nucleation is promoted by a variety of factors, including proteins and lipids.

Increased biliary secretion of cholesterol results in cholesterol supersaturation of bile. The result is excess secretion of mucus into the gallbladder, formation of a gel layer, and stasis, which causes cholesterol to nucleate and cholesterol crystals to be deposited.

Cholesterol monohydrate crystals are only several hundred micrometers in size and should easily be expelled through the cystic duct. However, the mucous sludge containing calcium salts, bilirubin, mucin, and crystals is not easily expelled by contraction of the gallbladder. Biliary sludge, also known as microlithiasis, can be seen as an echogenic, freely mobile mass in the gallbladder on US. Biliary sludge can cause the symptoms of gallstone disease, including cholecystitis, cholangitis, and pancreatitis.

Biliary sludge can resolve, persist, or progress to stones when its crystals grow to form plates, in part because of an impairment in gallbladder contractility. Cholesterol supersaturation of bile is associated with increased absorption of cholesterol by the gallbladder smooth muscle, a process that impairs smooth muscle contractility and reduces the gallbladder's response to cholecystokinin.

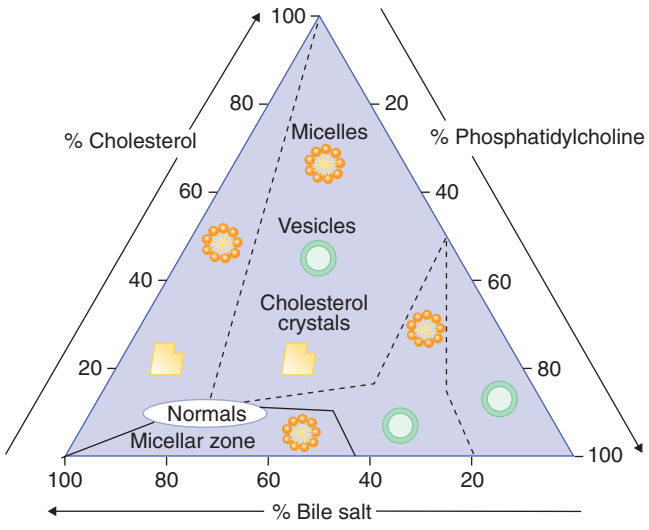

FIGURE 158-4. Equilibrium phase diagram for a lithogenic model bile system with a total lipid content of 10 g/dL.

Pigment Gallstones

Black pigment stones contain 10 to 90% calcium bilirubinate in combination with a variety of other calcium salts, such as hydroxyapatite and carbonate. These stones are common in India (40%) but rare in Minnesota (5%). Older age is associated with a higher incidence of pigment stones, as are total parenteral nutrition and hemolytic diseases.

Brown pigment stones represent 30% of gallstones in Japan and up to 90% of gallstones in rural China. They are related to low-calorie, high-vegetable diets; occur in both the biliary tract and the liver; and have a strong association with recurrent pyogenic cholangitis and cholangiohepatitis. In the United States, these stones are seen as postcholecystectomy cholelithiasis, presumably secondary to stasis and infection. Bacterial enzymes deconjugate bilirubin from its glucuronide and hydrolyze phospholipids, leading to precipitation of calcium, bilirubin, and free fatty acids. These stones, which are often soft and easy to crush endoscopically, are commonly treated by endoscopic extraction.

CLINICAL MANIFESTATIONS

The symptoms caused by gallstones are often nonspecific and include nausea, bloating, and right upper quadrant pain. Biliary pain, which is described as an intermittent right upper quadrant or epigastric pain occurring 15 to 30 minutes after a meal, often with radiation to the back, is unpredictable, severe, and usually constant rather than a true colic. The pain persists for 3 to 4 hours and may be associated with nausea and vomiting. In uncomplicated cholecystitis, fever and leukocytosis are absent, the pain can usually be adequately treated with a single dose of narcotic analgesics or nonsteroidal anti-inflammatory drugs (NSAIDs), and the pain generally subsides within 6 hours. Attacks of colic may be separated by days or months.

DIAGNOSIS

Asymptomatic Gallstones

Asymptomatic gallstones, which are frequently diagnosed by US performed for other indications, account for about 85% of gallstones. Patients with asymptomatic stones have a similar incidence of nonspecific symptoms of nausea and bloating as the general population, and complications of gallstone disease rarely develop. Biliary colic, however, is more predictive of gallstones, and it is an indicator of increased risk for cholecystitis or other complications. Because the current standard of care is to treat only symptomatic stones, it is critical to determine whether any symptoms are related to gallbladder stones.

Among patients with asymptomatic stones, biliary colic develops in about 2 to 3% annually. In the absence of antecedent symptoms, complications of gallstone disease (e.g., acute cholecystitis) develop at a rate of less than 1% per year. As a result, the recommendation is to delay cholecystectomy until after biliary colic develops, with prophylactic or incidental cholecystectomy recommended only for Amerindians, transplant recipients, or patients with sickle cell anemia, morbid obesity, an anomalous pancreatic ductal junction, porcelain gallbladder, or gallbladder polyps larger than 1 cm (see Cholecystectomy under Treatment).

Acute Calculous Cholecystitis

Acute cholecystitis, which is the most common serious complication of gallstone disease, can lead to perforation of the gallbladder, peritonitis, fistula into the intestine or duodenum with gallstone ileus or obstruction, and abscesses in the liver or abdominal cavity. Acute cholecystitis is caused by obstruction of the cystic duct, and the ensuing increased intraluminal pressure can lead to vascular compromise of the gallbladder. *Salmonella* and other less common microorganisms such as *Vibrio cholerae*, *Leptospira*, and *Listeria* can cause primary cholecystitis. Clinical differentiation of biliary colic from acute cholecystitis is difficult but can usually be made from clinical and radiologic findings (Table 158-7).

TABLE 158-7 CLINICAL FEATURES OF BILIARY COLIC COMPARED WITH ACUTE CHOLECYSTITIS

CLINICAL FINDINGS	BILIARY COLIC	ACUTE CHOLECYSTITIS
Right upper quadrant pain	Present	Present
Abdominal tenderness	Absent or mild	Moderate to severe, especially over the liver and/or gallbladder (Murphy's sign)
Fever	Absent	Usually present
Leukocytosis	Absent	Usually >11,000/μL
Duration of symptoms	<4 hr	>6 hr
Ultrasound	Gallstones	Gallstones, thickening of gallbladder wall
HIDA scan	Gallbladder visualized within 4 hr	No filling of gallbladder

HIDA = hepatobiliary iminodiacetic acid.

Blood Tests

In uncomplicated acute cholecystitis, laboratory testing usually shows leukocytosis but otherwise is not very helpful. Elevated liver enzyme levels, hyperbilirubinemia, and elevated amylase or lipase levels are not common in cholecystitis and suggest other complications of gallstone disease, such as cholangitis or pancreatitis. When acute cholecystitis is accompanied by an inflammatory mass, the gallbladder can compress the common duct and lead to bile duct obstruction (Mirrizzi's syndrome).

Imaging Studies

Right upper quadrant US noninvasively diagnoses gallstones in 95% of patients with cholecystitis (Fig. 158-5). US can also exclude common bile duct obstruction and may occasionally show bile duct stones. In cholecystitis, the gallbladder wall may be thickened, and free pericholecystic fluid may be present. Murphy's sign is also useful and can be elicited by the ultrasonographer or on physical examination. Gentle pressure is placed by the probe or hand at the border of the rectus sheath in the right upper quadrant, and the patient is asked to inspire. The gallbladder moves down with inspiration onto the examiner's hand or ultrasound probe, and the patient complains of pain when the inflamed gallbladder comes into contact with the examining hand. US can also exclude gangrenous cholecystitis with free air in the gallbladder wall, perforation, and abscess. The most specific test for acute cholecystitis is a technetium-labeled hepatobiliary iminodiacetic acid (HIDA) scan. Intravenously, HIDA is normally taken up by the liver, excreted into the biliary tract, and concentrated in the gallbladder. When a stone obstructs the cystic duct, the gallbladder fails to fill with HIDA; the sensitivity of HIDA scanning is 95%, but the specificity varies markedly and can be as poor as 50% in critically ill or jaundiced patients.

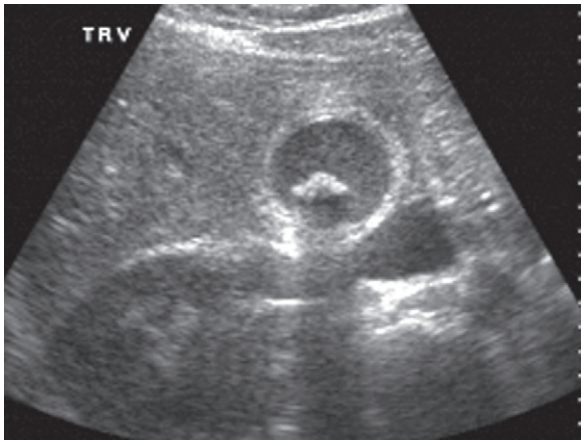

FIGURE 158-5. Ultrasound showing a gallstone.

TREATMENT

Medical Stabilization of Acute Cholecystitis

Treatment of uncomplicated acute cholecystitis is intravenous fluids, antibiotics for 7 to 10 days, and bowel rest. Antibiotic choices include ampicillin (2 g intravenously every 6 hours) and an aminoglycoside (gentamicin 5.1 mg/kg every 24 hours), but cephalosporins (ceftriaxone 1 to 2 g once daily) and ampicillin-sulbactam (1.5 to 3 g every 6 hours) can also be used. Broader coverage should be used in immunosuppressed patients, including the addition of metronidazole (500 mg every 8 hours), piperacillin-tazobactam (3.375 g every 6 hours), and levofloxacin (500 mg to 1 g once daily). Early cholecystectomy during the first hospital admission is generally recommended because it is safe and reduces total hospital stays.[4]

Cholecystectomy

Indications for cholecystectomy include biliary colic, acute and chronic cholecystitis, and acalculous cholecystitis. Diabetic patients may have fewer symptoms because of their neuropathy. As a result, their cholecystitis may be complicated more often by gangrene and perforation; however, prophylactic cholecystectomy is not recommended in patients with diabetes.

Laparoscopic cholecystectomy and small-incision cholecystectomy provide equivalent results for the treatment of gallstones,[4] with some data suggesting that small-incision cholecystectomy reduces operating time and complexity.[5,6] Most patients can be discharged a day after the procedure. A planned laparoscopic approach is changed to open cholecystectomy in only 3% of cases, usually because of difficulty identifying critical anatomic structures such as the cystic or common bile ducts.

Operative cholangiography can be performed during laparoscopic cholecystectomy, and bile duct stones can be removed concurrently or subsequently by ERCP. The incidence of unsuspected, retained common bile duct stones after laparoscopic cholecystectomy is about 2.3%.

The most serious complication of cholecystectomy is bile duct injury, which now occurs in 0.25% of cases. It is more common when the indication for surgery is acute cholecystitis, and it is less common after a surgeon has performed more than 25 laparoscopic surgeries. Bile duct injuries include cystic duct leak, laceration of the duct, complete transection of the duct, and thermal injuries to the duct. Early recognition permits primary open bile duct repair. Leakage from the cystic duct is usually recognized by jaundice, fever, and abdominal pain several days after the procedure; it can be treated successfully by ERCP, with insertion of an endoscopic stent, or by sphincterotomy.

Gallstone Dissolution Therapies

In patients who have relative or absolute contraindications to laparoscopic cholecystectomy, such as concomitant advanced cardiopulmonary or liver disease, a combination of chenodeoxycholic acid (10 mg/kg/day) and UDCA (7 to 15 mg/kg/day) or UDCA alone (15 mg/kg/day) can dissolve multiple small (<5 mm) stones in up to 60% of patients with functioning gallbladders. If CT shows the stones to be calcified, the efficacy is lower, and complete dissolution occurs in only about 10% of patients. Gallstones generally dissolve at a rate of 1 mm/month. After dissolution, gallstones recur at a rate of 10% per year for 5 years, but recurrence is unusual after that time. Continuous therapy may be necessary, thereby making this treatment unattractive except in selected patients in whom cholecystectomy cannot be performed safely.

Extracorporeal shock wave lithotripsy, which uses a focused ultrasound beam, can fragment larger stones. The fragmented stones can then be passed through the cystic duct and expelled into the common bile duct. The fragments that remain behind in the gallbladder should be treated with UDCA for dissolution. Gallstones disappear in more than 50% of patients, but they recur in 50% of successfully treated patients, particularly those with multiple stones and poorly functioning gallbladders.

Topical dissolution therapy involves the insertion of a catheter into the gallbladder under ultrasound guidance; stones are dissolved with methyl terbutyl ether or ethyl propionate. The technique is still experimental but may soon be ready for widespread testing.

Choledocholithiasis

Common bile duct stones can descend from the gallbladder or arise de novo in a tortuous, dilated common bile duct as a result of infection and biliary stasis (usually cholesterol stones), or they can occur in a postcholecystectomy patient (usually brown stones), in whom they are frequently missed at surgery (2% of cholecystectomies). The clinical findings are cholangitis, pancreatitis, or biliary obstruction; large, obstructing stones can cause jaundice.

Acute bacterial cholangitis, which is most frequently caused by common duct stones that obstruct the common bile duct and raise intrabiliary pressure, is a medical emergency (Fig. 158-6). The bile in these patients is generally infected with *Escherichia coli*, *Bacteroides*, *Klebsiella*, or *Clostridium* species, and the increase in pressure results in transient bacteremia.

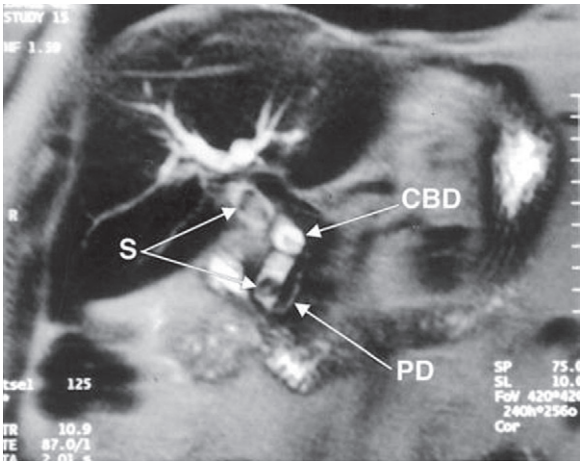

FIGURE 158-6. Magnetic resonance cholangiopancreatogram of a dilated biliary tract. The common bile duct (CBD), pancreatic duct (PD), and two large common duct stones (S) are shown.

DIAGNOSIS

Patients with bacterial cholangitis have Charcot's triad of jaundice, abdominal pain, and fever with rigors. Severe renal dysfunction and disseminated intravascular coagulation can complicate severe cholangitis. Aminotransferase, bilirubin, and alkaline phosphatase levels are usually increased. The diagnosis of common bile duct stones can be made with US, which generally shows dilated bile ducts and occasionally identifies a stone. MRCP can identify 95% of stones larger than 1 cm (see Fig. 158-6). ERCP remains the "gold standard" for the diagnosis and treatment of common bile duct stones. If cholangitis is suspected, ERCP should be performed.

TREATMENT

In patients with concomitant stones in both the gallbladder and the common bile duct, laparoscopic cholecystectomy and bile duct exploration are preferable to a two-stage procedure (ERCP extraction of the common duct stone followed by laparoscopic cholecystectomy).[2,3] For isolated common duct stones, endoscopic therapy includes sphincterotomy and stone extraction with a balloon or basket. Small (<2 cm) stones can be removed easily, whereas larger stones may be crushed with mechanical or ultrasound lithotriptors before removal. Fluids and antibiotics with broad gram-negative coverage (e.g., ceftriaxone 1 to 2 g once daily, ampicillin-sulbactam 1.5 to 3 g every 6 hours, piperacillin-tazobactam 3.375 g every 6 hours, levofloxacin 500 mg to 1 g once daily) are recommended for bacterial cholangitis. In an acutely ill patient, initial decompression of a pus-filled common bile duct with a stent may be the first-line treatment, followed by definitive endoscopic or surgical therapy. After successful endoscopic therapy, laparoscopic cholecystectomy should be performed routinely because of the high risk for recurrent biliary events.[4]

In certain situations, such as after Roux-en-Y choledochojejunostomy, ERCP may not be possible. Alternative approaches include radiologic percutaneous transhepatic cholangiography (PTC) or open exploration of the common bile duct. During PTC, the radiologist can decompress the bile ducts with catheters or stents, and the stones can be removed through the fistula tract by direct cholangiography.

Unusual Complications of Gallstone Disease

Gallstone pancreatitis (Chapter 146) is more common in patients with multiple small stones; it has also been associated with microlithiasis and biliary sludge. Patients have acute epigastric pain radiating into the back, hyperamylasemia, and an imaging study that demonstrates an edematous or necrotic pancreas. Rarely, concomitant cholangitis or jaundice can be seen if the stone is obstructive. Clinical features that suggest gallstone pancreatitis include elevated aspartate aminotransferase and alkaline phosphatase levels. Early ERCP with sphincterotomy plus stone extraction within 24 hours of suspected acute gallstone pancreatitis reduces morbidity and mortality, but in 50% of cases, the stones are not visible or have passed by the time of ERCP. After the successful treatment of common duct stones, any patient who still has a gallbladder should have it removed electively.

Vascular compromise to the gallbladder and the presence of gas-forming bacteria, which are more common in patients who have diabetes or are immunocompromised, can cause gangrenous or emphysematous cholecystitis. Clinically, patients are usually very ill with a high temperature, features of systemic sepsis, and obtundation. US may show air in the gallbladder or gallbladder wall; perforation of the gallbladder with peritonitis may then occur. Emergency cholecystectomy is required.

If a fistula develops from the gallbladder to the duodenum, stomach, or colon, a large gallstone can pass through the fistula and into the bowel. If obstruction occurs at the duodenum or the ileocecal valve, gallstone ileus occurs, with symptoms and signs of intestinal obstruction. A plain abdominal radiograph shows bowel obstruction with free air in the gallbladder or biliary tract. Treatment is generally cholecystectomy and removal of the obstructing gallstone.

PREVENTION

UDCA, 600 mg at night, markedly reduces gallstone formation in patients on low-fat, low-calorie diets. Primary prevention of cholesterol gallstones is based on dietary alteration to avoid cholesterol supersaturation (i.e., a diet rich in whole grains and roughage and low in cholesterol and saturated fats). Secondary prevention includes using bile acid therapy with UDCA to reduce cholesterol supersaturation, improving gallbladder motility with cholecystokinin analogues, and reducing mucin secretion with aspirin and NSAIDs. All these strategies have been used effectively in high-risk groups, such as patients on low-calorie diets or those maintained on total parenteral nutrition.

PROGNOSIS

Overall, the prognosis of gallstone disease is excellent for younger and otherwise healthy patients. However, with the aging population, there is a higher prevalence of complicated gallstone disease with common duct stones, cholangitis, and pancreatitis, each of which is associated with substantial morbidity and mortality.

ACUTE ACALCULOUS CHOLECYSTITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Acalculous cholecystitis is inflammation of the gallbladder or the presence of gallbladder-related symptoms in the absence of stones. Acute acalculous cholecystitis accounts for 2 to 17% of all cholecystectomies. Ischemia, infection, chemical injury by biliary contents, and obstruction of the cystic duct have all been implicated as causes (Table 158-8).

TABLE 158-8 RISK FACTORS AND ORGANISMS ASSOCIATED WITH ACALCULOUS CHOLECYSTITIS

RISK FACTORS
Fasting
Total parenteral nutrition
Septicemia, biliary infections
Major trauma
Burns
Major nonbiliary surgery
Childbirth
Multiple blood transfusions
Mechanical ventilation
Opiates
Immunosuppression—chemotherapy, HIV infection, transplantation
Diabetes
Ischemic heart disease
Malignancy
ORGANISMS IMPLICATED AS A PRIMARY CAUSE
Salmonella typhi
Vibrio cholerae
Staphylococcus
Leptospira
Listeria
Pneumocystis carinii
Mycobacterium spp
Cytomegalovirus
Candida
Ascaris
Echinococcus

CLINICAL MANIFESTATIONS

Primary infection may manifest as acute cholecystitis with unexplained fever, right upper quadrant pain, or clinical deterioration postoperatively or after transplantation, trauma to the abdomen, chemotherapy, or total parenteral nutrition. Pain, fever, leukocytosis, and abnormal liver enzyme test results are common.

DIAGNOSIS

The diagnosis is confirmed by US showing a distended gallbladder, often with a thin wall, pericholecystic fluid, or a positive Murphy's sign (see earlier) in the absence of gallstones. Sludge may be present. Intraluminal gas or bubbles, the so-called champagne sign, indicates emphysematous cholecystitis.

TREATMENT Rx

Treatment includes intravenous fluids, antibiotics as for gallstone disease, and general supportive measures. Because gangrene and perforation are more common in acalculous than calculous cholecystitis, urgent cholecystectomy is recommended. Postcholecystectomy complications such as leak, abscess, and wound infection are also more common and reflect the underlying multisystemic problems. In severely ill patients in whom cholecystectomy is contraindicated, radiologic decompression of the gallbladder via percutaneous cholecystostomy can be performed. The overall mortality associated with acute acalculous cholecystitis is 5 to 20%.

CHRONIC ACALCULOUS CHOLECYSTITIS

Chronic acalculous cholecystitis is a poorly understood clinical syndrome in which patients have symptoms of biliary colic in the absence of gallstones. The gallbladder may be normal or show changes of chronic inflammation. Cholesterolosis may also be present, with deposits of cholesterol in the mucosa and muscle layers of the gallbladder. Affected patients, who are often young and female, have abdominal pain and nonspecific symptoms such as nausea and intolerance of fatty food. Biliary dyskinesia may be diagnosed by food-cholecystokinin-stimulated US or a HIDA scan. In 80 to 90% of patients with abnormal stimulated motility, symptoms are relieved by cholecystectomy.

GALLBLADDER CANCER

Gallbladder cancer constitutes 0.76 to 1.2% of all cancers and is the most common biliary cancer, with about 7200 new cases reported in the United States each year. The highest incidence occurs in Amerindians, particularly in Chile, Mexico, and Colombia. Its incidence is also high in India, perhaps owing to the higher prevalence of pigmented gallstones. Gallbladder cancer is a disease of the elderly and is more common in women than in men. There is a strong association with cholelithiasis, chronic cholecystitis, and inflammation; 90% of patients with gallbladder cancer have concomitant stones. Patients who have a porcelain gallbladder, defined as calcification of the gallbladder wall, have a 25% risk for the development of gallbladder cancer, and patients with an anomalous pancreatic ductal junction in which the pancreatic duct drains into the lower common bile duct instead of the ampulla have an increased risk for gallbladder cancer. Both these lesions are indications for prophylactic cholecystectomy.

About 90% of gallbladder cancers are adenocarcinomas; the remainder are squamous cell or other cancers. Gallbladder cancer spreads locally, with invasion of the liver and to the local lymph nodes and peritoneal cavity. About 90% of patients have symptoms and signs suggestive of cholecystitis. Surgery, which is the only therapeutic option, can be curative when the tumor is confined to the gallbladder. Adjuvant radiation therapy and chemotherapy are not effective. The median survival for all patients with gallbladder cancer is 3 months, with a 1-year survival rate of 14% and a 5-year survival rate of 5%.

DISORDERS OF THE AMPULLA OF VATER

The ampulla of Vater is the final sphincter that controls entry of bile into the duodenum. Hormonal control of the sphincter is mediated by cholecystokinin, which causes the gallbladder to contract and the ampulla to relax. The most common disorder of the ampulla is stenosis or dysfunction after cholecystectomy, the so-called sphincter of Oddi dysfunction.

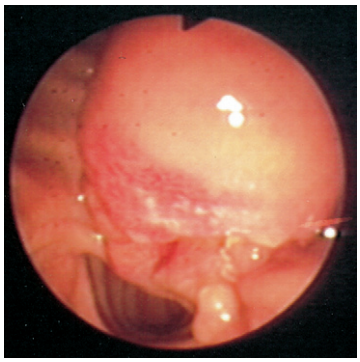

FIGURE 158-7. Carcinoma of the ampulla of Vater. The carcinoma can be seen toward the bottom of the picture. The bulging swelling above is the grossly dilated common bile duct, which is obstructed by the carcinoma. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

Sphincter of Oddi Dysfunction or Biliary Dyskinesia

In true sphincter stenosis, the sphincter is narrowed by inflammation and fibrosis secondary to pancreatitis, passage of a gallstone through the papilla, intraoperative trauma, infection, or adenoma. Sphincter stenosis can manifest as abdominal pain and pancreatitis. The common bile duct is often dilated above the stenosis, and treatment is a large sphincterotomy performed at ERCP.

In sphincter of Oddi dyskinesia, a functional disorder of the sphincter leads to intermittent biliary obstruction. Most patients have undergone cholecystectomy and are being evaluated for recurrent biliary pain or, less frequently, pancreatitis. The diagnosis is usually made by ERCP, which can demonstrate delayed excretion of contrast material. In patients who have pain associated with abnormal aminotransferase levels on two or more occasions, a dilated common bile duct, and delayed drainage of contrast material, sphincterotomy is recommended. Patients without all three of these criteria are usually given a trial of relaxants, such as nitrates or calcium-channel blockers.

Ampullary Tumors

Adenocarcinoma of the ampulla has an incidence of 3 per million. Adenomas appear as protruding ampullary lesions, may grow either inside the ampulla or into the duodenum, and can transform into adenocarcinomas (Fig. 158-7). The cancer tends to be locally invasive. Ampullary adenomas are associated with familial adenomatous polyposis (Chapter 199) and the *APC* gene: almost 80% of patients with the *APC* gene have adenomas of the ampulla, and their risk for ampullary cancer is significantly higher than that of the normal population.

The average age at diagnosis is 50 years, with a peak at 70 years; there is no gender predilection. About 80% of patients have jaundice, which is usually progressive and associated with abdominal pain and weight loss. Liver enzymes are generally abnormal, and the diagnosis is suggested by US or CT findings of dilated biliary and pancreatic ducts all the way to the ampulla. Confirmation is by endoscopy, with biopsy and brushings. Staging of the tumor, particularly for lesions growing into the ampulla, is best performed by endoscopic US. Adenomas and small cancers can be removed by endoscopic ampullectomy. The standard, recommended curative operation is pancreaticoduodenectomy (the Whipple procedure), which provides a 25 to 55% 5-year survival rate, depending on the extent of the tumor. Adjuvant chemotherapy and radiation therapy have no proven benefit in the treatment of ampullary lesions.

HEMATOPOIESIS AND HEMATOPOIETIC GROWTH FACTORS

KENNETH KAUSHANSKY

Hematopoiesis, the process by which bone marrow stem cells develop all of the cell types present in the blood, is an enormous undertaking in which approximately 4×10^{11} cells are produced each day, a number that can increase ten-fold or more in times of heightened demand. In a normal adult human 100 to 1000 multipotential stem cells undergo division each day, and after 25 to 30 cell doublings, during which time they progressively lose developmental potential, approximately 1×10^{9} cells emerge, each committed to a single blood cell lineage (erythrocyte, neutrophil, eosinophil, basophil, monocyte, platelet, T lymphocytes, B lymphocytes, natural killer cell) (Fig. 159-1). These latter, committed progenitors cells then continue to divide and differentiate into mature blood cell types through the combined action of several lineage specific and nonspecific transcription factor–induced gene expression programs. The regulation of the numbers of each cell type is carefully controlled by paracrine and endocrine hematopoietic growth factors, which exert antiapoptotic, proliferative, and differentiating effects on hematopoietic stem, progenitor, and maturing blood cells. In addition to their intrinsic scientific interest for molecular, cell, and developmental biologists, many of these glycoproteins are produced by recombinant DNA technology and have been among the most successful therapeutics in modern medicine.

HEMATOPOIETIC STEM AND PROGENITOR CELLS

Hematopoietic stem cells represent one in 10^{5} to 10^{6} marrow cells, are not morphologically distinguishable from other progenitors or small lymphocytes, but can be purified to homogeneity using physical characteristics and combinations of monoclonal antibodies to cell surface proteins. The two critical characteristics of a hematopoietic stem cell are its ability to differentiate into all blood cell types and its ability to self-renew. Although only rarely entering the cell cycle, stem cells can undergo symmetrical or asymmetrical cell division, yielding two stem cells or two differentiating progenitors, or one of each cell type, respectively. The decision to self-renew or differentiate is a stochastic process, at the stem cell stage and at the subsequent multipotent or unipotent stages of differentiation, that can be influenced by a number of cell extrinsic (growth factors and stromal proteins) and cell intrinsic (transcription factors) molecules.

HEMATOPOIETIC CELL LINEAGE DETERMINATION—HEMATOPOIETIC TRANSCRIPTION FACTORS

A large and growing number of transcription factors regulate stem cell number and differentiation state and include GATA2, SCL, LMO2, Notch, MYB, HOXB4, HOXA9, RUNX1, RBTN2, EKLF, PAX5, Ikaros, PU.1, and C/EBP. Several molecular switches have been identified that determine hematopoietic cell fate. One switch that determines whether a multipotential progenitor develops an erythroid or myeloid fate serves to illustrate the complex molecular mechanisms of hematopoiesis. GATA1 expression is restricted to erythroid-megakaryocytic progenitors and their progeny and drives the expression of proteins critical for erythrocyte and megakaryocyte function (e.g., globin and the erythropoietin and thrombopoietin receptors). PU.1 is expressed in granulocyte-monocyte progenitors and their progeny and drives the expression of genes critical for neutrophil and macrophage function (e.g., the receptors for granulocyte-macrophage colony-stimulating factor [GM-CSF] and macrophage colony-stimulating factor [M-CSF]). GATA1 also increases GATA1 expression levels and blocks the binding of PU.1 to its coactivator, c-jun. Likewise, PU.1 enhances PU.1 transcription but blocks the effect of GATA1 by inducing a repressor complex at its cognate-binding sites. Thus, because of the feed-forward enhancement of GATA1 expression and cross-inhibition of PU.1, should GATA1 levels stochastically rise higher than PU.1 in a pluripotent progenitor cell that can differentiate into either erythroid-megakaryocytic progenitors or granulocyte-monocyte progenitors, the GATA1 will quickly predominate and drive erythroid and megakaryocyte differentiation. Conversely, should PU.1 levels first rise above the levels of GATA1 in the same multipotential progenitor, the switch would close in the direction of granulocyte-monocyte differentiation. Other switches operate on other principles, such as the levels of c-Myb determining whether an erythroid-megakaryocytic progenitor assumes an erythroid (high levels) or megakaryocytic (low levels) fate.

HEMATOPOIETIC CELL EXPANSION—HEMATOPOIETIC GROWTH FACTORS

Equally important to hematopoiesis as the transcription factors is a group of acidic glycoproteins, the hematopoietic growth factors, which share structural homology and bind to nonredundant type I transmembrane proteins belonging to the cytokine receptor family. Many of these proteins are the physiologic regulators of a specific lineage of blood cells; others appear to represent redundant hematopoietic growth-promoting activities of molecules essential for other biologic functions. Erythropoietin, granulocyte colony-stimulating factor (G-CSF), and thrombopoietin serve as examples of the former; interleukin-3 (IL-3), GM-CSF, and IL-11 serve as examples of the latter class of hematopoietic growth factors.

The term erythropoietin was coined in 1905 to represent the humoral substance that regulates erythrocyte production. The hormone is produced predominantly by the kidneys, and to a lesser extent in the liver, and acts on marrow erythroid progenitors to enhance their survival, proliferation, and differentiation. Levels of erythropoietin are inversely related to hemoglobin concentrations in the blood, as reflected in renal oxygen tension. In the presence of tissue (renal) hypoxia, the transcription factor hypoxia-induced factor (HIF)1α is stabilized against proteasome-mediated destruction and drives erythropoietin transcription by binding to a critical hypoxia-responsive element located in the 3′ untranslated region of the gene. Genetic elimination of erythropoietin or its receptor results in embryonic lethality, establishing that although other cytokines can influence erythropoiesis, red cell production is absolutely dependent on the hormone.

G-CSF was identified in 1986 as a protein that stimulates the production of neutrophils from their marrow progenitors (Fig. 159-2). Levels of the hormone are also inversely related to neutrophil numbers but are regulated primarily by inflammatory stimuli, including tumor necrosis factor-α and IL-1α, acting on endothelial cells, fibroblasts, and macrophages. Like the action of erythropoietin on erythroid progenitors, G-CSF acts to enhance the survival, proliferation, and differentiation of neutrophil progenitors. In addition, the cytokine acts to functionally activate the mature cells it helps to produce. Genetic elimination of G-CSF or its receptor in mice reduces neutrophil levels to 25% of normal, the only hormone known to exert this great an impact on granulopoiesis.

Thrombopoietin, the primary regulator of platelet production, is produced in the liver and kidney and by marrow stromal cells and is regulated both by platelet receptor–mediated uptake and destruction and by transcriptional feedback inhibition of the thrombopoietin gene in marrow stromal cells by platelet granule proteins. Like G-CSF, thrombopoietin stimulates the survival, proliferation, and differentiation of its corresponding lineage, megakaryocytes and their precursors, and prime mature platelets to respond to platelet activation agonists. Genetic elimination of thrombopoietin or its receptor in mice and congenital non-sense or missense mutations in the thrombopoietin receptor in humans result in platelet levels approximately 10% of normal at birth and reflective of the effects of thrombopoietin on the hematopoietic stem cell. Elimination of the thrombopoietin receptor in children leads to aplastic anemia by 1 to 2 years of age.

Other cytokine and receptor systems related to erythropoietin, G-CSF, and thrombopoietin essential for one or more aspects of hematopoiesis include IL-7, critical for all types of lymphocyte production; IL-5, the primary regulator of eosinophil production; IL-4, responsible for immunoglobulin class switching in B-lymphocytes; IL-15, essential for normal natural killer cell differentiation; and IL-2, a lymphocyte activation cytokine. In contrast, several members of the hematopoietic growth factor family display modest effects on blood cell growth, as evidenced by enhanced levels of the corresponding blood cells on the administration of the recombinant protein to mouse or human, but their genetic elimination fails to affect basal or stimulated production of those cells. For example, IL-3 enhances the production of erythrocytes, leukocytes, and megakaryocytes when added to tissue cultures containing marrow cells and erythropoietin, G-CSF, or

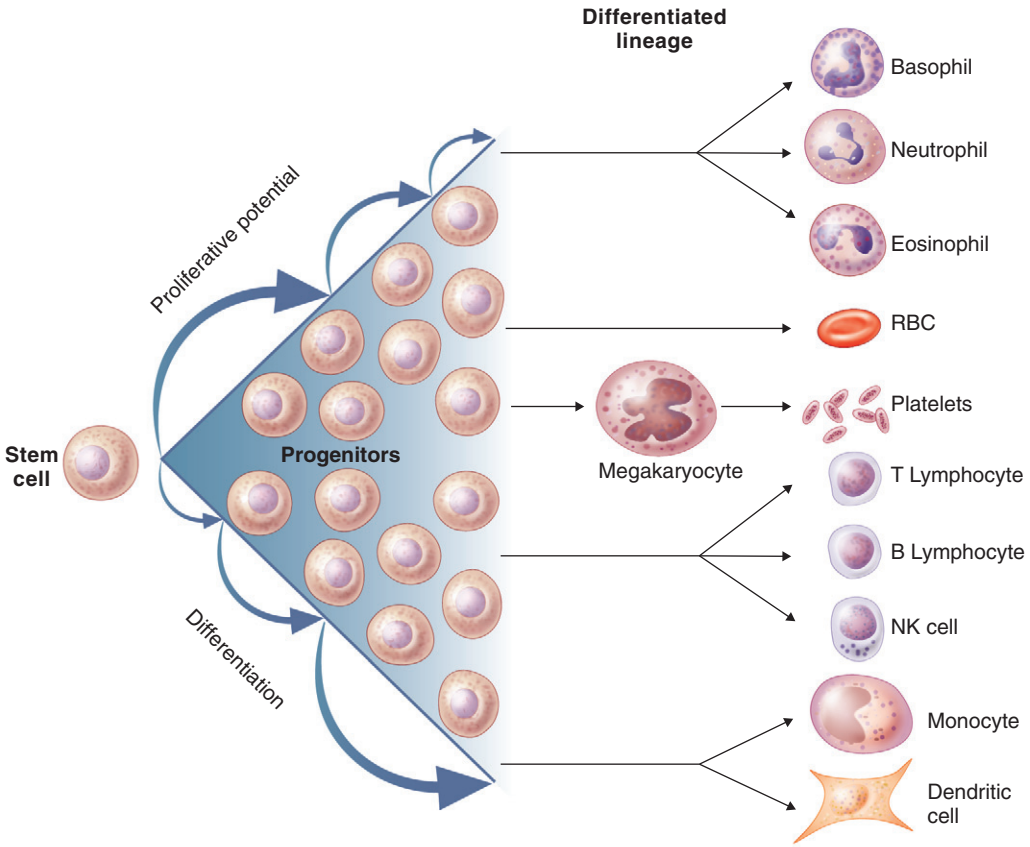

FIGURE 159-1. Hierarchical model of lympho-hematopoiesis. NK = natural killer; RBC = red blood cell.

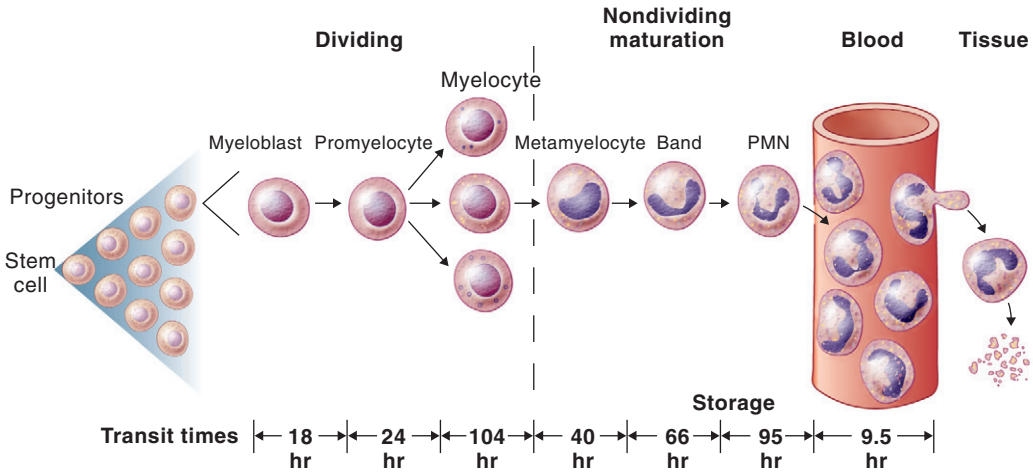

FIGURE 159-2. Neutrophil production system. PMN = polymorphonuclear leukocyte.

thrombopoietin, respectively, but the genetic elimination of IL-3 fails to affect any blood cell type. Rather, IL-3 knockout mice are deficient only in type I hypersensitivity reactions. Likewise, genetic elimination of GM-CSF factor fails to affect either granulocyte or monocyte production, but in mouse and humans, its absence impairs pulmonary alveolar macrophage function, resulting in pulmonary alveolar proteinosis. And although IL-11 stimulates megakaryocyte growth in vitro and modestly enhances platelet production when administered at pharmacologic levels in vivo, its genetic elimination has no effect on thrombopoiesis.

A second class of cytokines and receptors that influences hematopoiesis is exemplified by the c-kit receptor, a member of the receptor tyrosine kinase family of surface proteins, and its cognate ligand, stem cell factor (also termed *steel factor* or *kit-ligand*). Although the c-kit receptor is structurally distinct from members of the hematopoietic cytokine receptor family, possessing an intrinsic tyrosine kinase motif in its cytoplasmic domain, stem cell factor is structurally related to the cytokines that bind to members of the hematopoietic growth factor family. Genetic elimination of stem cell factor or the c-kit receptor results in the near elimination of hematopoietic stem cells, erythroid precursors, and basophils and mast cells. Two other hematopoietic members of this family of cytokines and receptors are Flt3 ligand and its receptor Flt-3, and monocyte colony-stimulating factor and its receptor, c-Fms. Like stem cell factor, both Flt3 ligand and monocyte colony-stimulating factor play nonredundant roles in hematopoiesis, inducing the formation of dendritic cells and monocytes, respectively.

The molecular mechanisms by which the hematopoietic growth factors affect blood cell survival, proliferation, and differentiation are becoming increasingly well understood. Binding of cognate ligand to each of the hematopoietic cytokine receptors results in activation of one or more tyrosine kinases, either tethered cytoplasmic kinases of the Janus (JAK) family for the hematopoietic cytokine receptor family or the intrinsic kinase of the cytokines that employ the receptor tyrosine kinase class of receptors (stem cell factor, Flt3 ligand, and monocyte colony-stimulating factor). Once activated, these kinases phosphorylate tyrosine residues within the cytoplasmic domains of each receptor, providing docking sites for cytoplasmic signaling intermediates possessing Src homology (SH)2 domains. Among the best characterized SH2 domain–containing proteins that bind to hematopoietic receptors are nascent transcription factors, such as the signal transducers and activators of transcription (STAT) proteins, adapter proteins, including

Grb2, Gab1, tensin2 and SHC, phosphatases (e.g., SHP1 and SHP2), and the regulatory subunit (p85) of phosphoinositol-3-kinase (PI3K). Once bound to one or more of the newly induced phosphotyrosine residues of the cytokine receptor or receptor tyrosine kinase, these secondary molecules are phosphorylated, either by the JAK kinase or by other kinases, making them competent to bind additional molecules (e.g., the adapters that ultimately activate Ras, and p85 PI3K that binds its kinase [p110] subunit) or are activated as transcription factors (e.g., STATs). The downstream effector molecules then activated include a number of kinases (e.g., mitogen-activated protein kinases), transporter molecules (e.g., GLUT4), and transcription factors (e.g., Ets family members, HIF1α, HOX family members), ultimately leading to hematopoietic cell survival, proliferation, and differentiation.

CLINICAL USES OF HEMATOPOIETIC CELLS AND GROWTH FACTORS

The clinical development of erythropoietin, G-CSF, and thrombopoietin mimetics represents some of the very best examples of harnessing recombinant DNA technology for therapeutic benefit. Patients with renal failure, widespread inflammation, or marrow replacement and those undergoing chemotherapy for cancer all suffer from variable degrees of anemia, often very debilitating. The first clinical trials of recombinant erythropoietin, in patients with renal failure, were reported in 1987 and led to licensing of the drug for that indication by the U.S. Food and Drug Administration (FDA) soon thereafter. Since then, clinical trials have demonstrated the efficacy of erythropoietin in patients with cancer and inflammation. Administration of the drug almost invariably results in a rapid reticulocyte response and correction of the anemia. The only patients who regularly demonstrate a poor response are

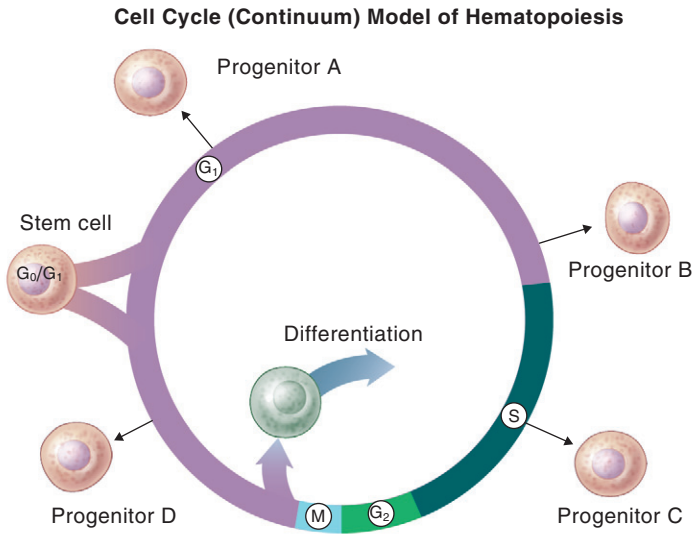

FIGURE 159-3. Cell cycle–based model of stem cell regulation.

individuals with severe inflammation. Most patients undergo an enhanced sense of well-being as the blood hemoglobin concentration rises to 10 g/dL. However, quality-of-life studies of doses of erythropoietin higher than those needed to result in a hemoglobin level of 10 g/dL failed to further enhance patient well-being and surprisingly resulted in a number of adverse effects. For example, patients receiving the drug for anemia secondary to kidney failure progressed to requiring dialysis more frequently and experienced greater cardiovascular events, such as myocardial infarction and stroke, than patients on low levels of the hormone sufficient to maintain their blood hemoglobin at 10 g/dL. Patients receiving erythropoietin for cancer also experienced greater relapses of their tumors than individuals not receiving the hormone. Overall, erythropoietin is a safe and effective drug for anemia due to a wide range of conditions, but its use and dose must be carefully considered.

Many patients undergoing cytotoxic therapy for cancer experience severe neutropenia and are thus at substantial risk for life-threatening infection. Clinical trials of recombinant G-CSF in patients undergoing aggressive chemotherapy for leukemia and solid tumors were reported in the late 1980s and resulted in the FDA approval of the drug for use in patients undergoing chemotherapy of intensity sufficient to produce severe neutropenia. The use of the drug is associated with the more rapid return of neutrophils to safe levels if administered soon after the inciting chemotherapy is completed, but not at the nadir of neutrophil production, and results in lower numbers of severe infections. However, the use of G-CSF has not enhanced survival in patients with any tumor type. Like the use of erythropoietin in patients with cancer, the administration of G-CSF to some patients receiving cytotoxic chemotherapy for cancer (e.g., breast cancer) has been associated with a statistically significant increase in cancer recurrence, although this finding is controversial.

Thrombopoietin was cloned and characterized in 1994 and was quickly advanced to clinical trials following the model of G-CSF use in patients undergoing cancer chemotherapy. Initial results with the intact hormone and a truncated version that included only the receptor-binding domain were mixed, accelerating platelet recovery in some but not all drug-induced settings of thrombocytopenia. One novel use of the truncated form of the drug, administration to healthy volunteer donors to improve platelet apheresis yields, resulted in a significant number of subjects developing antidrug antibodies, which cross-reacted with their native thrombopoietin, resulting in severe thrombocytopenia. This experience caused both manufacturers of thrombopoietin to cease clinical trials. Instead, a series of small molecule mimics have been developed that bind to the thrombopoietin receptor and stimulate thrombopoiesis. Two such drugs are approved by the FDA for use in patients with severe immune thrombocytopenia, one a peptibody, which contains four thrombopoietin receptor–binding peptides grafted onto an immunoglobulin scaffold, and one a small organic molecule that is orally bioavailable and binds to a spatially distinct site on the thrombopoietin receptor. The use of each drug results in a high rate of platelet responses into the normal range in patients with severe immune thrombocytopenia who were refractory to conventional therapies. However, because thrombopoietin mimics do not affect the underlying immune destruction of platelets and megakaryocytes in patients with this disease, discontinuation of each drug results in rapid relapse to thrombocytopenia. Current clinical trials in other settings of transient myelosuppression are expected to improve platelet recovery but not be associated with rapid relapse.

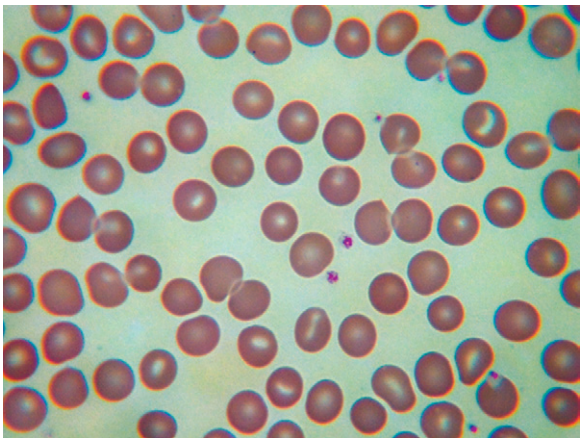

FIGURE 160-1. Normal peripheral blood smear. These normal red cells are described as *normocytic* (i.e., of normal size) and *normochromic* (i.e., their staining characteristics are normal). Normal erythrocytes are biconcave discs, causing them to have an area of central pallor that does not exceed one third the diameter of the cell. There are also scattered normal platelets (×1000).

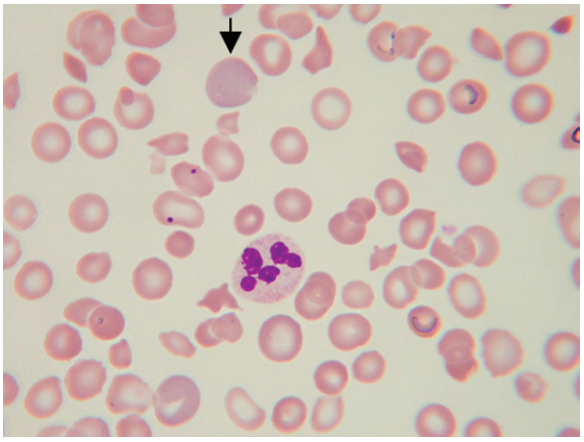

FIGURE 160-2. Smear showing multiple abnormalities. There is *anisocytosis,* defined as an increased variation in cell size; *poikilocytosis,* defined as an increased variation in cell shape; and *polychromasia,* defined as the presence of erythrocytes with a blue tinge to their cytoplasm—indicating a young cell recently released from the bone marrow in which the polychromasia is due to the presence of RNA. *Polychromatic cells* are erythrocytes with a blue tinge; because polychromatic cells are larger than normal mature erythrocytes, they are known as *polychromatic macrocytes (arrow)*. The film also shows two cells containing bluish purple *Howell-Jolly bodies;* these inclusions are nuclear remnants (×1000).

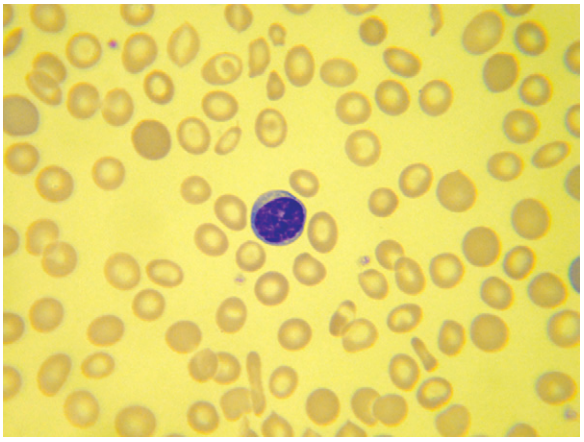

FIGURE 160-3. Microcytic red cells from a case of thalassemia minor. In a blood smear, a *microcyte* can be defined as a cell with a diameter less than that of the nucleus of a normal small lymphocyte. There are also some cells showing *hypochromia*, an area of central pallor that is larger than one third of the diameter of the red cell. In addition, there are two *target cells*, with a hemoglobinized area in the center of the area of pallor (×1000).

160 THE PERIPHERAL BLOOD SMEAR

BARBARA J. BAIN

With the development of sophisticated automated instruments to count and characterize blood cells, Romanowsky (Wright-Giemsa or May-Grünwald-Giemsa)-stained peripheral blood smears are now performed on only a minority of blood specimens received in a hematology laboratory. Nevertheless, the blood smear remains important for a number of reasons: it can (1) verify the result of an automated instrument, (2) provide an immediate specific diagnosis, or (3) indicate a narrow range of diagnostic possibilities, permitting a focused rather than indiscriminate investigation. A blood film can provide a rapid diagnosis in cases in which speed is crucial, such as in acute promyelocytic leukemia, thrombotic thrombocytopenic purpura, or Burkitt's lymphoma. Sometimes a smear provides unexpected information that is of value in patient management.

Usually, blood smears are initially interpreted by a laboratory scientist. In some countries it is customary for clinicians to examine the blood smears of their own patients because the clinician has the final responsibility for integrating all information and making a diagnosis. However, the interpretation of a blood smear can be difficult, and a trained laboratory hematologist or hematopathologist has a major role in interpreting smears that may have been initially examined by a laboratory scientist. It is crucial that, when requesting a blood count, the clinician provide all the essential information needed to interpret the count and any associated smear. Regardless of whether the clinician examines the blood film, he or she must be able to interpret the written report issued by the laboratory. To do so, the clinician must be familiar with the terms generally used by laboratory staff and the possible significance of the abnormalities described. The most important of these terms are illustrated in Figures 160-1 through 160-20.

REASONS FOR PERFORMING A BLOOD SMEAR

A blood smear may be requested by a clinician or initiated by a laboratory scientist or a laboratory hematologist. Clinical findings that should lead a clinician to request a blood smear are summarized in Table 160-1.

Laboratory scientists and physicians may initiate a blood smear that has not been requested by the clinician if the clinical details indicate the possibility of a significant hematologic abnormality. However, they are

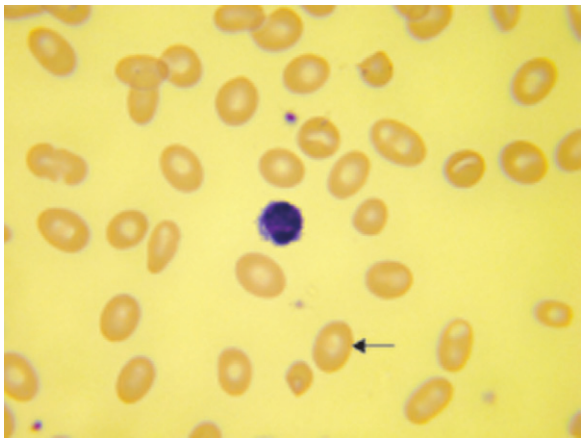

FIGURE 160-4. Macrocytic anemia. A *macrocyte* is recognized on a blood film as a cell with a diameter that is considerably greater than that of the nucleus of a small lymphocyte. In addition, this smear shows *oval macrocytes* (also known as *macro-ovalocytes*), defined as cells that are larger than normal and oval in shape *(arrow)*. They are of considerable diagnostic importance, being characteristic of megaloblastic anemia; they can also be seen in dyserythropoiesis (×1000).

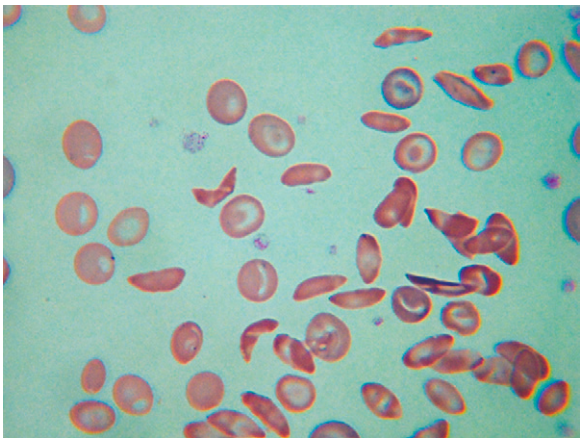

FIGURE 160-7. Sickle cells. A *sickle cell* is a cell with a sickle or crescent shape resulting from the polymerization of hemoglobin S. These cells are seen not only in sickle cell anemia (homozygosity for hemoglobin S) but also in compound heterozygous states such as sickle cell/hemoglobin C disease and sickle cell/β-thalassemia, which also lead to sickle cell disease. This smear also shows target cells and boat-shaped cells with a lesser degree of polymerization of hemoglobin S than in a classic sickle cell (×1000).

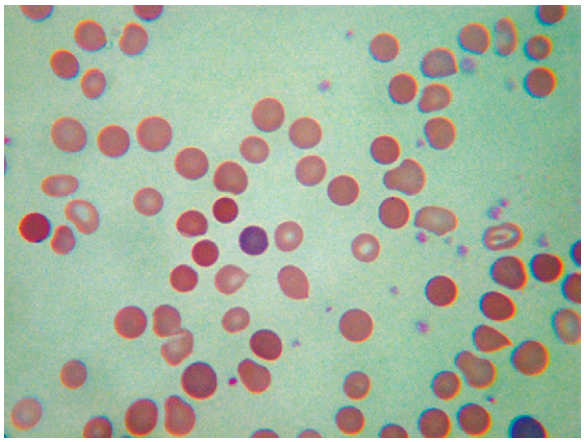

FIGURE 160-5. Hereditary spherocytosis. A *spherocyte* is a red cell that lacks central pallor because of its spherical shape. In hereditary spherocytosis, there are usually cells in which the central pallor is reduced rather than absent, and they are intermediate in shape between a spherocyte and a *discocyte,* which is an erythrocyte with the normal shape of a biconcave disc (×1000).

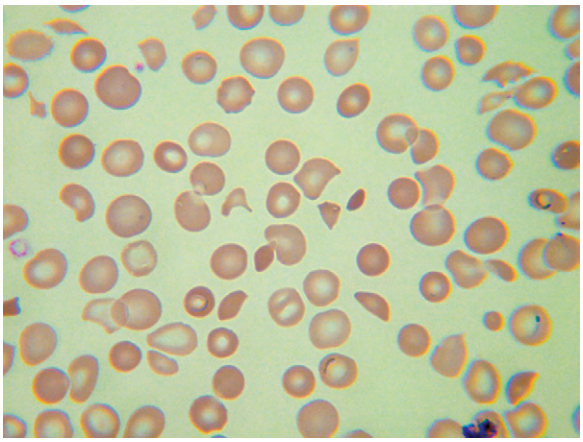

FIGURE 160-8. Red cell fragmentation. *Red cell fragments* or *schistocytes* are defined as fragments of erythrocytes. In addition to small angular fragments, there may be *microspherocytes,* cells of reduced size and spherical in form (also known as *spheroschistocytes*), and *keratocytes,* cells with two horn-like projections. Schistocytes are seen in microangiopathic hemolytic anemias and in mechanical hemolysis (×1000).

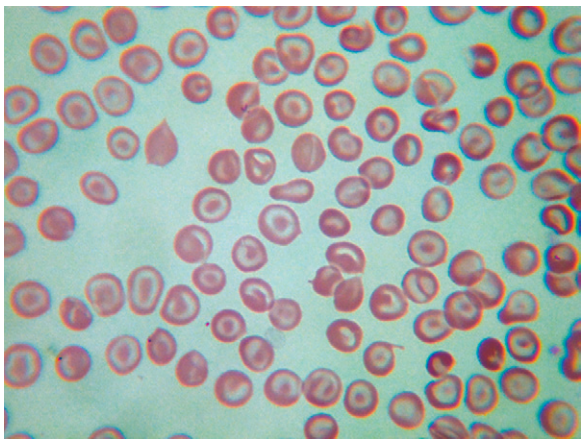

FIGURE 160-6. Target cells. A *target cell* is an erythrocyte with a hemoglobinized area in the middle of the normal area of central pallor (×1000).

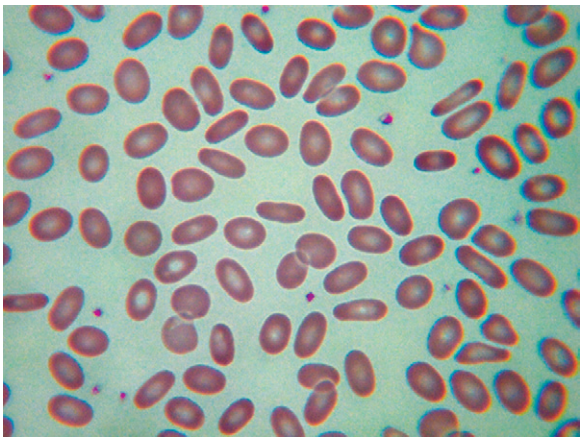

FIGURE 160-9. Hereditary elliptocytosis. An *elliptocyte* is an elliptical red cell. When seen in the numbers present in this smear, they are indicative of hereditary elliptocytosis; smaller numbers are seen in other conditions such as iron deficiency anemia, in which they are sometimes referred to as *pencil cells* (×1000).

also likely to evaluate a blood smear in response to abnormalities revealed by an automated instrument. These abnormalities may be quantitative or qualitative. Quantitative abnormalities that require evaluation include anemia, polycythemia, macrocytosis, microcytosis, neutrophilia, lymphocytosis, eosinophilia, thrombocytopenia, and thrombocytosis.

Modern automated instruments are able to "flag" the presence of qualitative abnormalities that require a blood film to be examined for confirmation of the abnormality or for further elucidation. "Flags" are generated in response to the electrical impedance or the light scattering characteristics of individual cells. Some instruments are dependent on cytochemical

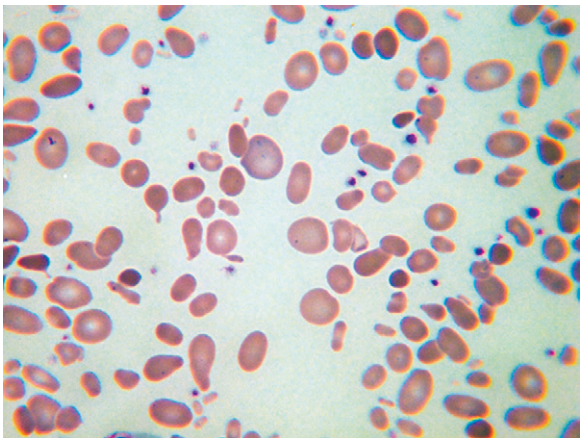

FIGURE 160-10. Hereditary pyropoikilocytosis. This smear shows striking poikilocytosis, including elliptocytes, microspherocytes and other fragments, and teardrop cells. This congenital condition, which is related to hereditary elliptocytosis, usually results from the inheritance of two different mutated genes from the two parents and is characterized by a severe hemolytic anemia (×1000).

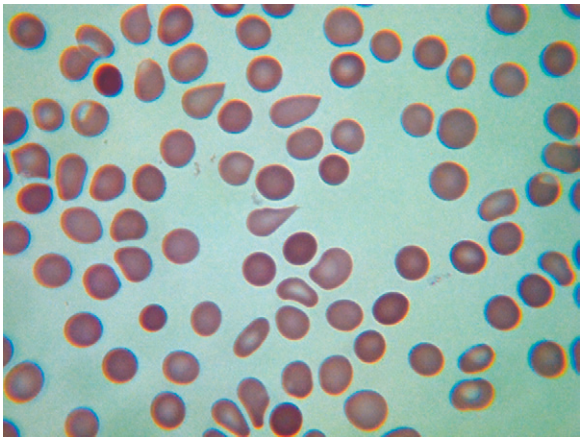

FIGURE 160-11. Teardrop poikilocytes. *Teardrop poikilocytes,* or *dacrocytes,* are teardrop-shaped red cells; they are characteristic of primary myelofibrosis but are also seen in megaloblastic anemia (×1000).

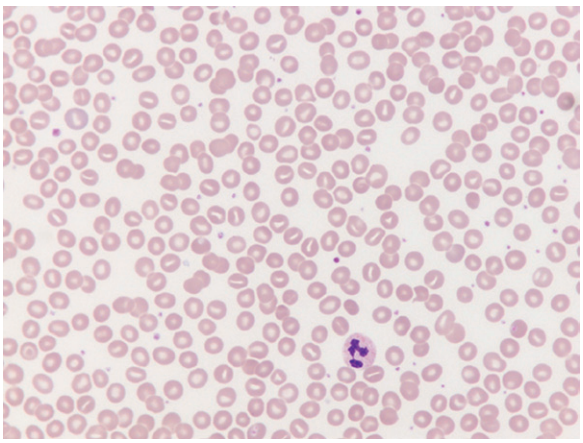

FIGURE 160-12. Stomatocytosis. A *stomatocyte* is a cell that appears to have a central mouth-shaped or slit-like stoma. Among the less common causes is hereditary stomatocytosis. Alcohol and hydroxycarbamide therapy are more common causes (×400).

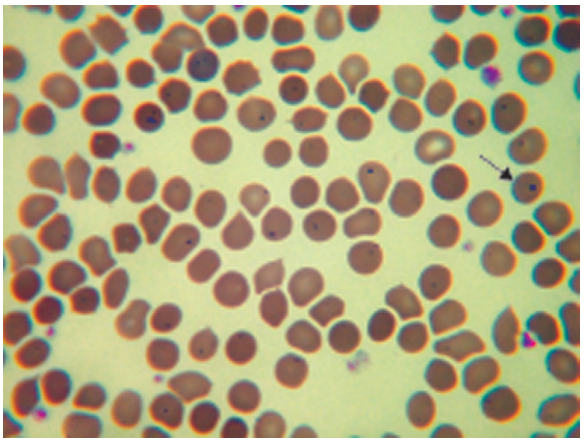

FIGURE 160-13. Numerous Pappenheimer bodies. A *Pappenheimer body* is an iron-containing red cell inclusion *(arrow)*. It is smaller and more angular than a Howell-Jolly body and stains navy blue rather than purple. Pappenheimer bodies are seen following splenectomy and in sideroblastic anemias (×1000).

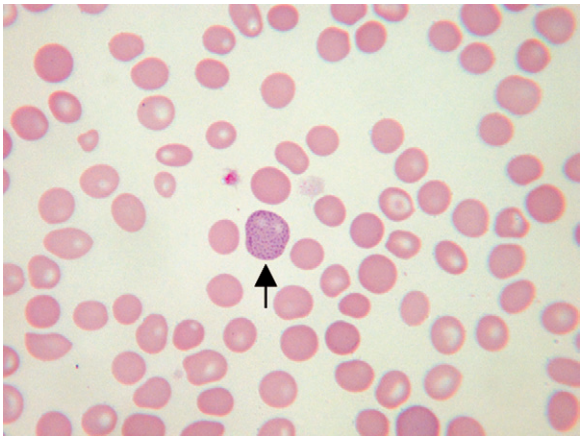

FIGURE 160-14. Basophilic stippling. *Basophilic stippling* means that there are fine (as in this case) or coarse purplish blue dots dispersed through the red cell *(arrow)*. They are a very nonspecific feature occurring in thalassemia trait, lead poisoning, 5′-nucleotidase deficiency, and dyserythropoiesis in general (×1000).

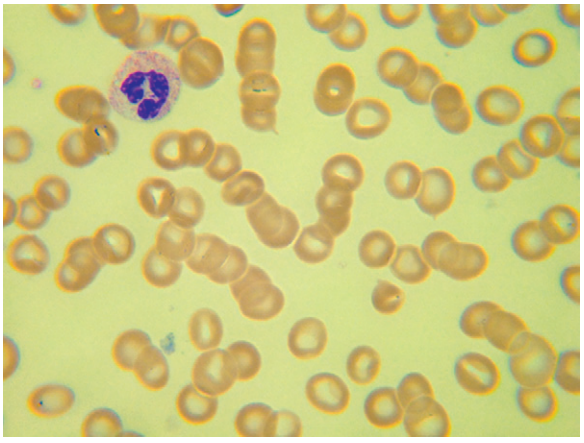

FIGURE 160-15. Rouleau formation. *Rouleaux* are stacks of red cells, often compared to stacks of coins. They result from an increase of high-molecular-weight globulins in the plasma, either as a reactive change or as a result of secretion of a paraprotein in a plasma cell neoplasm (×1000).

reactions of cells or on the cells' ability to polarize light. Most instruments can indicate the possibility of the presence of blast cells, reactive or other atypical lymphocytes, granulocyte precursors, or nucleated red blood cells. Instruments using a cytochemical reaction for peroxidase to help identify neutrophils, eosinophils, and monocytes may flag the appearance of large, unstained (i.e., peroxidase-negative) cells; such cells may indicate a harmless inherited peroxidase deficiency, but sometimes such cells are lymphoma cells, reactive lymphocytes, or leukemic blast cells. Instruments often flag the possibility of an erroneous platelet count, such as when there is an overlap in size between platelets and red cells or when light scattering characteristics suggest the presence of platelet aggregates (a potential cause of pseudothrombocytopenia).

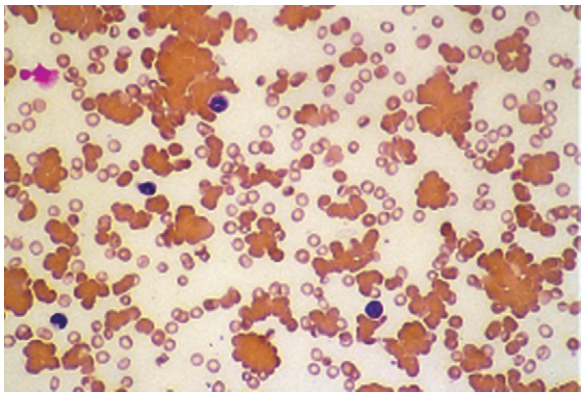

FIGURE 160-16. Red cell agglutination. *Red cell agglutinates* are irregular aggregates of red cells, as seen in *Mycoplasma pneumoniae* infection. They are also seen in other infections, such as infectious mononucleosis, and in chronic cold hemagglutinin disease (×100). (Courtesy of Jean Schafer.)

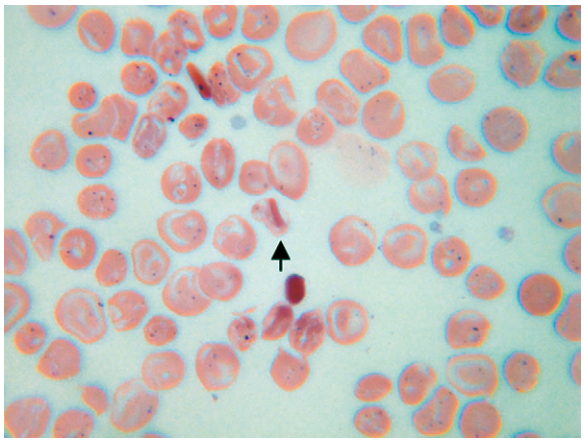

FIGURE 160-17. Homozygous hemoglobin C. Three *hemoglobin C crystals* are present, one indicated by an arrow. Hemoglobin C crystals are usually six-sided, with a long axis having parallel edges (×1000).

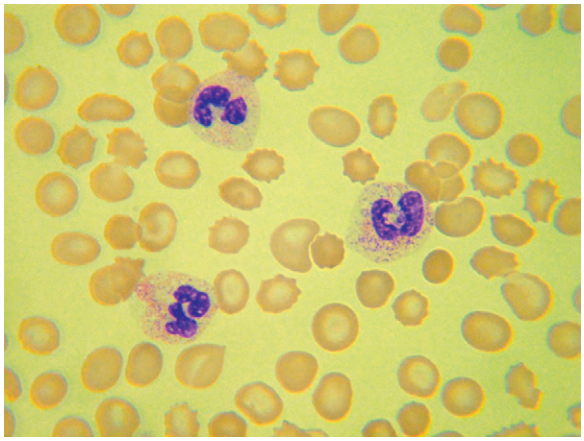

FIGURE 160-18. Toxic granulation. *Toxic granulation* refers to heavy staining of azurophilic granules of neutrophils. When accompanied by neutrophil vacuolation, it is often indicative of infection, but it can also result from inflammation, tissue damage, and normal pregnancy (×1000).

International consensus guidelines indicate which automated instrument results require blood smear review. Whether a review is needed is determined in part by whether that specimen is the first one obtained from that patient and whether there has been a significant change from a previously validated result (referred to as a delta check). Laboratory computers can be programmed to indicate when a result meets the criteria for smear review.

Automated red cell measurements can, to some extent, replace examination of the blood film. An increased red cell distribution width indicates the

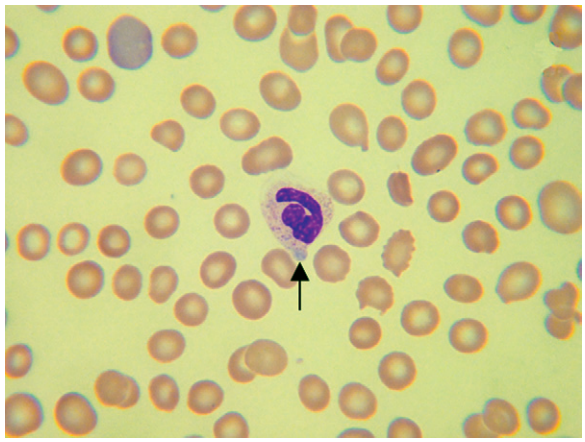

FIGURE 160-19. Döhle's body. A *Döhle's body* (arrow) is a pale blue-gray amorphous inclusion near the cell membrane of a neutrophil. Döhle's bodies can result from infection and inflammation. Similar but different inclusions (larger and more angular) are seen in the May-Hegglin anomaly (×1000).

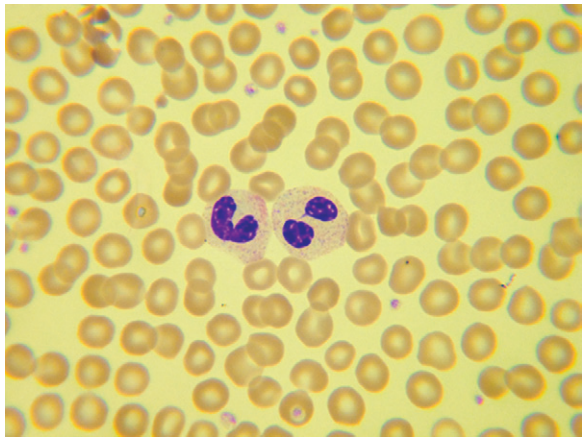

FIGURE 160-20. Pelger-Huët anomaly. A *Pelger-Huët anomaly* is a cytologic abnormality of neutrophils in which there is hypolobulation of nuclei and increased chromatin clumping. Nuclei may have a shape resembling a peanut or a pince-nez, as in the examples shown. The Pelger-Huët anomaly is inherited, but similar Pelger neutrophils are seen in myelodysplastic syndromes, in which the neutrophils may also be hypogranular (×1000).

TABLE 160-1 CLINICAL FEATURES SUGGESTING THE NEED FOR A BLOOD SMEAR

CLINICAL FEATURE	REASON TO PERFORM A BLOOD SMEAR
Lymphadenopathy or splenomegaly	May be indicative of infectious mononucleosis or another reactive condition, or of leukemia or lymphoma
Clinically evident anemia	Helps in the differential diagnosis
Bruising or bleeding tendency, including unexplained retinal hemorrhages	May confirm thrombocytopenia or show morphologically abnormal platelets (which may have defective function); sometimes owing to acute leukemia or other condition causing bone marrow failure
Acute renal failure	Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura should be confirmed or excluded
Jaundice and hypertension in a pregnant woman	May show schistocytes, supporting a diagnosis of HELLP syndrome
Bone pain	May indicate multiple myeloma, bone marrow infiltration, or sickle cell disease
Unexplained chest or abdominal pain or acute splenic enlargement in a child	Possible sickle cell disease
Unexplained hyperbilirubinemia	Assessment of possible hemolysis

HELLP = hemolysis, elevated liver enzymes, low platelets.

presence of anisocytosis. A decreased mean cell volume is usually a reliable indicator of microcytosis. A reduction in the mean cell hemoglobin concentration indicates hypochromia (for most instruments, however, this measurement is less sensitive than the human eye in the detection of hypochromia). An increased mean cell volume usually indicates macrocytosis, but examination of a smear is necessary both to confirm that the result is not artifactual and to elucidate the cause. Some instruments can measure the hemoglobin concentration in individual cells and thus flag the presence of hyperdense cells; however, a blood film is still necessary to distinguish spherocytes from irregularly contracted cells. Most instruments produce a histogram of the size distribution of red cells, and some do the same for the distribution of hemoglobin concentration; either of these graphic representations may show dimorphic red cells (i.e., two populations of cells).

THE BLOOD SMEAR IN THE DIFFERENTIAL DIAGNOSIS OF ANEMIA

Microcytic Anemias (Chapter 162)

In microcytic anemias, the automated count is of considerable importance and may permit a distinction between iron deficiency and thalassemia heterozygosity. In iron deficiency, there is initially a normocytic normochromic anemia; only when the deficiency becomes more severe is there microcytosis. Conversely, in β-thalassemia heterozygosity, there is usually a normal or near-normal hemoglobin concentration, but the red blood cell count is increased and there is marked microcytosis (low mean cell volume) together with a parallel reduction in mean cell hemoglobin. The blood film provides supplementary information that can favor one diagnosis or the other. Iron deficiency is more likely to be associated with hypochromia and elliptocytes ("pencil cells"), whereas in β-thalassemia heterozygosity there is microcytosis, hypochromia is less marked, and there are more likely to be target cells and basophilic stippling. Individuals with α-thalassemia involving the deletion of two α genes (–α/–α) or (– –/α α) have red cell indices similar to those of β-thalassemia heterozygosity; in this case, the blood film usually does not provide any additional diagnostically useful information, although individuals with nondeletional α-thalassemia due to hemoglobin Constant Spring have prominent basophilic stippling. When there is deletion of a single α gene, the blood count is either less abnormal or normal, and the blood smear does not provide any extra diagnostically useful information. The blood smear is, however, a useful supplement to the blood count in suggesting a diagnosis of hemoglobin H disease (Chapter 165). The count shows anemia, marked microcytosis (low mean cell volume and mean cell hemoglobin), and sometimes a reduction in the mean cell hemoglobin concentration. The smear usually shows marked poikilocytosis in addition to microcytosis, and there may be polychromasia, correlating with an elevated reticulocyte count. Iron deficiency anemia also needs to be distinguished from anemia of chronic disease. The blood counts may be quite similar, but in anemia of chronic disease, the smear often shows features of inflammation, such as increased rouleau formation, background staining (as a result of increased plasma proteins), and sometimes neutrophilia. Other rare microcytic anemias that must be distinguished from iron deficiency include congenital sideroblastic anemia and lead poisoning. In congenital sideroblastic anemia, the film is dimorphic, with one population of hypochromic microcytes and another of normochromic normocytic cells. In lead poisoning, the presence of basophilic stippling and polychromasia in a patient with microcytosis can suggest the diagnosis.

Macrocytic Anemias

A blood film can be important in distinguishing true macrocytosis from factitious macrocytosis as a result of the presence of red cell agglutinates (see Fig. 160-16). Diagnostic features that can suggest the cause of macrocytosis are shown in Table 160-2.

A smear is particularly important in evaluating the possibility of a megaloblastic anemia (Chapter 167) (Figs. 160-4 and 160-21). Sometimes assays of vitamin B_{12} and folate are normal despite a deficiency, and only the blood film features suggest the true diagnosis and indicate the need for further investigation.

Normocytic Normochromic Anemia (Chapter 161)

A blood smear is only occasionally useful in determining the cause of a normocytic normochromic anemia. Signs of inflammation may be present in anemia of chronic disease. Increased rouleau formation and background staining can also indicate multiple myeloma. Polychromasia suggests the possibility of young red cells as a result of recent blood loss or hemolysis. Small numbers of acanthocytes may indicate hypothyroidism or anorexia nervosa. Dysplastic features, such as in neutrophils, suggest a myelodysplastic syndrome.

TABLE 160-2 USEFUL FEATURES FOR DETERMINING THE CAUSE OF MACROCYTIC ANEMIA

CAUSE	SMEAR FEATURES
Megaloblastic anemia (vitamin B_{12} or folic acid deficiency)	Oval macrocytes, teardrop poikilocytes, hypersegmented neutrophils; when severe, marked anisocytosis and poikilocytosis, which may include red cell fragments
Ethanol excess	Target cells and stomatocytes; anisocytosis and poikilocytosis less than in megaloblastic anemia
Liver disease	Target cells, stomatocytes
Myelodysplastic syndromes, including sideroblastic anemias	Other dysplastic features such as hypogranular and hypolobulated neutrophils; if erythropoiesis is sideroblastic, a population of hypochromic microcytic cells and Pappenheimer bodies
Chronic hemolytic anemia	Polychromasia; characteristic poikilocytes sometimes present (e.g., irregularly contracted cells if there is an unstable hemoglobin)

TABLE 160-3 BLOOD SMEAR FEATURES SUGGESTING A SPECIFIC CAUSE OF INHERITED OR ACQUIRED HEMOLYTIC ANEMIA

BLOOD SMEAR FEATURES	CONDITIONS SUGGESTED
Spherocytes	Hereditary spherocytosis, autoimmune hemolytic anemia, alloimmune hemolytic anemia (e.g., hemolytic disease of the newborn, delayed hemolytic transfusion reaction), drug-induced immune hemolytic anemia, *Clostridium perfringens* sepsis
Irregularly contracted cells	Glucose-6-phosphate dehydrogenase deficiency, oxidant damage from chemicals or drugs in individuals with normal red cell enzymes (e.g., dapsone administration), liver failure due to Wilson disease (release of copper from liver), unstable hemoglobin, hemoglobin C homozygosity
Sickle cells and boat-shaped cells	Sickle cell disease (e.g., sickle cell anemia or compound heterozygous states such as S/C, S/D-Punjab, S/O-Arab, S/β-thalassemia)
Target cells	Hemoglobin C homozygosity, other hemoglobinopathies, hereditary xerocytosis
Stomatocytes	Hereditary stomatocytosis
Acanthocytes	Liver failure (spur cell hemolytic anemia)
Basophilic stippling	Lead poisoning, pyrimidine 5′-nucleotidase deficiency
Red cell fragments (schistocytes)	Microangiopathic hemolytic anemia (including hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, HELLP syndrome, and hemolysis associated with disseminated intravascular coagulation), mechanical hemolytic anemia (e.g., defective cardiac prosthetic valve, march hemoglobinuria)

HELLP = hemolysis, elevated liver enzymes, low platelets.

Hemolytic Anemias

The possibility of hemolysis is suggested by the presence of polychromasia and macrocytosis. Specific causes of hemolysis are suggested by the presence of various poikilocytes, as shown in Table 160-3.

The distinction between spherocytes and irregularly contracted cells is important; both are dense cells with absent central pallor, but the differential diagnosis is quite different. Recognition of the features of oxidant damage is important in diagnosing glucose-6-phosphate dehydrogenase (G6PD)

deficiency, because sometimes an assay for G6PD performed during an acute hemolytic episode is normal (Chapter 164). In addition to irregularly contracted cells, there may be ghost cells, hemi-ghost cells ("blister cells"), and even Heinz bodies protruding from the red cells and confirmed on a Heinz body preparation. The observation of these features is an indication to repeat the assay when the acute hemolytic episode is over.

ASSESSMENT OF THROMBOCYTOPENIA, THROMBOCYTOSIS, AND PLATELET MORPHOLOGY

A blood smear is essential to validate the cell count whenever an automated count shows thrombocytopenia (e.g., a count $<60 \times 10^9$/l). This should be done quickly before patient management is altered, such as by postponing surgery or initiating further diagnostic work-up. A platelet transfusion should never be given for an unexpected thrombocytopenia without microscopic confirmation of the count. A factitiously low platelet count is often the result of in vitro platelet aggregation and is occasionally the result of platelet satellitism (Chapter 174). To detect aggregates reliably, the edges and the tail of the smear should be examined for aggregates. The presence of fibrin strands also suggests the activation of coagulation and an erroneous count.

If a low platelet count is confirmed, the film may give clues to the cause (Chapter 175). Giant platelets (Figs. 160-22 and 160-23) occur in a number of inherited thrombocytopenias, including Bernard-Soulier syndrome and the May-Hegglin anomaly. Small platelets are less common but are a feature of Wiskott-Aldrich syndrome. Agranular platelets occur in the gray platelet syndrome, and platelets with a reduced number of larger-than-normal granules are seen in Jacobsen/Paris-Trousseau syndrome. The presence of May-Hegglin inclusions (Döhle-like bodies; see Fig. 160-19) in neutrophils indicates that this anomaly is the cause of the thrombocytopenia. In acquired thrombocytopenias, increased platelet turnover is often accompanied by the presence of large platelets, whereas bone marrow failure is associated with platelets of normal size. It is important to look for red cell fragments to confirm or exclude a diagnosis of thrombotic thrombocytopenic purpura in any patient with the apparent recent onset of thrombocytopenia; because platelet transfusions are usually contraindicated in this condition, the smear should be examined before platelet transfusion is contemplated. The smear of any patient with the apparent recent onset of severe thrombocytopenia should be examined carefully for evidence of acute promyelocytic leukemia; the leukemic cells may be infrequent in the circulating blood. Hemorrhagic manifestations and a low platelet count can also be indicative of meningococcal septicemia; in some patients, organisms are seen in the blood smear and the diagnosis is confirmed; in other patients, only marked toxic changes in neutrophils are detected.

Thrombocytosis should also be confirmed on a smear. Factitiously elevated counts may be the result of the presence of red cell fragments (in microangiopathic or mechanical hemolytic anemia, burns, or accidental in vitro heating of the blood sample), white cell fragments (in acute leukemia and, less often, in lymphoma), cryoglobulin precipitates, or microorganisms (particularly *Candida* species). If the count is confirmed, the blood smear may be useful to indicate a likely cause (e.g., features of hyposplenism or the presence of basophilia in a myeloproliferative disorder).

It is sometimes necessary to examine a smear to confirm that an apparently normal platelet count is valid. This should always be done in patients with acute leukemia and an elevated white cell count; the presence of white cell fragments of a similar size to platelets can suggest that the platelet count is at a safe level when it is in fact dangerously low. Counting the ratio of platelets to other particles of similar size permits the count to be corrected. Any unexpectedly normal count should be confirmed; for example, the sudden rise of the automated platelet count in a patient being treated for a hematologic neoplasm may be the result of fungi that have colonized an indwelling intravenous line and are being shed into the blood stream.

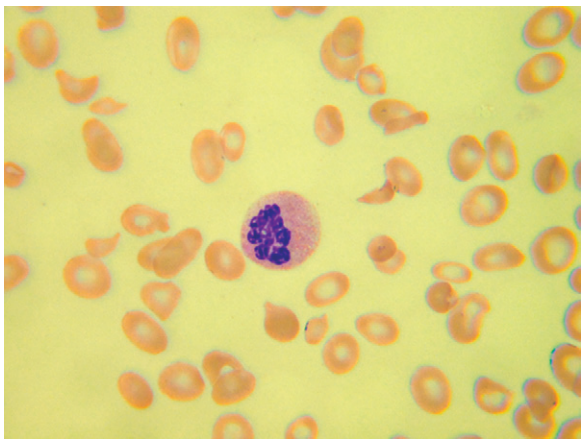

FIGURE 160-21. Hypersegmented neutrophils. A *hypersegmented neutrophil* is a neutrophil with more than five nuclear segments or lobes, as in this example from a patient with megaloblastic anemia. Neutrophil hypersegmentation is also said to be present if there are increased numbers of neutrophils with five lobes or if the median lobe count is increased (×1000).

LEUKOCYTOSIS AND LEUKOPENIA (CHAPTER 170)

The finding of leukocytosis is not necessarily an indication for a blood smear. For example, this finding would be expected in a patient with infection or following surgery or trauma, in which case smear confirmation is not required. However, unexpected leukocytosis requires a smear. Artifactual elevation is unusual but can occur as a result of cryoglobulinemia, hyperlipidemia, or the presence of *Candida* species. Distinguishing reactive changes from leukemia on the basis of morphology is usually straightforward. In reactive leukocytosis, there is usually toxic granulation, and Döhle's bodies may be present (see Figs. 160-18 and 160-19). Vacuolation is particularly characteristic of bacterial infection, and there may be some degranulation of neutrophils. The hematologist should be aware of the changes induced by granulocyte colony-stimulating factor so that they are not confused with a response to infection;

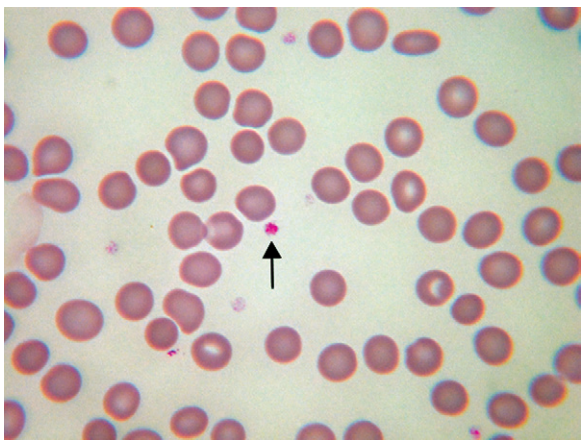

FIGURE 160-22. Normal-sized platelet (arrow). Platelets have central granules, although this is not apparent in this photomicrograph (×1000).

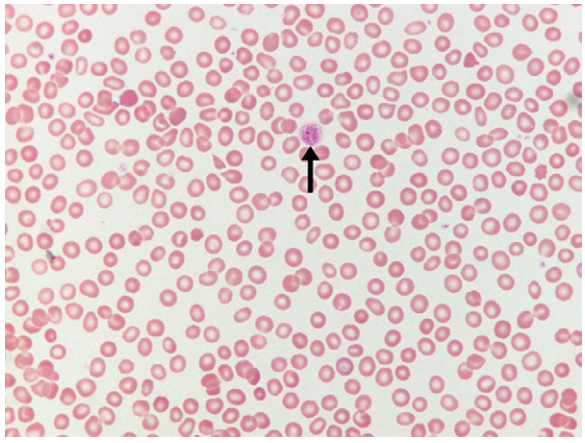

FIGURE 160-23. Giant platelet (arrow). Giant platelets are as large as or larger than normal red cells. Giant platelets can indicate increased platelet turnover or an inherited or acquired defect in thrombopoiesis (×1000).

this cytokine can cause toxic granulation, Döhle's bodies, vacuolation, and the presence of macropolycytes (giant neutrophils) and circulating neutrophil precursors. The changes typical of leukemia are discussed later.

Leukopenia usually requires a film for confirmation and elucidation. The exception is when it is expected in a given clinical context, such as when a patient has had recent chemotherapy. Rarely, an apparent leukopenia is artifactual, owing to the aggregation of neutrophils mediated by an autoantibody or resulting from infection-induced changes in adhesion molecules of the leukocyte surface membrane.

With some automated instruments, it is necessary to confirm that neutropenia is real. If the automated count is based on peroxidase cytochemistry, the presence of an inherited deficiency will lead to an apparent neutropenia associated with an increase of large, unstained (i.e., peroxidase-negative) cells. The scatter plot is characteristic, but because the same features could be due to acute leukemia with neutropenia and circulating blast cells, a smear is needed for confirmation.

LEUKEMIAS AND LYMPHOMAS

The blood smear is critical in the diagnosis of leukemias and lymphomas. The lymphoblasts of acute lymphoblastic leukemia are usually medium-sized agranular cells with relatively scanty cytoplasm (Fig. 160-24), whereas in acute myeloid leukemia, blast cells are generally larger, with more plentiful cytoplasm that may contain granules or Auer rods (Fig. 160-25). Myeloid blast cells vary in appearance according to whether they are myeloblasts or monoblasts. Myeloblasts are usually medium sized and may have plentiful granules, scanty granules, or no visible granules; they may contain Auer rods. Monoblasts are much larger cells with plentiful cytoplasm containing few granules and, very rarely, Auer rods. Megakaryoblasts are present in some patients and are sometimes cytologically distinctive because of their tendency to form cytoplasmic blebs or develop platelet-type granules.

Chronic myelogenous leukemia has a very characteristic blood smear (Fig. 160-26) in which the most numerous cells are myelocytes and mature neutrophils. Eosinophils and basophils are also present. Dysplastic features are generally absent. In atypical Philadelphia chromosome–negative chronic myeloid leukemia, monocytosis is more frequent and dysplastic features are present. Chronic myelomonocytic leukemia is characterized by increased monocytes, some of them immature, with inconspicuous dysplastic features and infrequent granulocyte precursors.

Chronic lymphocytic leukemia also has a very characteristic blood film, with an increase of small, mature lymphocytes of rather uniform appearance. The chromatin is often irregularly clumped, creating a mosaic effect (Fig. 160-27). Smear cells are almost always increased in number but are not pathognomonic.

Lymphoma in leukemic phase often has cytologic features that aid in the diagnosis. Follicular lymphoma, Burkitt's lymphoma, and splenic marginal zone lymphoma can all be distinctive.

THE INCIDENTAL DETECTION OF CLINICALLY SIGNIFICANT ABNORMALITIES

Sometimes the examination of a blood film reveals unexpected but clinically significant information. Examples are given in Table 160-4. Detection of microorganisms is particularly likely in patients with acquired immunodeficiency syndrome (AIDS), hyposplenic patients, and patients with overwhelming sepsis, but sometimes they are detected in immunologically normal patients with only trivial symptoms. It should be noted that microorganisms in blood smears sometimes represent contaminants, particularly if

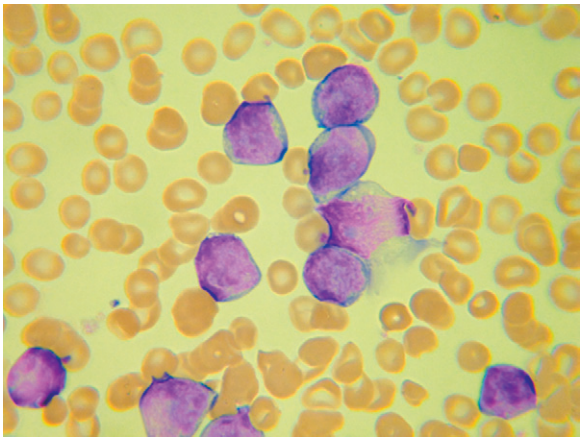

FIGURE 160-24. Acute lymphoblastic leukemia. Numerous agranular blast cells with a high nuclear-to-cytoplasmic ratio are present. Platelets are decreased in number (×1000).

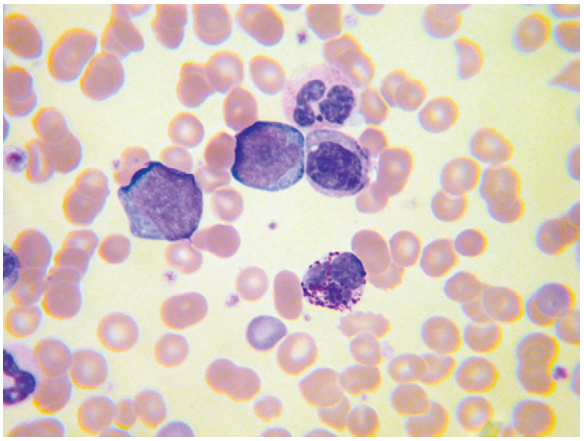

FIGURE 160-26. Chronic myelogenous leukemia. In this view there are myeloblasts, a myelocyte, a basophil, and a segmented neutrophil (×1000).

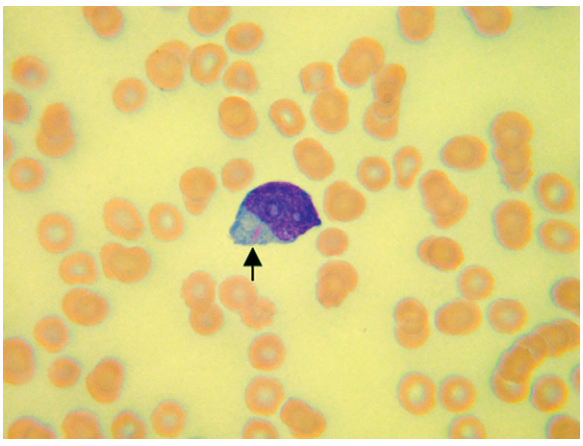

FIGURE 160-25. Auer rod. An Auer rod (arrow) is a rod-shaped inclusion in the cytoplasm of cells of myeloid lineage formed by the crystallization of azurophilic granule constituents. Auer rods are seen only in acute myeloid leukemia and high-grade myelodysplastic syndromes. They are usually seen in blast cells but are occasionally found in maturing cells (×1000).

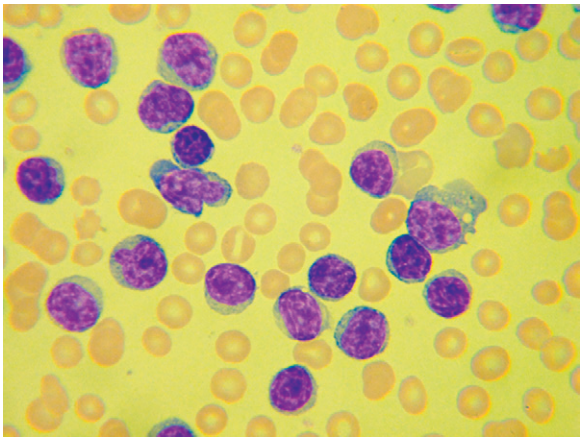

FIGURE 160-27. Chronic lymphocytic leukemia. There are large numbers of rather monotonous, mature small lymphocytes with chromatin clumping. Smear cells, reflecting the mechanical fragility of the cells, are characteristic but are not seen in this photomicrograph (×1000).

TABLE 160-4 INCIDENTAL BUT CLINICALLY RELEVANT BLOOD SMEAR OBSERVATIONS

OBSERVATION	POSSIBLE SIGNIFICANCE
Acanthocytes	Abetalipoproteinemia, neuroacanthocytosis, McLeod phenotype
Howell-Jolly bodies, target cells, and acanthocytes	Hyposplenism (congenital, previous splenectomy, celiac disease, amyloidosis)
Cryoglobulin	Hepatitis C, multiple myeloma
Vacuolated lymphocytes	Inherited metabolic disorders
Parasites (e.g., malaria parasites, *Babesia,* microfilaria, trypanosomes, *Leishmania*)	Parasitic infection
Fungi (*Candida* spp, *Histoplasma capsulatum, Penicillium marneffei, Cryptococcus neoformans, Malassezia furfur*)	Disseminated fungal infection or, in the case of *Candida,* colonization of an indwelling intravenous line
Bacteria (e.g., pneumococcus, meningococcus, *Capnocytophaga canimorsus, Borrelia, Ehrlichia, Anaplasma, Yersinia pestis*)	Bacterial infection
Leukoerythroblastic blood film	Bone marrow infiltration (e.g., metastatic malignancy)

specimens have been obtained by skin prick or from the umbilical cord and if there has been a delay in making the film.

CONCLUSION

Despite major advances in other diagnostic methods, the blood smear remains very useful in hematologic diagnosis. Sometimes it is critical either because it yields a diagnosis very quickly or because it provides information that is not available in any other way.

SUGGESTED READINGS

TABLE 161-1 NORMAL VALUES FOR RED BLOOD CELL MEASUREMENTS

MEASUREMENT	UNIT	NORMAL RANGE (APPROXIMATE)*
Hemoglobin	g/dL	Males: 13.5-17.5 Females: 12-16
Hematocrit	%	Males: 40-52 Females: 36-48
Red blood cell (RBC) count	$\times 10^6/\mu L$ of blood	Males: 4.5-6.0 Females: 4.0-5.4
Mean cell volume (MCV)	fL	81-99
Mean cell hemoglobin (MCH)	pg	30-34
Mean cell hemoglobin concentration (MCHC)	g/dL	30-36
RBC size distribution width		
RDW-CV	%	12-14
RDW-SD	fL	37-47
Reticulocyte count (absolute number)	No./μL of blood	20,000-100,000
Reticulocyte percentage	% of RBCs	0.5-1.5

*Actual normal ranges for many of these values may vary slightly, depending on factors such as the location and type of laboratory instruments used, altitude above sea level, and patient age.

O_2 Delivery = Blood Flow × Hb Concentration × (Asat − Vsat)

In anemia: ↑ Cardiac output, Altered flow distribution | ↑↑ Plasma Erythropoietin | ↓ RBC 2,3-DPG, RBC O_2 affinity

FIGURE 161-1. The Fick equation expresses the three independent variables that determine the transport of oxygen to a given organ or tissue. The impact of anemia on each of these variables is shown beneath the equation. Asat = oxygen saturation of arterial blood (oxyhemoglobin/oxyhemoglobin + deoxyhemoglobin); 2,3-DPG = 2,3-diphosphoglycerate (2,3-bisphosphoglycerate); Hb = hemoglobin; RBC = red blood cell; Vsat = oxygen saturation of venous blood.

161 APPROACH TO THE ANEMIAS

H. FRANKLIN BUNN

Anemia is defined as a significant reduction in the mass of circulating red blood cells. As a result, the oxygen binding capacity of the blood is diminished. Because blood volume is normally maintained at a nearly constant level, anemic patients have a decrease in the concentration of red cells or hemoglobin in peripheral blood. As shown in Table 161-1, hemoglobin and hematocrit levels vary with the age of the individual and, in adults, with gender. The values in women of childbearing age are 10% lower than those in men. At altitude, higher values are found, roughly in proportion to the elevation above sea level. Anemic patients' values are more than one standard deviation below the mean values for their gender. However, because of the wide range in normal hemoglobin and hematocrit levels, it is often difficult to document mild anemia.

Sometimes the diagnosis of anemia is confounded by a concomitant change in the plasma volume. For example, if a patient with a low red cell mass sustains a loss of plasma volume from dehydration, diarrhea, vomiting, or severe burns, the blood hemoglobin and hematocrit levels will be increased and may even be in the normal range. Another important example, discussed in detail later in this chapter, is acute hemorrhage, in which the loss of both red blood cells and plasma results in a false elevation of hemoglobin and hematocrit. In contrast, hemoglobin and hematocrit values may be falsely low in patients with an expanded plasma volume, such as in pregnancy or congestive heart failure.

PATHOBIOLOGY

Impact of Anemia on Oxygen Transport

In any organ or region of the body, the transport of oxygen is a product of three independent variables expressed in the Fick equation (Fig. 161-1). The middle variable—the oxygen carrying capacity of the blood—is, by definition, low in anemic patients. The two other variables in the Fick equation undergo compensatory changes that, as explained later, greatly enhance oxygen transport.

Blood Flow

Anemia has a marked impact on blood flow, the left-hand variable in the Fick equation. In all anemic individuals, there is enhanced flow to vital organs, including the heart, brain, liver, and kidneys, at the expense of nonvital organs. Anemic patients are pale because blood is diverted away from the skin and mucous membranes to preserve oxygen supply to the critical organs. Resting cardiac output is normal in patients with mild or moderate anemia, but with exercise, it increases more than that of a normal individual. In severe anemia, resting cardiac output is increased, putting patients at risk of developing high-output cardiac failure, particularly those with coronary artery insufficiency or other types of preexisting cardiac disease.

Oxygen Binding to Hemoglobin

The variable on the right side of the Fick equation is the difference in fractional oxygenation between the arterial and venous blood. This difference in

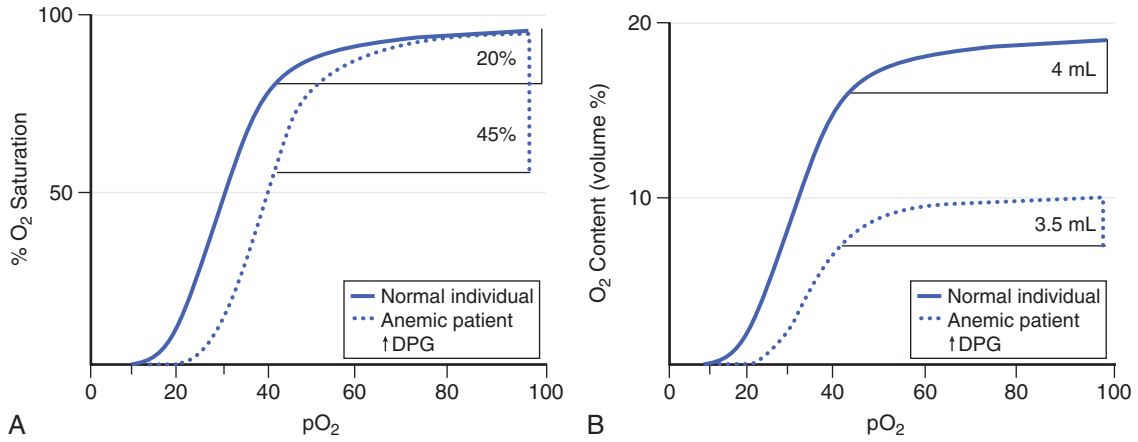

FIGURE 161-2. Oxygen binding curves for hemoglobin of a normal individual and a patient with anemia. A, Conventional plot of percent of oxygen (O_2) saturation versus oxygen tension (pO_2). **B,** The Y-axis shows the volume of oxygen in milliliters per 100 mL of blood. DPG = diphosphoglycerate.

oxygen saturation is determined by the hemoglobin oxygen binding curve. A comparison between a normal individual and an anemic patient is shown in Figure 161-2. As shown in part A, the curve is shifted to the right in an anemic patient. At any given oxygen tension (Po_2), the oxygen saturation of hemoglobin is lower. Thus, red cells of anemic patients have decreased oxygen affinity. This change is due entirely to elevated levels of red cell 2,3-diphosphoglycerate (2,3-DPG) in red cells. This glycolytic intermediate is the principal determinant of oxygen affinity in human red cells. The Po_2 in arterial blood is normally approximately 95 mm Hg, resulting in nearly 100% oxygen saturation. During the transit of red cells from an artery through its capillary bed to its vein, oxygen is released to respiring cells. In normal individuals, at a normal venous Po_2 of about 40 mm Hg, the oxygen saturation is approximately 80%. Thus, as shown in Figure 161-2A, 20% of the oxygen in the blood is unloaded. In contrast, in patients with anemia and elevated red cell 2,3-DPG levels, the lower oxygen affinity of their red cells enables a much higher fraction of the oxygen (about 45%) to be unloaded. In Figure 161-2B, the oxygen binding curves are depicted with the volume fraction of oxygen plotted on the Y-axis. One gram of hemoglobin binds up to 1.34 mL of oxygen under standard conditions of temperature and pressure. Thus, in a normal individual having a hemoglobin of 15 g/dL, the oxygen carrying capacity of the blood is 15 × 1.34, or 20 mL O_2/dL. As mentioned earlier, 20% of this oxygen will be unloaded—that is, 4 mL O_2/100 mL blood during arterial-venous transit. In contrast, an anemic patient with a hemoglobin of 7.5 g/dL has an oxygen binding capacity that is half normal, or 10 mL O_2/dL. If this patient had red cells with normal oxygen affinity, 20%, or only 2 mL of oxygen, would be unloaded per 100 mL of blood. However, because the patient's red cells have a lower affinity for oxygen, 3.5 mL is unloaded, nearly as much as normal. Thus, the decrease in oxygen affinity is an important mechanism by which anemic patients compensate for the deficit in red cell mass.

Methemoglobinemia

In order for hemoglobin to reversibly bind oxygen, the iron atom in the heme must be in the reduced (Fe^{2+}) valence state. As red cells circulate, the heme iron slowly auto-oxidizes to Fe^{3+}, forming methemoglobin, which is incapable of binding oxygen. Normal red cells are endowed with a very efficient enzymatic pathway composed of cytochrome b_5, cytochrome b_5 reductase, and NADH that rapidly reduces the iron in methemoglobin back to its functional Fe^{2+} form. Thus, normal red cells contain less than 0.5% methemoglobin. However, either an inherited deficiency in cytochrome b_5 reductase or exposure to an oxidant drug or toxin can result in methemoglobinemia. Laboratory samples of blood containing methemoglobin are dark brown, whereas patients with greater than 10% methemoglobinemia have cyanosis, a blue discoloration of the skin indistinguishable from that commonly seen in patients having normal hemoglobin but low oxygen saturation owing to pulmonary or cardiac disease. In many hospitals and large clinical laboratories, the instrument that measures oxygen saturation in blood samples also provides an accurate determination of methemoglobin.

Patients with congenital methemoglobinemia inherit an autosomal recessive deficiency in cytochrome b_5 reductase. Heterozygote relatives have low or undetectable methemoglobin levels, whereas affected individuals (homozygotes and compound heterozygotes) generally have 10 to 35% methemoglobin. These individuals are generally asymptomatic owing to the fact that the methemoglobin is distributed primarily in the older population of red cells. Nevertheless, many affected individuals have cosmetic concerns. Treatment with oral ascorbic acid or riboflavin is effective in lowering the level of methemoglobin below the threshold of detectable cyanosis.

A variety of drugs can cause methemoglobinemia, including acetaminophen (Tylenol), dapsone, nitroprusside, amyl nitrate, and procaine congeners used for local anesthesia. It is not clear why only a very small fraction of those using these drugs develop this complication, but some affected individuals have been shown to be heterozygous for cytochrome b_5 reductase deficiency. When these drugs are taken in prescribed doses, methemoglobinemia seldom reaches levels high enough to cause clinical concern.

In contrast, individuals exposed to industrial toxins such as nitrite, nitrate, or aniline may develop life-threatening levels of methemoglobin. The threshold at which symptoms occur is highly variable. Acute induction of 20% methemoglobin may cause fatigue; at 30%, individuals often develop tachycardia. When methemoglobin exceeds 50%, patients experience weakness, breathlessness, and confusion. At 70 to 80%, coma and death may occur. The toxicity of methemoglobinemia is not just because of the oxidized hemes' inability to bind oxygen; the remaining functional (Fe^{2+}) hemes in the hemoglobin tetramer have increased oxygen affinity and therefore, as suggested in Figure 161-2, are much less effective in releasing oxygen to tissues. Patients with toxic methemoglobinemia can be effectively treated with intravenous infusion of methylene blue (1 to 2 mg/kg).

Regulation of Erythropoiesis by Erythropoietin

Anemia also impacts the middle component of the Fick equation (see Fig. 161-1). As mentioned earlier, hemoglobin levels are, by definition, low in anemic patients. The resultant decrease in the oxygen carrying capacity of the blood causes cellular hypoxia. In all cells of the body, a molecular sensor detects even modest degrees of low oxygen tension and induces a hypoxia-inducible transcription factor called HIF. HIF upregulates expression of the hormone erythropoietin in the kidney and, to a lesser extent, in the liver. Erythropoietin (Chapter 159) binds to a specific receptor abundantly expressed on erythroid progenitor cells in the bone marrow and salvages these cells from apoptosis, thereby enhancing red blood cell production. Normal individuals maintain nearly constant levels of circulating red cells by finely tuned regulation of erythropoietin production. In anemic patients, the hypoxic signal in the kidneys and, to a lesser extent, in the liver results in a robust induction of erythropoietin expression. As the hematocrit falls, the plasma erythropoietin level rises markedly; in severely anemic patients, it may be 1000-fold higher than normal (Fig. 161-3). In patients with anemia due to impaired red cell production, their erythroid progenitors are unresponsive to such high levels of plasma erythropoietin. In contrast, in patients whose anemia is due to hemolysis or blood loss, elevated erythropoietin levels maximize red cell production.

CLINICAL MANIFESTATIONS

Figure 161-4 is a 17th-century painting of a pale young woman clutching her chest, apparently complaining of palpitations. Her physician is feeling her

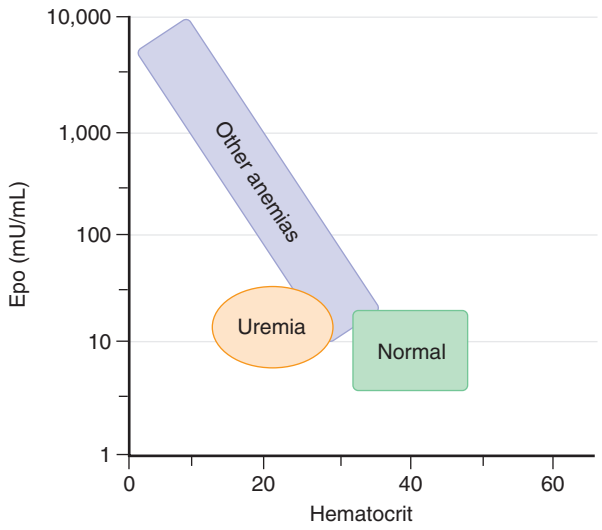

FIGURE 161-3. Plasma erythropoietin (Epo) levels in patients with different degrees of anemia. The subset of anemia patients with chronic renal disease (labeled "Uremia") have much lower plasma erythropoietin levels than those with other types of anemia. Values for normal individuals are also shown.

FIGURE 161-4. "The Sick Lady," a 17th-century painting attributed to Caspar Netscher, from the Royal Collection, Buckingham Palace.

pulse, documenting her rapid, forceful heartbeat. These signs and symptoms, common in patients with very low hemoglobin levels, can be readily explained by the cardiovascular adjustments discussed in the preceding section. These clinical findings pertain to anemia per se, irrespective of cause, and are dependent on its severity and chronicity. The history and physical examination may reveal additional findings peculiar to specific causes of anemia or to other comorbid conditions. The degree to which symptoms occur in an anemic patient depends on several contributing factors. If the anemia has developed rapidly, there may not have been adequate time for compensatory adjustments to take place, and the patient may have more marked symptoms than if an anemia of equivalent severity had developed insidiously. Furthermore, the patient's complaints may depend on the presence of local vascular disease. For example, symptoms owing to ischemia in patients with angina pectoris, intermittent claudication, or transient cerebral episodes may be triggered by the development of anemia.

Symptoms

Many individuals with mild anemia have no complaints and are unaware that they have "tired blood." Others may complain of fatigue as well as dyspnea and palpitations, particularly following exercise. Patients with severe anemia are often symptomatic at rest and are unable to tolerate significant exertion.

TABLE 161-2 INITIAL ASSESSMENT OF ANEMIA

Decreased red cell production
Usually acquired
Onset is insidious
Reticulocyte count is inappropriately low
Red cell indices (MCV, MCHC) are informative
Bone marrow examination is often required for diagnosis
Increased red cell destruction (hemolysis)
Often inherited
Onset may be abrupt or insidious
Reticulocyte count is increased
Red cell morphology is usually informative
Bone marrow examination is usually not indicated
Blood loss—must be ruled out in any patient with anemia

MCHC = mean cell hemoglobin concentration; MCV = mean cell volume.

If the hemoglobin concentration falls below 7.5 g/dL, resting cardiac output is likely to rise, with an increase in both stroke volume and heart rate. The patient may be aware of this hyperdynamic state and complain of a rapid, pounding sensation in the precordium. Patients with compromised myocardial reserve may develop complaints due to cardiac failure.

The symptoms of severe anemia often extend beyond the cardiac or circulatory system. Patients sometimes experience dizziness and headache and, less often, syncope, tinnitus, or vertigo. Many are irritable and have difficulty sleeping or concentrating. Because blood flow is shunted away from the skin, patients may complain of increased sensitivity to cold. In like manner, gastrointestinal symptoms such as indigestion, anorexia, or even nausea are attributable to the shunting of blood away from the splanchnic bed. Females commonly develop abnormal menstruation, either amenorrhea or increased bleeding. Males may experience impotence or loss of libido.

Physical Findings

Pallor is the most commonly encountered physical finding in patients with anemia. As mentioned earlier, this sign is due to the shunting of blood away from the skin and other peripheral tissues, permitting enhanced blood flow to vital organs. The usefulness of pallor as a physical finding is limited by other factors that affect the appearance of the skin. Blood flow to the skin may undergo wide fluctuations. Moreover, the skin's thickness and texture vary widely among individuals. Those with a fair complexion may appear pale even though they are not anemic, while pallor is difficult to detect in deeply pigmented individuals. The amount of melanin in the epidermis is an important determinant of skin color. Pallor may be difficult to detect in patients who have increased melanin pigmentation due to Addison's disease or hemochromatosis. Nevertheless, even in blacks, the presence of anemia may be suspected by the color of the palms or of noncutaneous tissues such as oral mucous membranes, nail beds, and palpebral conjunctivas. When the creases of the palm are as pale as the surrounding skin, the patient usually has a hemoglobin of less than 7 g/dL.

In addition to tachycardia, wide pulse pressure, and hyperdynamic precordium, a systolic ejection murmur is often heard over the precordium, particularly at the pulmonic area. In addition, a venous hum may be detected over the neck vessels. These findings disappear when the anemia is corrected.

DIAGNOSIS

Laboratory Evaluation of the Patient with Anemia

In the clinical assessment of the anemic patient, it is important to proceed in a systematic way so that the diagnosis can be established with a minimum of laboratory tests and procedures. A thorough history and careful physical examination are critical in the initial evaluation of the anemic patient. For example, a family history that reveals a dominant inheritance pattern would reinforce the tentative diagnosis of hereditary spherocytosis. The presence of fever, a new heart murmur, and splenomegaly is an anemic patient suggests subacute bacterial endocarditis.

In evaluating the anemic patient, the clinician must first ask whether the anemia is caused by decreased production of red cells or by loss of blood cells as a result of hemorrhage or hemolysis (Table 161-2). Blood loss may be either the sole cause of the anemia or a significant contributor. Therefore, examination of the stool for occult blood is an indispensable part of the evaluation of all anemic patients.

The laboratory work-up of anemia includes a complete blood count, red cell indices, reticulocyte count, and microscopic examination of the blood

smear. In addition, in many cases a bone marrow examination is a critical component of the initial laboratory assessment.

Complete Blood Count

Most hospitals and clinical laboratories use equipment that provides high-throughput analyses of red cell, platelet, and white cell counts and white cell differential, along with measurements of cell size. The mean red cell volume (MCV) is normally 81 to 99 fL. These instruments also provide accurate determinations of hemoglobin concentration. The hematocrit, or fraction of packed red cells over total blood volume, is determined indirectly from the red cell count and the MCV. The mean concentration of hemoglobin within the red cell population (MCHC) is the quotient of hemoglobin divided by hematocrit. The MCV is particularly useful in classifying the anemias caused by decreased red cell production. Microcytic anemias have low MCV values and often low MCHC. Microscopic examination reveals small and often pale red cells. The MCV in the macrocytic anemias is increased, and large, oval cells (macro-ovalocytes) are seen. In contrast to the anemias of underproduction, the hemolytic anemias are either normocytic or slightly macrocytic owing to the preponderance of young red cells that are relatively large. Severe forms of thalassemia (Chapter 165) are an exception; there, microcytic red cells may be accompanied by brisk hemolysis.

Reticulocyte Count

This simple and cost-effective test is extremely useful for distinguishing anemias secondary to decreased red cell production from those caused by hemolysis. With the application of an appropriate supravital stain, the 1- to 2-day-old red cells in the peripheral blood reveal a network of purple strands, which are aggregates of ribosomes. The reticulocyte count in normal individuals is about 1%, consistent with a red cell lifespan of approximately 120 days. An elevated reticulocyte count reflects the release of an increased number of young cells from the bone marrow. The rate of red cell production can be assessed more quantitatively by determining the absolute reticulocyte count, the product of the percentage of reticulocytes and the red cell count. Thus, normal blood contains about 50,000 reticulocytes/mm^3. In interpreting this test, one should consider the distribution of reticulocytes between the bone marrow and the peripheral blood. When erythropoiesis is robust, marrow reticulocytes enter the circulation prematurely. These "shift reticulocytes" appear larger than average on a routine (Wright-stained) blood smear and have a lavender hue, called polychromatophilia. Because the circulation of shift reticulocytes in the peripheral blood is prolonged, the reticulocyte count should be divided by two. This correction should always be made if normoblasts are encountered in the peripheral blood because this finding indicates the premature release of newborn red cells into the circulation.

A failure to produce red cells is reflected in an inappropriately low reticulocyte count. In contrast, a significant elevation of reticulocytes is suggestive of hemolysis. Exceptions include the following:

- The brisk reticulocyte response seen in patients with hemorrhage
- Reticulocytosis encountered in patients recovering from impaired erythropoiesis (e.g., an individual with pernicious anemia who received an injection of cobalamin 1 week earlier)
- Mild to moderate elevations in reticulocytes (3 to 7%) encountered in myelophthisic anemia (Chapter 160), in which the orderly release of cells is affected by alterations of the marrow stroma owing to tumor, fibrosis, or granuloma

These exceptions are generally appreciated in the initial evaluation of the patient.

A number of ancillary laboratory tests described later under Hemolytic Anemias are useful in determining both the extent and the cause of hemolysis.

Examination of the Blood Smear

In the evaluation of any patient with unexplained anemia, the physician should take the time to examine a well-stained peripheral blood film (Chapter 160). Many subtleties escape the attention of the technologist, whose primary aim is to confirm or refine the white cell differential count provided by automated cell counters. The clinician approaches the specimen with a prepared mind and can scrutinize it for specific abnormalities. Examination of the blood film can confirm the size and color of red cells estimated by red blood cell indices. In contrast to the mean statistical values provided by automated cell counters, microscopic examination can reveal variations in red cell size (anisocytosis) or shape (poikilocytosis), abnormalities that are helpful in diagnosing specific anemias. Examination of the blood smear is particularly important in a patient with hemolysis. Many types of hemolytic anemia have characteristic abnormalities in red cell morphology. The presence of abnormal white cells may be the first clue to a lymphoproliferative or primary bone marrow disorder.

Bone Marrow Examination

A microscopic examination of the bone marrow (aspirate with or without a core biopsy) is often useful and may be critical in the work-up of any *unexplained* anemia. Study of the bone marrow is informative in the diagnosis of anemias of underproduction, particularly those accompanied by abnormalities in white cells and/or platelets, suggesting disordered hematopoiesis. The more severe the anemia, the more likely it is that the procedure will be informative. An assessment of the quantity and quality of red cell precursors may identify a defect in cell production due to either hypoplasia or ineffective erythropoiesis. A marrow biopsy is required for estimating overall cellularity. The ratio of myeloid (M) to erythroid (E) precursors is normally about 2 : 1, but it may be artifactually increased by the inclusion of circulating leukocytes. The ratio is increased in patients with infection, a leukemoid reaction, or neoplastic proliferation of myeloid cells. Rarely, a high M/E ratio is due to selective aplasia of the red cell precursors. A decreased M/E ratio indicates erythroid hyperplasia. Erythroid maturation is normal in hemolysis and hemorrhage, but it is disordered when erythropoiesis is ineffective, such as in megaloblastic and sideroblastic anemias and in β-thalassemia major or intermedia. The bone marrow examination is also important in demonstrating the presence of cellular infiltrates such as those found in leukemia, lymphoma, or multiple myeloma. The demonstration of tumor, fibrosis, or granuloma usually requires a bone marrow biopsy, not just a bone marrow aspiration. A portion of the marrow specimen should be stained with Prussian blue. In addition to providing an assessment of iron stores, this iron stain is required for the identification of erythroid sideroblasts.

ANEMIA DUE TO BLOOD LOSS

The clinical presentation of anemia resulting from blood loss varies considerably, depending on the site, severity, and rapidity of the hemorrhage. At opposite extremes are acute fulminant bleeding producing hypovolemic shock and chronic occult blood loss leading to iron deficiency anemia.

Acute Blood Loss

Patients who have had a sudden hemorrhage present with clinical findings secondary to hypovolemia and hypoxia. Symptoms and signs depend on the severity of the process. The patient may experience weakness, fatigue, lightheadedness, or stupor and may appear pale, diaphoretic, and irritable. The vital signs reflect cardiovascular compensation for the acute blood loss. The degree of hypotension and tachycardia depends on the extent of the hemorrhage. Elicitation of postural signs is useful in the initial evaluation of a patient with acute blood loss. When a patient is lifted from a supine to a sitting position, an increase in the pulse of 25% or more or a fall in the systolic blood pressure of 20 mm Hg or more signifies significant hypovolemia (blood loss >1000 mL). Acute blood loss in excess of 1500 mL usually leads to cardiovascular collapse.

Following acute hemorrhage, the red cell mass and plasma volume are contracted in parallel; accordingly, there is often not a significant decrease in the hemoglobin or hematocrit level initially. This stress induces a moderate leukocytosis and a "shift to the left" in the white cell differential count. In both acute and chronic blood loss, the platelet count is often increased, particularly if the patient is already iron deficient. During the first few days after acute blood loss, there is usually an increase in reticulocytes. Severe hypoxia may trigger the release of nucleated red cells from the bone marrow into the peripheral blood. Because young red cells are larger than old ones, the MCV generally rises slightly. If significant blood loss continues, reticulocytosis will persist until iron stores have been exhausted. Internal bleeding is often accompanied by an increase in unconjugated bilirubin, reflecting an increase in the catabolism of heme from extravasated red cells. Patients with acute gastrointestinal blood loss sometimes have an elevation of blood urea nitrogen owing to impaired renal blood flow and perhaps to the absorption of digested blood protein.

These patients must be assessed promptly, and treatment must be initiated without delay. Patients with severe acute blood loss require transfusion of packed red cells, with central monitoring of the appropriate amount of volume replacement. The site or sites of bleeding should be emergently identified and controlled. In addition, an emergency coagulation profile should

be obtained. The approach to the patient with shock is discussed in detail in Chapter 106.

Chronic Blood Loss

Chronic blood loss is usually due to lesions in the gastrointestinal tract or the uterus. Testing of stool specimens for occult blood is an essential but frequently overlooked part of the evaluation of anemia. It is sometimes necessary to examine serial specimens over a prolonged period because gastrointestinal bleeding may be intermittent. The hematologic manifestations of chronic blood loss are those of iron deficiency anemia, discussed in detail in Chapter 162.

ANEMIAS DUE TO DECREASED RED CELL PRODUCTION

As shown in Table 161-3, anemias caused by the underproduction of red cells can be conveniently classified according to red cell size: microcytic, macrocytic, and normocytic.

Microcytic Anemias

The presence of small red cells (MCV <77 fL) indicates a defect in the production of hemoglobin. As shown in Figure 161-5, hemoglobin is composed of globin subunits into which heme is inserted. Heme is produced by the insertion of an iron atom into porphyrin (protoporphyrin IX). A defect in any of these three key components can cause microcytic anemia. Most individuals with microcytosis have either iron deficiency anemia (Chapter 162) or thalassemia (Chapter 165). A congenital or, more often, acquired impairment in porphyrin synthesis can lead to a buildup of excess iron in erythroid cells, resulting in the morphologic entity of ringed sideroblasts, which are identified in red cell precursors in the bone marrow (Chapter 162). Most patients with acquired sideroblastic anemia actually have a normal or somewhat elevated MCV but a broad distribution of red cell size, including a population of microcytes (because of this ambiguity, sideroblastic anemia appears in parentheses in Table 161-3). Iron deficiency anemia, the thalassemias, and sideroblastic anemia all involve some degree of ineffective erythropoiesis.

The anemias of chronic inflammation and malignancy, described in detail later, may be slightly microcytic owing to a defect in the availability of iron. However, these disorders are more often normocytic. Measurement of serum iron and iron binding capacity (Fig. 161-6A) and evaluation of marrow iron stores are particularly useful in distinguishing between iron deficiency and the anemia of chronic inflammation.

Macrocytic Anemias

A modest increase in red cell size is encountered in a variety of conditions, including liver disease, hypothyroidism, acute blood loss, hemolytic anemia, aplastic anemia, and alcoholism. The macrocytes in liver disease and hypothyroidism may be related to an increased deposition of lipid in the red cell membrane. If the MCV exceeds approximately 105 fL, the patient is likely to be deficient in either cobalamin (vitamin B_{12}) or folic acid. The bone marrow reveals megaloblastic morphology, reflecting impaired replication of DNA. Because nuclear maturation lags behind cytoplasmic development, large red cells tend to be produced in the bone marrow. Megaloblastic anemias are discussed in detail in Chapter 167. Like the microcytic anemias, these disorders are maturation defects associated with ineffective erythropoiesis.

TABLE 161-3 ANEMIAS DUE TO DECREASED RED CELL PRODUCTION

Microcytic	Abnormal erythroid maturation
Iron deficiency	
Thalassemias	
(Sideroblastic anemia)	
Macrocytic	
Megaloblastic	
Cobalamin deficiency	
Folic acid deficiency	
Other—hemolysis, acute blood loss, aplasia, ethanol	
Normocytic	Decreased erythroid progenitors
Primary bone marrow failure	
Aplasia	
Myelophthisis	
Secondary to a chronic disease

Normocytic Anemias

The normocytic anemias of underproduction are a diverse group of disorders. They can be conveniently divided into two categories: those due to intrinsic pathology within the bone marrow, and those secondary to some other underlying disease.

Primary Bone Marrow Disorders

The primary disorders of the bone marrow, such as the leukemias (Chapters 189 and 190), myelodysplasia (Chapter 188), aplastic anemia (Chapter 168), and myelophthisis, are best approached by microscopic examination of a marrow aspirate and biopsy. This group of anemias is often accompanied by leukopenia and thrombocytopenia. A lesser degree of pancytopenia can also occur in hypersplenism and in the megaloblastic anemias.

Anemias of Chronic Disease

Among the most common anemias and the ones most prevalent in patients hospitalized on a medical service are those secondary to an underlying chronic disease. The diagnosis is usually quite straightforward. However, in some patients the predisposing illness may not be apparent. Thus, the presence of an unexplained normocytic anemia should prompt the search for the disorders listed in Table 161-4. Even if the presence of an underlying illness is established, the physician should investigate whether other factors such as blood loss or a nutritional deficiency are contributing to the patient's anemia. Generally, the anemias due to chronic inflammation, an endocrinopathy, or liver disease are of only moderate severity. In contrast, the anemia of uremia is often severe.

ANEMIA OF CHRONIC INFLAMMATION

If a systemic inflammatory disorder persists for more than a few weeks, it is nearly always accompanied by anemia. As shown in Table 161-4, the most common causes of chronic inflammation are infection, tumor, or a connective tissue disorder. Many chronic infections can be responsible, including tuberculosis, lung abscess, subacute bacterial endocarditis, pyelonephritis, and osteomyelitis. The pathogenesis is more complex in some types of chronic infections. For example, in AIDS, the human immunodeficiency virus can directly attack hematopoietic cells and suppress erythropoiesis. In malaria and babesiosis, the parasite enters circulating red cells and triggers their destruction.

There is considerable variability in tumors' ability to evoke an inflammatory response. Many tumors express inflammatory cytokines as part of their profile of abnormal gene expression. In some cases, impaired supply of oxygen or nutrients to the interior of the tumor mass can lead to necrosis and an inflammatory response. Red cell production may be further compromised by encroachment of the bone marrow with leukemia, lymphoma, or metastatic tumor.

Anemia is also a feature of a broad range of inflammatory conditions that are not associated with either infection or cancer. In some of these disorders, the autoimmune attack on the patient's cells and tissues is met with a robust inflammatory response. Rheumatoid arthritis (Chapter 272) is the most commonly encountered connective tissue disorder and gives rise to the prototypical anemia of chronic inflammation. Even more intense inflammation and, accordingly, more severe anemia are seen in polymyalgia rheumatica and temporal arteritis (Chapter 279). In patients with systemic lupus erythematosus (Chapter 274), the anemia of chronic inflammation is often compounded by either immune hemolysis (Chapter 163) or renal insufficiency (discussed later).

Aging

PATHOBIOLOGY

Recently, the mechanism underlying the anemia of chronic inflammation has been elucidated by the discovery that plasma hepcidin levels are markedly increased as a result of induction by inflammatory cytokines. As shown in Figure 161-7, hepcidin blocks both iron absorption from the gut and the exit of iron from macrophages, thus explaining both reduced levels of serum iron and increased iron stores.

DIAGNOSIS

The anemia of chronic inflammation is associated with disordered iron homeostasis. Increased storage of iron in macrophages within the bone marrow, liver, and spleen results in elevated levels of serum ferritin (Fig. 161-6B). However, because of a block in the transfer of this excess iron into the plasma, serum iron is low (see Fig. 161-6A). The level of total transferrin in the serum is also low for unclear reasons. With the recent development of a reliable assay for hepcidin, elevated serum levels of this "master regulator" of iron homeostasis should become useful in the diagnosis of the anemia of chronic inflammation. Because of the impairment in iron availability, erythropoiesis is somewhat "iron deficient." The amount of cytoplasmic iron is

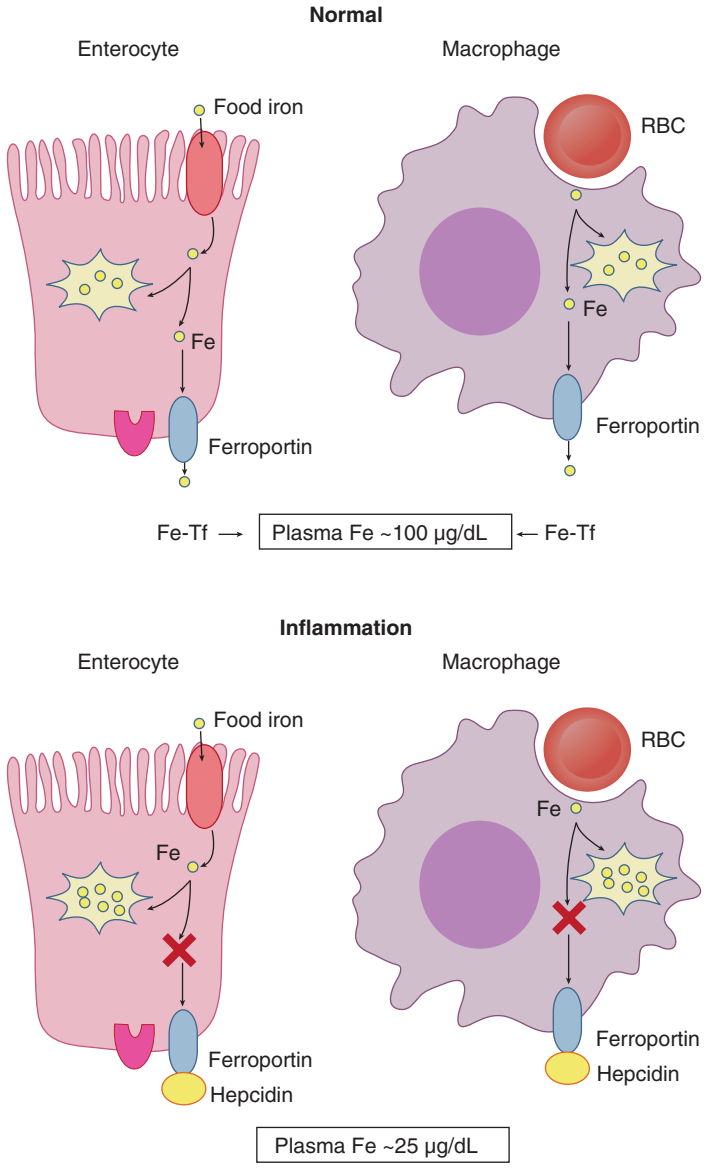

FIGURE 161-7. Pathogenesis of the block in iron availability in the anemia of chronic inflammation. The primary sources of iron in the plasma are from the breakdown of senescent red blood cells (RBCs) within macrophages and from duodenal absorption. **A,** In the presence of physiologically low levels of hepcidin in the plasma, there is efficient release of iron from the duodenal enterocyte and from macrophages via ferroportin. **B,** In patients with inflammation, the induction of plasma hepcidin by interleukin-6 and other cytokines results in the inactivation of ferroportin and the loss of iron egress from the duodenal enterocyte and from the macrophage.

decreased in erythroid precursors in the bone marrow, and the red cells that enter the circulation are slightly microcytic. This suppression of red cell production is earmarked by a low reticulocyte index. Because this block in iron utilization is subtle, the degree of anemia is seldom severe in patients with inflammatory disorders. If the hemoglobin is less than 8 g/dL, it is necessary to look for additional contributors such as hemolysis or bleeding.

TREATMENT Rx

Because the anemia of chronic inflammation is not severe, patients seldom require red cell transfusions. Some patients may benefit from recombinant erythropoietin therapy. However, the anemia is not fully corrected unless the underlying disease is effectively treated.

ANEMIA OF RENAL INSUFFICIENCY

A normocytic anemia almost always accompanies uremia (Chapter 132). Although the hemoglobin level is highly variable, the severity of the anemia is roughly proportional to the degree of impaired renal function. The cause of the kidney failure usually has little bearing on the extent of anemia. However, for any level of serum creatinine, patients with polycystic disease tend to be less anemic than those with other types of renal disease. In contrast to the anemias associated with other chronic disorders, the anemia of uremia can be very severe, with hemoglobin levels as low as 4 g/dL.

Examination of the bone marrow seldom reveals any abnormalities. Red cell morphology is usually normal. In a minority of patients, the peripheral blood smear reveals so-called burr cells characterized by an evenly scalloped border. Neither the degree of anemia nor the red blood cell lifespan is influenced by the presence of burr cells. In most patients, the corrected reticulocyte count is low, and the red blood cell survival is only modestly decreased. Thus, the low red blood cell mass is due to decreased red blood cell production.

PATHOBIOLOGY

The primary basis for the anemia is the diseased kidneys' inability to secrete adequate amounts of erythropoietin. Plasma erythropoietin levels are lower than those of nonuremic patients with a comparable degree of anemia (see Fig. 161-3). Erythropoiesis is further impaired but not abolished in patients who have undergone bilateral nephrectomy. In addition, red blood cell production may be suppressed by the accumulation of substances that are normally cleared by the kidneys.

Other factors may aggravate the anemia of renal disease. Uremic patients have a propensity to hemorrhage, owing to a qualitative defect in platelet function. As in other patients, chronic gastrointestinal blood loss leads to iron deficiency. Folic acid deficiency may also occur, owing to the poor nutrition of many patients or to the loss of this vitamin during dialysis. Patients whose renal failure is due to thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome (Chapter 175) have a severe form of microangiopathic hemolytic anemia, with characteristic abnormalities of red blood cell morphology (Chapter 160).

TREATMENT Rx

Treatment of the anemia of uremia first focuses on reversing the renal failure. A prompt and dramatic correction of the anemia follows successful renal transplantation. Occasionally, polycythemia may be encountered following renal engraftment and may be a harbinger of impending rejection.

In patients who are not candidates for renal transplantation, the treatment of anemia of uremia has been revolutionized by the administration of recombinant human erythropoietin (rHuEPO). The rapid and complete responses that occur underscore the importance of erythropoietin in the pathogenesis of anemia. Figure 161-8 shows the hematologic response of one of the first patients treated with rHuEPO. Within a few days of initiating rHuEPO therapy, the hematocrit approached normal, necessitating a reduction in dose. Before rHuEPO treatment, this patient was overloaded with iron, as documented by increased serum ferritin and nearly full saturation of serum transferrin. As the red cell mass increased rapidly following treatment, the robust utilization of iron stores resulted in a decline in serum ferritin and transferrin saturation. In contrast to this patient with iron overload, many uremic patients on dialysis therapy have normal or low iron stores before rHuEPO therapy and need the concomitant administration of iron to maximize the erythropoietic response.

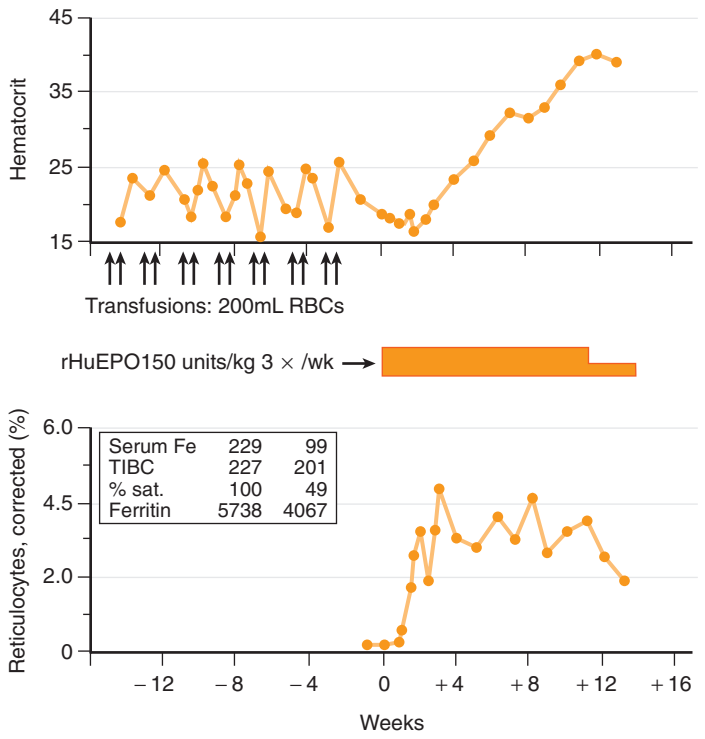

FIGURE 161-8. Response of a uremic patient to recombinant human erythropoietin (rHuEPO) therapy. Before therapy, the patient was severely anemic and transfusion dependent. Treatment with rHuEPO resulted in a reticulocytosis, followed by a progressive increase in hemoglobin. The dose of rHuEPO had to be lowered to prevent the hemoglobin from rising too high. Before rHuEPO therapy the patient was severely iron overloaded. The marked increase in red cell mass following therapy was accompanied by a significant reduction in iron stores. RBC = red blood cell; TIBC = total iron binding capacity. (From Eschbach JW, Egrie JC, Downing MR, et al. Correction of the anemia of end-stage renal disease with recombinant human erythropoietin: results of a combined phase I and II clinical trial. *N Engl J Med.* 1987;316:73-78.)

ANEMIA OF ENDOCRINE HYPOFUNCTION

The in vitro proliferation of erythroid cells is stimulated by a number of hormones, including thyroxine, glucocorticoids, testosterone, and growth hormone. Therefore, it is not surprising that a mild to moderate normocytic anemia generally accompanies endocrine deficiency states, including hypothyroidism, Addison's disease, hypogonadism, and panhypopituitarism.

In the anemia of hypothyroidism, erythropoiesis is suppressed, and the red blood cell lifespan is normal. A minority of patients have macrocytic red blood cells, often owing to cobalamin deficiency. Patients with hypothyroidism have an increased incidence of pernicious anemia. Some patients, particularly females with menorrhagia, develop iron deficiency and a microcytic anemia. The anemia of hypothyroidism may be masked because of a reduction in plasma volume. Because the signs and symptoms of hypothyroidism are sometimes elusive (Chapter 233), this diagnosis should be considered in any patient with unexplained anemia.

The anemia of adrenal insufficiency, including Addison's disease, may also be masked by a decrease in plasma volume. Untreated patients have an average hemoglobin level of about 13 g/dL. Upon hormone replacement, the plasma volume is rapidly reconstituted, and the hemoglobin level falls to 80% of its pretreatment value. With continued therapy, the red blood cell mass returns to normal.

Testosterone influences erythropoiesis in a physiologic manner. In males, the mean hemoglobin level increases from 13 to 15 g/dL during the transition from puberty to adulthood. Eunuchoid males usually have a mild anemia (hemoglobin ≈ 13 g/dL). Pituitary dysfunction or ablation is also associated with a mild anemia.

The anemias secondary to endocrine failure are all readily corrected when adequate hormone replacement is given.

ANEMIA OF CHRONIC LIVER DISEASE

Chronic liver disease, regardless of cause (Chapter 148), is usually accompanied by mild or moderate anemia that is normocytic or slightly macrocytic. An increased plasma volume may artificially lower the hematocrit, making

the anemia seem worse than it is. Red cell morphology is normal, except for the presence of target cells and occasional stomatocytes that have a slitlike rather than a circular area of central pallor. These morphologic features reflect an increased red cell membrane surface area due to increased deposits of cholesterol and phospholipid. The bone marrow is usually normal. Erythropoiesis fails to compensate for a modest shortening of the red cell lifespan. The mechanism underlying the anemia of chronic liver disease is not understood. The anemia is usually corrected if the patient regains normal hepatic function.

In patients with alcoholic liver disease (Chapters 155 and 156), the situation is much more complex. Many factors can contribute to the development of anemia. Alcohol in high doses suppresses not only erythropoiesis but also neutrophil and platelet production. In alcoholics who continue to drink up to the time of clinical evaluation, the bone marrow often reveals vacuoles in the cytoplasm of red and white blood cell precursors. In addition, ringed sideroblasts may be observed, especially if there is concurrent malnutrition. Folic acid deficiency is common in alcoholics because of both a suboptimal diet and an impairment of folate utilization. Moreover, the anemia in alcoholics is often compounded by gastrointestinal hemorrhage as a result of gastric erosions, duodenal ulcers, or esophageal varices. The risk of blood loss is further increased by the presence of thrombocytopenia and/or deficiencies in soluble clotting factors. Although alcoholics usually have increased iron stores, they may become iron deficient after prolonged gastrointestinal bleeding. Rarely, patients with alcoholic cirrhosis develop a severe hemolytic anemia accompanied by the appearance of rigid blood cells with irregular borders called acanthocytes or "spur" cells.

ANEMIA OF THE ELDERLY

As individuals age there is a slight and gradual fall in hemoglobin and hematocrit levels. Elderly individuals whose values fall below two standard deviations of normal have significantly enhanced morbidity and mortality. As people age, there is also an increased incidence of cancer, myelodysplasia, renal insufficiency, and chronic inflammatory disorders, all of which can suppress red cell production. Because of the high likelihood of comorbid conditions among the elderly, it is not possible to affirm with any certainty whether aging per se is a cause of anemia. Nevertheless, a fall in hemoglobin in any patient, old or young, should prompt an investigation into the possible presence of one of these underlying disorders.

HEMOLYTIC ANEMIAS

With the exception of sickle cell disease (Chapter 166), hemolytic anemias are encountered much less frequently than those caused by decreased red cell production. Although they are a diverse group, the hemolytic anemias share a number of clinical and laboratory features. Patients with moderate or severe hemolysis may have icterus owing to an elevation in nonconjugated (indirect) bilirubin. In addition, individuals with various types of hemolytic anemia often have splenomegaly, signifying the primary site of enhanced red cell destruction.

PATHOBIOLOGY

The presence of hemolysis is established by the laboratory tests outlined in Table 161-6. Further evaluation is required to establish the specific diagnosis. The clinician saves both time and money by using the available tests in a rational and orderly manner. Diagnosis of hemolytic anemias is greatly facilitated by the use of a logical and pathophysiologically based classification scheme. Table 161-5 groups these disorders going from the outside of the red cell into the cytoplasm, as well as by whether the defect is inherited or acquired. Hemolytic anemias due to environmental factors such as immune destruction or traumatic rupture (Chapter 163) are acquired. Abnormalities of red cell membrane proteins can also cause hemolysis. Mutations in proteins of the red cell cytoskeleton may cause hemolysis of varying severity. The most commonly encountered is hereditary spherocytosis (Chapter 164). Acquired red cell membrane defects are rare. Paroxysmal nocturnal hemoglobinuria is discussed in Chapter 163, and spur cell anemia was mentioned earlier in the section on anemias secondary to chronic liver disease. The proteins in the cytosol of the red cell include hemoglobin and enzymes. Mutations in these proteins can result in inherited hemolytic anemias. Sickle cell disease (Chapter 166) and the thalassemias (Chapter 165) are the most commonly encountered hemoglobinopathies. Homozygous SS disease and the compound heterozygous states SC disease and S/β-thalassemia are pure hemolytic anemias. In contrast, anemia in the clinically significant forms of β-thalassemia is primarily due to ineffective erythropoiesis. By far the most common red cell enzyme defect is glucose-6-phosphate dehydrogenase deficiency (Chapter 164).

TABLE 161-5 CLASSIFICATION OF THE HEMOLYTIC ANEMIAS*

Environmental factors	Acquired
Antibody: immunohemolytic anemias	
Mechanical trauma: TTP, HUS, heart valve	
Toxins, infectious agents: malaria, etc.	
Membrane defects	
Paroxysmal nocturnal hemoglobinuria	
Spur cell anemia	
Hereditary spherocytosis, etc.	
Defects of cell interior	Congenital
Hemoglobinopathies: sickle cell, thalassemia	
Enzymopathies: G6PD deficiency, etc.	

*A more detailed differential diagnosis of the hemolytic anemias is presented in Table 163-2 in Chapter 163.
G6PD = glucose-6-phosphate dehydrogenase; HUS = hemolytic-uremic syndrome; TTP = thrombotic thrombocytopenic purpura.

TABLE 161-6 LABORATORY FEATURES COMMON TO HEMOLYTIC ANEMIAS

Peripheral blood	
Increased reticulocyte count	
Polychromasia	
Bone marrow—erythroid hyperplasia	
Serum	
Increased nonconjugated (indirect) bilirubin	
Elevated lactate dehydrogenase (isoenzymes 1, 2, and 3)	
Decreased or absent haptoglobin	
Plasma hemoglobin:	
Extravascular hemolysis: moderately increased	
Intravascular hemolysis: markedly increased	
Urine	
Hemoglobinuria	In intravascular hemolysis
Hemosiderin in urine sediment	In intravascular hemolysis

DIAGNOSIS

A number of laboratory tests are used to establish the presence of accelerated breakdown of red cells (Table 161-6). As mentioned in the section Laboratory Evaluation of the Patient with Anemia, the reticulocyte count is the simplest and most cost-effective way to distinguish between hemolytic anemias and those due to decreased red cell production. In this test, a supervital stain or a probe for RNA reveals strands of polyribosomes that are present for only 24 to 48 hours after red cells exit the bone marrow. On a routine Wright or Romanowsky stain, these cells often appear relatively large, with a blue-gray hue (so-called polychromasia). The reticulocyte count is nearly always elevated in patients with hemolysis (unless there is concomitant marrow suppression, such as by folic acid or iron deficiency). This test is a reliable index of red cell production. Thus, in patients with hemolytic anemia, the bone marrow nearly always exhibits erythroid hyperplasia. Because this result is predictable, a bone marrow examination is seldom helpful in patients with hemolytic anemia, unless there is suspicion that the hemolysis is due to an underlying lymphoma.

A number of serum and urine tests are available to confirm the presence of hemolysis and assess its magnitude. As mentioned earlier, serum nonconjugated bilirubin is elevated in proportion to the severity of the hemolysis. Lactate dehydrogenase (LDH) isoforms type 1 through 3 are released from red cells during hemolysis, resulting in increased serum LDH. Most kinds of hemolytic anemia are extravascular, with red cell destruction mediated by macrophages in the spleen, liver, and bone marrow. In these patients, a relatively small amount of hemoglobin is released from engulfed red cells into the plasma, where it binds specifically to haptoglobin. The hemoglobin-haptoglobin complex is rapidly cleared from the circulation. Measurement of serum haptoglobin is a useful test of hemolysis. The great majority of patients with clinically significant hemolysis have very low or absent levels. Less often, patients have intravascular hemolysis with much higher levels of free hemoglobin in the plasma, sufficient to traverse renal glomeruli and exceed the

tubular reabsorption capacity. These patients have red or brown urine that, after centrifugation, tests positive with a "dipstick" that detects heme protein. Hemoglobinuria can be readily distinguished from myoglobinuria. In the former, both the plasma and the urine are pigmented. In the latter, the plasma remains colorless because the smaller myoglobin molecule rapidly traverses the glomeruli. Hemoglobinuria is often transient. For a week or so after the episode has abated, the urine sediment will contain hemosiderin, which can be readily detected with the Prussian blue iron stain.

Once these general laboratory tests confirm the presence of hemolysis, an array of specific tests is available to establish the specific cause (Chapters 163 through 165).

APPROACH TO THE TREATMENT OF ANEMIA

As in other disorders, the effective treatment of anemia is based on a thorough diagnostic evaluation. Hematinics such as iron, cobalamin, or folic acid should not be administered unless a specific deficiency has been demonstrated or is anticipated. Although indiscriminate treatment with cobalamin is not harmful per se, it lulls both the patient and the physician into a false sense of security. In contrast, the inappropriate use of iron preparations over a prolonged period can be directly harmful, leading to a state of iron overload.

Many kinds of anemias can be corrected if a precipitating cause can be uncovered and reversed. If a drug or toxin is responsible, its withdrawal may allow full recovery. Correction of anemia secondary to a chronic disease usually depends on whether the underlying condition can be reversed. One of the most dramatic dividends of successful renal transplantation is the rapid correction of the anemia of uremia.

Erythropoietin Therapy

The administration of rHuEPO is remarkably effective in certain circumstances. In addition to those with the anemia of chronic renal failure, selected patients with other types of anemia may benefit from rHuEPO. Treatment can lower transfusion requirements in patients with cancer or HIV infection in whom anemia has been aggravated by chemotherapy. In comparison to patients with renal failure, higher doses are required for those with cancer or AIDS to achieve the same increase in red cell mass. Treatment with rHuEPO has also been effective in some patients with primary bone marrow disorders, particularly myelodysplasia (Chapter 188). Transfusion requirements in surgical patients, both perioperatively and postoperatively, may be reduced by prior short-term administration of rHuEPO. Treatment may also benefit rare patients who are unable to receive blood transfusions because of either antigen incompatibility or religious convictions.

A note of caution has emerged from a number of large studies suggesting that high doses of rHuEPO that drive the hemoglobin level above 12 g/dL are associated with a slight but significant increase in the risk of thrombosis and cardiovascular mortality. A meta-analysis of randomized controlled clinical trials of chronic kidney disease patients treated with rHuEPO showed that targeting higher levels of hemoglobin was associated with an increased risk of all-cause mortality and arteriovenous access thrombosis.[1] Administration of the erythropoiesis-stimulating agents erythropoietin and darbepoetin to patients with cancer has been associated with an increased risk of venous thromboembolism and mortality.[2] The possibility of increasing the risk of tumor progression may be mediated by erythropoietin receptors on malignant cells.

Primary bone marrow disorders pose a formidable therapeutic challenge when considering rHuEPO therapy. Aplastic anemia (Chapter 168) can be cured by both immunosuppressive therapy and stem cell transplantation. Long-lasting remissions can be achieved in an increasing fraction of patients with acute leukemias by chemotherapy, often coupled with stem cell transplantation (Chapter 181). Other primary bone marrow disorders that are unresponsive to these interventions are treated with supportive measures such as transfusions of red cells and platelets.

Red Cell Transfusion

The decision whether to transfuse an anemic patient is often challenging. The risks and complications of the administration of blood products are discussed in Chapter 180. Patients with chronic or long-standing anemia are able to compensate in several ways, discussed earlier in this chapter. A considerable reduction in red cell mass can be surprisingly well tolerated, especially if the patient is young or sedentary. Transfusion is seldom indicated in a patient with chronic anemia whose hemoglobin is 9 g/dL or greater. Those who are expected to respond to the administration of a specific agent such as iron, folic acid, or vitamin B_{12} can usually be spared transfusions. However, if the anemia is severe and accompanied by myocardial or cerebral ischemia or by congestive heart failure, prompt but slow administration of packed red cells is indicated. Whole blood should be given only if the patient is hypovolemic.

Splenectomy

Splenectomy is indicated in the treatment of certain hemolytic anemias. The efficacy of splenectomy correlates with the degree to which the abnormal or defective red cells are destroyed or sequestered in the spleen. Splenectomy is curative in nearly all patients with hereditary spherocytosis (Chapter 164). The operation may be also beneficial in selected patients with immunohemolytic anemia, congestive splenomegaly, spur cell anemia, and certain hemoglobinopathies and enzymopathies. The operative morbidity and mortality from elective splenectomy are very low. The procedure can often be done via mini-laparotomy. Occasional patients develop postoperative left subphrenic abscess. Following splenectomy, young children are at risk of developing overwhelming septicemia. This complication can be partially circumvented by vaccination against pneumococcus and meningococcus. Post-splenectomy sepsis occurs rarely in adults. The risk of sepsis can be circumvented by partial splenectomy. Thrombocytosis generally develops promptly following splenectomy. However, in most cases it is transient. In patients with continued hemolysis or with a myeloproliferative disorder (Chapter 169), the thrombocytosis usually persists and may occasionally be associated with thromboembolic complications.

162 MICROCYTIC AND HYPOCHROMIC ANEMIAS

GORDON D. GINDER

The oxygen-carrying hemoglobin molecule executes the principal function of the mature erythrocyte. The hemoglobin content of erythrocytes is determined by the coordinated production of globin protein, the heme porphyrin ring, and the availability of iron. A deficiency in any of these three critical components of hemoglobin results in hypochromic and/or microcytic anemia (see Fig. 161-5 in Chapter 161). Microcytic anemia is typically reported initially by automated red blood cell (RBC) indices. Hypochromic microcytic anemia can be confirmed on the peripheral blood smear (Fig. 162-1). Disorders of globin protein production typically produce microcytosis but not hypochromia and are discussed elsewhere (Chapter 165).

IRON DEFICIENCY ANEMIA

EPIDEMIOLOGY

Iron deficiency is by far the most common cause of anemia worldwide and is among the most frequently encountered medical problems seen by primary

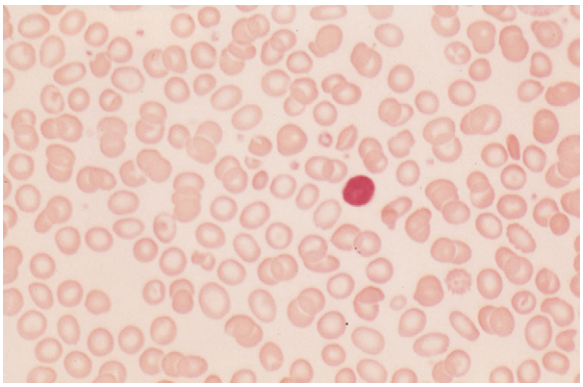

FIGURE 162-1. Iron deficiency anemia. Many of these red blood cells are microcytic (smaller than the nucleus of the normal lymphocyte near the center of the field) and hypochromic (with central areas of pallor that exceed half the diameter of the cells).

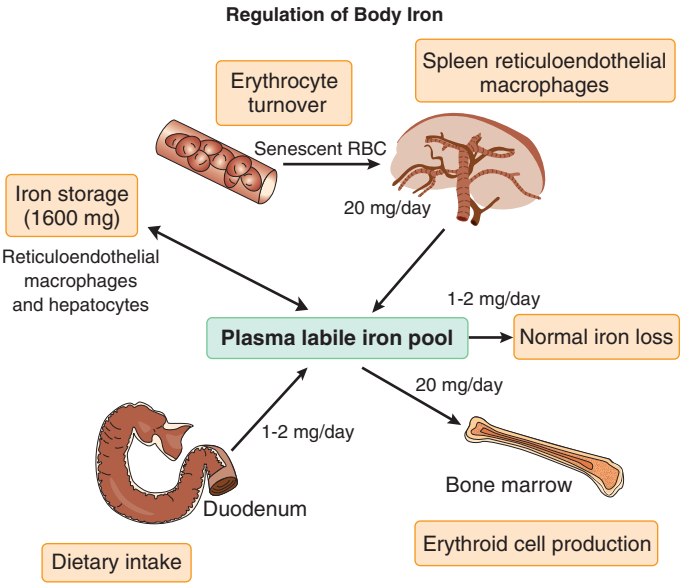

FIGURE 162-2. Iron homeostasis in normal humans. RBC = red blood cell.

care physicians in the United States. It is estimated that between 2 and 5% of adolescent females in the United States have iron deficiency sufficient to cause anemia. Elsewhere, the prevalence of iron deficiency–induced anemia is much higher, with estimates that up to 10% of the world population, or more than 500 million people, are affected. The prevalence rates are especially high in developing countries where dietary insufficiency and intestinal parasites are prevalent.

PATHOBIOLOGY

The majority of the approximately 4 g of iron in the adult human body is incorporated into hemoglobin (approximately 2100 mg) in erythrocytes or myoglobin (approximately 300 mg) in muscle. The remainder is chiefly present as storage iron in the liver (1000 mg) and in the reticuloendothelial macrophages of the bone marrow and spleen (600 mg) (Fig. 162-2). Only a small amount of iron (3 to 7 mg) is freely circulating in plasma bound to transferrin, but this pool is kinetically very active, turning over every 3 to 4 hours. Because of the potent conservation mechanisms of iron recycling through the reticuloendothelial macrophage system, only an average of about 1 to 2 mg of iron is normally lost per day, largely through mucosal sloughing, desquamation, and, in females of reproductive age, menstruation.

The ability of iron to donate or accept electrons readily through conversion between the ferrous (Fe^{2+}) and ferric (Fe^{3+}) states makes it a critical component of the hemoglobin and myoglobin porphyrin rings that transport oxygen as well as cytochromes and various other vital enzymes. Free iron is extremely toxic owing to its capacity to catalyze the formation of free radicals, which lead to cellular damage. Therefore, the majority of body iron that is not stably incorporated into porphyrin rings is associated with proteins. Transferrin is the major protein associated with circulating plasma iron, and ferritin is the major protein associated with stored intracellular iron both in the cytoplasm and in mitochondria. Because the normal rate of iron loss is low, only about 1 to 2 mg/day of dietary iron is needed to maintain homeostasis. The average Western diet contains about 20 mg/day, and the efficiency of iron absorption in the duodenum is usually sufficient to maintain the amount of iron required for homeostatic balance.

Control of iron absorption by the duodenal crypt cells is critical because of the lack of any regulated physiologic mechanism for iron excretion. As a result, excessive iron intake can lead to deleterious iron overload, with concomitant organ damage (Chapter 219). Nonheme dietary iron is dissolved in part by the low pH of the stomach effluent. After reduction to the ferrous state by ferroreductase, iron is transferred across the apical crypt cell membrane by divalent metal transporter-1 (DMT-1). Several levels of regulation are involved in iron absorption by the intestine. One of these is modulated by dietary intake; thus, after a large influx of dietary iron, the duodenal absorptive capacity is diminished. A second regulatory mechanism modulates the iron absorption capacity based on total body iron stores. Finally, the so-called erythropoietic regulator modulates the capacity for enterocyte absorption based on the iron needed for erythropoiesis. A paradoxical increase in iron absorption through this mechanism occurs in certain types of anemia characterized by intravascular and intramedullary destruction of erythroid cells: sideroblastic anemia, the thalassemias (Chapter 165), and congenital dyserythropoietic anemias.

Once inside the intestinal absorbing cell, iron is stored in complex with ferritin. Circulating plasma iron is complexed with the iron transport protein transferrin. The transferrin-iron complex is then taken up by erythroid precursors via the transferrin receptor. The high density of transferrin receptors on erythroid precursors ensures the preferential uptake of iron by these cells and explains why erythropoiesis proceeds normally until a critical deficiency of transferrin-bound iron, reflecting a depletion of total body iron, is present. The levels of transferrin, transferrin receptor, ferritin, and other proteins important in iron metabolism are regulated by the iron regulatory proteins IRP-1 and IRP-2.

Hepcidin, a 25–amino acid peptide, is the central regulator of iron homeostasis through its effects on intestinal absorption, macrophage recycling of iron from senescent RBCs, and iron mobilization from hepatic stores. Thus, hepcidin affects all major sites of iron uptake and storage. Hepcidin is produced in the liver and acts as a negative regulator of iron absorption by the intestine and of iron release from storage in the macrophages and hepatocytes (see Fig. 161-7 in Chapter 161). It is believed that hepcidin binds to ferroportin, the major iron transporter in the membranes of the enterocyte, macrophage, and hepatocyte, causing the internalization and degradation of ferroportin. This process blocks the transport of iron across the membrane of the basolateral crypt cell, preventing its incorporation into transferrin-bound plasma iron. Likewise, loss of ferroportin function blocks the major export pathway of iron stores from macrophages and hepatocytes. Hepcidin production is upregulated by iron and downregulated by hypoxia, consistent with its homeostatic role. Because hepcidin is also upregulated by inflammatory cytokines, it is believed to play an important role in the paradoxical lack of transferrin-bound iron available for erythropoiesis in the face of adequate or even excess iron stores found in the anemia of chronic inflammation (see later and Chapter 161).

Blood Loss

Iron deficiency anemia results from an imbalance between available body iron for hemoglobin production and the minimal amount needed to sustain normal hemoglobin production during erythropoiesis (see Fig. 162-2). Because of the combined effectiveness of dietary absorption and retention of iron under normal circumstances, this mismatch is most often due to blood loss, with the gastrointestinal (GI) tract being the most common site (Chapter 137). In developed countries, the blood loss is usually secondary to benign or neoplastic lesions of the GI tract (Chapters 198 and 199) or chronic ingestion of drugs that cause GI mucosal damage (Chapter 141). The most common offending agents are alcohol and salicylates or other nonsteroidal anti-inflammatory agents. In developing countries, helminthic infections, including hookworm (Chapter 365) and schistosomiasis (Chapter 363), are among the most common causes of GI blood loss.

Genitourinary tract blood loss resulting in iron deficiency is most common in menstruating women. Less common are urinary tract malignancies (Chapter 203) and hemoglobinuria due to intravascular hemolysis (Chapter

TABLE 162-1 LABORATORY FINDINGS FOR IRON STUDIES IN MICROCYTIC AND HYPOCHROMIC ANEMIAS

ANEMIA	SERUM IRON	TIBC	TRANSFERRIN SATURATION (%)	SERUM FERRITIN	SERUM TRANSFERRIN RECEPTOR	MARROW RE IRON	MARROW RINGED SIDEROBLASTS

Sideroblastic anemia	High	Normal	60-90	High	Normal or high	High	Present

RE = reticuloendothelial; TIBC = total iron binding capacity.

163). Respiratory tract blood loss is far less common as a cause of iron deficiency.

Reproduction and Growth

In most cases, an increased iron requirement is due to blood loss; other causes include rapid growth in infancy and adolescence and pregnancy and lactation in adulthood. It is estimated that failure to satisfy the increased iron requirements during pregnancy with supplemental iron may result in a deficiency equivalent to a cumulative blood loss of up to 1500 mL.

Inadequate Iron Intake

The other major cause of iron deficiency is inadequate iron intake. Only diets that lack 1 to 2 mg/day fail to provide adequate iron. The average Western meal contains about 6 mg of iron, so dietary insufficiency is not a common cause of iron deficiency. Certain diets that lack iron or contain large quantities of phytates from cereals or tannate from tea, both of which inhibit intestinal iron absorption, may result in iron deficiency. Although iron is usually readily absorbed, primarily in the duodenum, pathologic states that can impair the process include generalized intestinal malabsorption (Chapter 142), atrophic gastritis (Chapter 141) with achlorhydria, and extensive gastric surgery. In contrast, chronic use of H_2-receptor blockers or proton pump inhibitors does not appear to cause iron deficiency. In the United States, celiac disease (Chapter 142) is an increasingly common cause of iron deficiency, with resulting anemia.

CLINICAL MANIFESTATIONS

Because of compensatory physiologic mechanisms, patients with mild iron deficiency anemia may be asymptomatic. Iron deficiency in these patients may be recognized during the evaluation of an underlying disease process or as part of routine laboratory studies. The findings of microcytosis and hypochromia occur only after the hematocrit has fallen to approximately 30%, so neither finding may be present in early stages.

The anemia of iron deficiency, like other anemias, manifests with nonspecific symptoms such as weakness, pallor, dizziness, decreased exercise tolerance, or irritability. Because iron is a critical component of the porphyrin complex in muscle as well as many essential metabolic enzymes, its deficiency affects other organ systems besides the erythron, often resulting in a degree of fatigue, exercise intolerance, and weakness out of proportion to the hemoglobin level. Repletion of iron in iron-deficient individuals may improve cognitive and exercise performance. In addition, intravenous iron treatment in patients with heart failure and coexisting iron deficiency (to which heart failure patients are prone) can improve symptoms, functional capacity, and quality of life, irrespective of the presence or absence of anemia.■

Rare patients, most frequently elderly women, may have dysphagia due to an esophageal stricture or web (Plummer-Vinson syndrome). A clinical manifestation unique to iron deficiency is pica, which is an unusual craving for certain non-nutritional substances. Pica may manifest as a craving for ice (pagophagia) or, less commonly, for clay (geophagia) or starch (amylophagia); pagophagia is believed to be the most specific for iron deficiency.

Physical findings that may be associated with the iron-deficient state include glossitis and angular stomatitis. Other less common but highly specific findings are spooning of the fingernails (koilonychia) and blue-tinged sclerae.

DIAGNOSIS

The diagnosis of iron deficiency anemia is made by laboratory testing. Because microcytic hypochromic RBCs are a sine qua non of this type of anemia, initial screening consists of a determination of hemoglobin levels, mean corpuscular volume, erythrocyte hemoglobin content, and reticulocyte count. In experienced hands, the peripheral blood smear (Chapter 160) is an excellent indicator of iron deficiency anemia. In iron deficiency anemia, most erythrocytes are smaller in diameter than the nucleus of a typical lymphocyte, and the area of central pallor is greater than 50% of the total diameter of the erythrocyte (see Fig. 162-1). Variability of erythrocyte size distinguishes iron deficiency anemia from other conditions that give rise to microcytosis; the calculated variability in RBC volume (the so-called RBC volume distribution width, or RDW) is elevated early in iron deficiency anemia.

The definitive diagnosis of iron deficiency anemia is made by tests that measure total body iron stores: the absence of iron stores that can be mobilized is unique to this microcytic hypochromic anemia. Transferrin and transferrin-bound iron levels may not be reliable indicators of iron deficiency because they are also abnormal in the anemia of chronic disease, despite adequate total body iron stores (see Fig. 161-6 in Chapter 161).

The serum ferritin level is the most reliable, noninvasive, and cost-effective indicator that is routinely available in most clinical laboratories (Table 162-1). In a large study of 259 anemic patients, a serum ferritin level less than 18 µg/L was diagnostic of iron deficiency with greater than 95% specificity and a 55% sensitivity. At a serum ferritin level of 45 µg/L, the sensitivity rose to approximately 70%, and a level higher than 100 µg/L in populations with a less than 40% prevalence of iron deficiency excluded a diagnosis of iron deficiency with more than 90% sensitivity. Although some recent studies have questioned the accuracy of the routine determination of stainable marrow iron, this test is still generally considered to be the "gold standard" for tests of iron deficiency. However, determination of total bone marrow iron stores is rarely necessary to diagnose iron deficiency anemia, except when there is some other complicating process.

One setting in which serum ferritin levels can be spuriously elevated is chronic inflammation or chronic disease. The soluble serum transferrin receptor (StFR) level is an excellent measure of total erythroid precursor mass. The StFR is aberrantly elevated in the presence of iron deficiency, so it is considered a useful test for this condition. A number of studies have demonstrated the utility of the StFR/ferritin ratio in distinguishing iron deficiency from the anemia of chronic disease. However, the lack of reliable standards has prevented this assay from becoming routinely available in clinical practice.

TREATMENT Rx

The treatment of iron deficiency anemia is replenishment of body iron stores. However, the underlying cause should always be investigated before treatment is begun, because in many cases it is a correctable and potentially fatal GI lesion (Chapter 137).

Oral Administration

The preferred route of iron administration is oral. Oral iron is most readily absorbed in the absence of food, especially in the setting of decreased stomach acid production owing to atrophic gastritis, gastric surgery, or chronic suppression of gastric acid with an H_2 antagonist or proton pump inhibitor. The major obstacle to oral iron replacement is unacceptable side effects, chiefly epigastric discomfort or nausea; diarrhea or constipation also occurs in some patients. Reducing the dose often eliminates nausea and epigastric discomfort. Despite the development of a number of orally effective iron-containing compounds, the original salt, ferrous sulfate (325 mg three times daily), remains the most useful. Although some newer oral iron preparations, such as ferrous gluconate (300 mg two or three times daily) or ferrous fumarate (325 mg two or three times daily), may induce fewer GI side effects per milligram of iron, they are also less well absorbed, so there is no net advantage to these costlier formulations except for patients who cannot tolerate ferrous sulfate. Given both the low toxicity and the low cost of oral iron replacement, a therapeutic trial is an alternative means of confirming a diagnosis of iron deficiency anemia.

Parenteral Administration

In situations in which primary blood loss is uncontrollable, iron cannot be absorbed owing to severe malabsorption, or oral iron is not tolerated despite concerted efforts to minimize side effects, parenteral iron is an effective alternative treatment.[1] Intramuscular dosing is limited to 100 mg/injection, so intravenous administration is recommended. Sodium ferric gluconate (given intravenously at a dose of 125 mg over 10 minutes) is the preferred form of parenteral iron owing to the low incidence of adverse reactions. A multiinstitutional, double-blind, randomized, placebo-controlled trial of more than 2500 patients showed similar adverse events in patients receiving sodium ferric gluconate versus those receiving placebo, and only one life-threatening complication occurred; in comparison, there were 23 such events among 3768 patients treated with iron dextran in a historical control arm.[2] One limitation of sodium ferric gluconate is that the maximum dose deliverable in a single injection is approximately 125 mg, and a total dose of 500 to 2000 mg is usually required for adequate repletion. Although large doses of iron dextran can be delivered in a single intravenous injection, this is currently reserved for situations in which rapid iron replacement is required because of the life-threatening anaphylactic and delayed adverse reactions that occur in 0.6 and 2.5% of cases, respectively. If iron dextran is to be given intravenously, premedication with diphenhydramine and a slow test-dose injection of 30 to 40 mg diluted in normal saline are recommended.

The response to iron repletion therapy is usually quite rapid, with elimination of symptoms within a few days. Increased reticulocytosis usually begins within 4 to 5 days, and the hemoglobin level often rises within 1 week and reaches a normal level after 6 weeks of therapy if adequate iron replacement is achieved. The goal of therapy, which is to reach a serum ferritin level of greater than 50 mg/L, usually takes 4 to 6 months. Therapy must be continued after adequate replacement is achieved if the underlying cause of iron deficiency is not reversible. Because of the avidity of transferrin receptor–rich erythroid precursors for transferrin-bound iron, the serum ferritin level usually does not rise until hemoglobin levels reach normal.

Failure to Respond to Iron Therapy

An incomplete or lack of response to oral iron therapy, as determined by failure to normalize the hemoglobin level, usually means either that iron replacement has not been adequate (most commonly due to noncompliance with oral iron because of its side effects) or that iron deficiency is not the primary cause of the anemia (e.g., coexisting anemia of chronic disease). Less common causes of failure to respond to oral iron include iron malabsorption (e.g., celiac disease, atrophic gastritis) or blood loss in excess of iron replacement.

TMPRSS6, also called matriptase-2, is a type II transmembrane serine protease that suppresses hepcidin production. Several types of mutations in *TMPRSS6* that are either sporadic or familial (usually autosomal recessive) have recently been described as causes of iron-refractory iron deficiency anemia (IRIDA). Associated with inappropriately increased levels of urinary hepcidin, the defect causes impaired iron absorption and recycling, leading to IRIDA. Characteristically, these patients exhibit no hematologic improvement in response to oral iron intake and are only partially responsive to parenteral iron because of abnormal iron utilization.

PROGNOSIS

In most cases, iron deficiency anemia can be corrected rapidly by either oral or parenteral replacement, but the long-term prognosis ultimately depends on the clinical course of the underlying cause. It is critical that the patient undergo a full evaluation to determine the underlying cause of the iron deficiency, especially because an occult gastrointestinal lesion, often malignant, may be present, particularly in patients older than 50 years (Chapters 198 and 199).

ANEMIA OF CHRONIC DISEASE AND INFLAMMATION

DEFINITION

Anemia of chronic disease refers to anemia that occurs in the setting of a chronic disease state, usually one associated with elevated levels of inflammatory cytokines. Because of this association, the condition is also referred to as anemia of inflammation. Although anemia of chronic inflammation usually manifests as a normochromic normocytic process (Chapter 161), between 20 and 50% of cases are associated with microcytic RBC indices. The anemia is usually mild to moderate, and it may not be symptomatic.

EPIDEMIOLOGY

Anemia of chronic inflammation is believed to be the second most common cause of anemia, after iron deficiency. It is the most common type of anemia encountered among hospitalized patients. The wide spectrum of underlying diseases includes acute and chronic infections, inflammatory and autoimmune diseases, cancers, and chronic kidney diseases.

PATHOBIOLOGY

There are three major mechanisms of anemia of chronic inflammation, and all are believed to result from the effects of abnormal levels of inflammatory cytokines. The first is dysregulated iron homeostasis, manifested by low serum iron (hypoferremia) in the presence of normal or elevated serum ferritin levels and abundant reticuloendothelial macrophage iron stores. The functional consequence is a limited availability of iron for erythroid progenitor cells and resultant restriction of erythropoiesis. Pro-inflammatory stimuli, including lipopolysaccharides, interferon-γ, and tumor necrosis factor-α (TNF-α), upregulate DMT-1, which increases iron uptake by the reticuloendothelial cells. At the same time, these stimuli cause the downregulation of ferroportin expression; ferroportin is the protein required for the release of ferrous iron from storage cells and for the transport of dietary iron from duodenal enterocytes into the circulation.

Because hepcidin is an iron-regulated, acute phase reactant peptide that blocks both iron uptake in the gut and iron release from hepatocytes and macrophage stores, its upregulation by lipopolysaccharides, interleukin (IL)-6, and possibly IL-1 (indirectly, through induction of IL-6) results in another mechanism of anemia. Also, patients with hepatic adenomas that secrete high levels of hepcidin have iron-refractory anemia in the presence of normal or elevated ferritin and macrophage iron stores, despite the absence of elevated inflammatory cytokine levels. Elevated urinary hepcidin concentrations correlate with ferritin levels in patients with anemia of inflammation, iron overload, and iron deficiency. These relationships are depicted in Figure 161-7 in Chapter 161.

A third pathophysiologic feature of anemia of chronic inflammation is the inhibition of erythroid progenitor expansion. Interferon-γ is the most potent inhibitory factor of erythropoiesis, but similar inhibition is believed to be mediated by IL-1, TNF-α, and interferon-β. These mediators of inflammation act to increase erythroid progenitor apoptosis, downregulate erythropoietin receptors, and antagonize pro-hematopoietic factors. The action of erythropoietin appears to be directly antagonized by these pro-inflammatory cytokines, which would explain why responsiveness to erythropoietin seems to be inversely related to the severity of the underlying chronic inflammation and the levels of interferon-γ and TNF-α. Finally, increased erythrophagocytosis in the presence of inflammation results in a modest shortening of RBC half-life.

CLINICAL MANIFESTATIONS

The clinical manifestations in patients with anemia of chronic inflammation are usually dominated by the underlying disease process. The anemia in this condition is usually mild, with hemoglobin levels in the range of 8 to 10 g/dL. However, supervening blood loss, absolute iron deficiency, or other aggravating factors can produce life-threatening anemia. Even mild to moderate anemia contributes to the debilitating effects of the underlying disease, adversely impacting performance status and quality of life. Moreover, the presence of anemia is associated with a poorer overall prognosis in many of the underlying chronic diseases, although correction of anemia has not been directly demonstrated to improve survival.

DIAGNOSIS

The clinical diagnosis of anemia of chronic disease presenting with microcytic hypochromic RBC indices is one of exclusion, based on low serum iron in the presence of normal or increased total body iron stores (see Table 162-1). Serum ferritin is the best single laboratory marker for assessing iron storage, and it is almost invariably normal or elevated in anemia of chronic disease. If both the serum iron and the transferrin saturation are reduced, reflecting dysregulation of iron homeostasis, the diagnosis of anemia of chronic disease can be made in the appropriate clinical setting after the exclusion of other causes of anemia, such as coexistent blood loss, thalassemia (Chapter 165), and drug-induced suppression of erythropoiesis. In the presence of inflammation, however, up to 30% of patients with true iron deficiency have serum ferritin levels greater than 100 μg/L, potentially obscuring the diagnosis of iron deficiency. Assays for StFR are useful to diagnose iron deficiency in the presence of the inflammation associated with anemia of chronic disease, but problems with standardization have limited this test's availability in clinical practice. Examination of the bone marrow for reticuloendothelial macrophage iron stores (hemosiderin) and erythroblasts containing iron granules (sideroblasts) can provide definitive evidence

of absent iron stores in the setting of anemia of chronic inflammation. A low serum erythropoietin level is also useful in supporting a diagnosis of anemia of chronic inflammation, but only when the hemoglobin level is less than 10 g/dL.

TREATMENT Rx

Treatment of the Underlying Disease

The most effective treatment for anemia of chronic disease is successful treatment of the underlying inflammatory disease process, whether it is an acute or chronic infection, treatable cancer, renal failure, or rheumatoid arthritis. Even if definitive treatment is not possible, quality of life and perhaps prognosis can improve if symptomatic anemia is treated directly. Unfortunately, anemia of chronic inflammation remains undertreated, even in developed countries.

Blood Transfusion

Blood transfusion (Chapter 180) offers the immediate resolution of anemia, but it is indicated chiefly when the anemia is life threatening or seriously limits the patient's functioning. These situations almost always involve supervening blood loss or some other acute process that compounds the anemia of chronic disease. Transfusion is not recommended for the long-term treatment of mild or moderate anemia of chronic inflammation because of the secondary risks, which include transfusional iron overload, human leukocyte antigen (HLA) sensitization in the case of potential renal transplantation, and other side effects of transfusion.

Intravenous Iron and Erythropoietin Therapy

If iron replacement is needed for anemia of chronic inflammation, parenteral iron administration is usually required to replenish stores because of the block in intestinal absorption. In hemodialysis patients receiving erythropoietin therapy, intravenous iron therapy improves anemia; however, when intravenous iron replacement raises the transferrin saturation to greater than 20%, there appears to be an increased risk of developing bacteremia, underscoring the complex relationship between iron homeostasis and immunity.

Erythropoietin therapy is currently approved for use in patients with chronic kidney disease, those with HIV infection, and cancer patients who are undergoing myelosuppressive treatment. Patients with demonstrated iron deficiency should receive supplemental iron with intravenous iron gluconate (see the earlier discussion) while being treated with erythropoietin.

In patients undergoing chemotherapy for cancer whose hemoglobin is less than 10 g/dL, erythropoietin therapy improves quality of life and performance status.[1] However, erythropoietin therapy may be associated with cancer progression in some settings. Because of the decreased survival and increased thromboembolic complications that have been reported in cancer patients receiving erythropoiesis-stimulating agents, current recommendations are for cautious use during chemotherapy and against routine use in inpatients not receiving chemotherapy.[2-4]

PROGNOSIS

The overall prognosis of anemia of chronic inflammation is determined almost exclusively by the course of the underlying disease. It is well established that the degree of anemia correlates well with the severity of the underlying disease process and therefore with levels of inflammatory cytokines. In the absence of a supervening process, anemia of chronic inflammation is not life threatening, and treatment of the anemia per se has not been proved to affect overall survival.

SIDEROBLASTIC ANEMIAS

DEFINITION

This heterogeneous group of anemias is distinguished by the characteristic finding of excessive mitochondrial iron in erythroblasts, as manifested by iron-laden, ringed sideroblasts in the bone marrow in the presence of moderate to severe anemia. These disorders result from mitochondrial defects either in the biosynthesis of the heme porphyrin ring or in the metabolism of iron. Both hereditary and acquired types of sideroblastic anemia have been described. Although often characterized by microcytic and sometimes hypochromic anemia, these disorders can manifest with normochromic normocytic RBCs; if the anemia is associated with myelodysplasia (Chapter 188), macrocytic RBC indices may be present.

EPIDEMIOLOGY

Although acquired sideroblastic anemias are relatively rare, they are much more prevalent than hereditary forms. The true incidence of acquired sideroblastic anemia is not well established, in part owing to the heterogeneity of causes and clinical presentations. Hereditary X-linked sideroblastic anemias usually manifest in childhood or early adulthood.

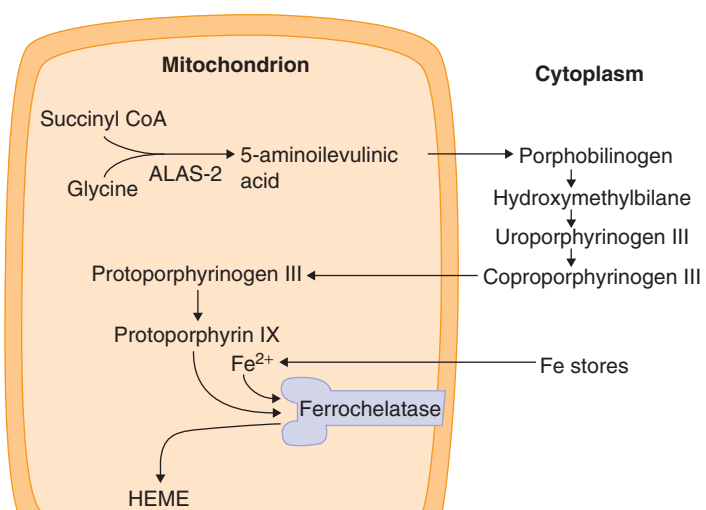

FIGURE 162-3. The heme synthesis pathway. ALAS-2 = δ-aminolevulinic acid synthase; CoA = coenzyme A.

PATHOBIOLOGY

Genetics

The pathophysiologic mechanisms of hereditary sideroblastic anemias are much better understood than those of the more common idiopathic, acquired variety associated with myelodysplasia. Two main forms of X-linked hereditary sideroblastic anemia have been characterized, and both result from defects in the heme synthesis pathway (Fig. 162-3). The first type is caused by mutations in the gene coding for erythroid-specific δ-aminolevulinic acid synthase, known as ALAS-2, on the X chromosome. These mutations may affect the affinity of the enzyme for pyridoxal phosphate or its structural stability, catalytic site, or susceptibility to mitochondrial proteases. In those cases in which the affinity of ALAS-2 for pyridoxal phosphate is altered, pyridoxine supplementation can ameliorate the associated anemia. The other major group of X-linked sideroblastic anemias results from defects in the adenosine triphosphate binding cassette (ABC) protein known as hABC7. The hABC7 protein is believed to be involved in iron-sulfur [FeS] cluster formation. Because [FeS] cluster–associated proteins include ferrochelatase and the cytosolic IRP-1, defects in hABC7 are believed to result in defective iron metabolism or inadequate incorporation of iron into the heme porphyrin ring by ferrochelatase. This type of X-linked sideroblastic anemia is associated with ataxia.

In addition to the two X-linked causes, both autosomal dominant and recessive forms of hereditary sideroblastic anemia have been described. However, the exact mechanisms involved in these disorders are not known.

Other types of hereditary sideroblastic anemia are believed to result from mutations in the mitochondrial genome rather than in nuclear genes. The inheritance of these disorders is complex, owing to the exclusively maternal inheritance pattern of mitochondria; the ovum is the only source of embryonic mitochondria.

Exposure to Drugs or Toxins

The most common form of acquired sideroblastic anemia results from nutritional deficiency or exposure to exogenous drugs or toxins, especially alcohol. Although sideroblastic anemia is not a common finding in alcoholism, the high incidence of alcohol abuse in Western cultures accounts for its frequency as a cause. Alcohol directly inhibits erythropoiesis, but sideroblastic anemia is usually seen only in the setting of concurrent alcoholism and nutritional deficiencies. Other well-documented drug exposures associated with sideroblastic anemia include isoniazid, chloramphenicol, and cycloserine. Sideroblastic anemia has also been attributed to lead exposure (Chapter 21), but there are limited primary data to support this association. Deficiency of

pyridoxine causes sideroblastic anemia in animals and may also occur in the setting of alcoholism in humans, although ethanol is believed to be an antagonist of the interaction of pyridoxal phosphate with 5-aminolevulinic acid as a cofactor in the first step of heme biosynthesis. Copper deficiency, though rare, has also been associated with sideroblastic anemia, usually in the setting of an overdose of bivalent cation chelators such as penicillamine or trientine, used to treat the copper overloading found in Wilson disease (Chapter 218).

Idiopathic Forms

The major cause of acquired sideroblastic anemia is idiopathic, in association with myelodysplastic syndromes (Chapter 188). Refractory anemia with ringed sideroblasts is characterized by abnormalities in all three hematopoietic cell lineages, in addition to the presence of ringed sideroblasts.

A second form, known as pure sideroblastic anemia, is less frequently associated with cytogenetic abnormalities, is characterized by dysplasia only in erythroid progenitors, and lacks cytopenias other than anemia. The prognosis in this type of acquired idiopathic sideroblastic anemia is much better than that in refractory anemia with ringed sideroblasts, in part because of a very low incidence (≈10%) of evolution to acute leukemia.

Because of the important differences in prognosis, it is imperative to evaluate cytogenetics and marrow morphology at the time of diagnosis. Recent evidence suggests that mitochondrial DNA mutations and attendant mitochondrial cytopathies account for many, if not all, cases.

CLINICAL MANIFESTATIONS

Because of the heterogeneous nature of the sideroblastic anemias, many of the clinical manifestations vary according to the underlying pathophysiologic cause. The anemia is usually moderate to severe, with hemoglobin levels in the range of 4 to 10 g/dL. The peripheral blood smear frequently reveals hypochromia, often with basophilic stippling. Microcytosis is often seen in hereditary forms, but normochromic, normocytic, or even macrocytic RBCs may be seen, especially in the setting of myelodysplasia or in a rare X-linked hereditary form known as Pearson's syndrome.

DIAGNOSIS

The most useful diagnostic laboratory test for sideroblastic anemia is bone marrow morphology with Prussian blue iron staining, which reveals abnormally large and numerous bluish green siderosomes within at least 15% of erythroblasts, giving the characteristic appearance of ringed sideroblasts (Fig. 162-4). These ringed sideroblasts distinguish this disorder from iron deficiency anemia and anemia of chronic inflammation. Bone marrow findings in idiopathic acquired sideroblastic anemias include dyspoietic features of erythroid and/or myeloid and megakaryotic cell lineages.

Iron studies usually reveal normal iron stores or evidence of iron overload, which is caused by the ineffective erythropoiesis found in sideroblastic anemia as well as by the transfusion therapy often required for its treatment. Iron deficiency can occur coincident with sideroblastic anemia, complicating the diagnosis owing to the lack of characteristic ringed sideroblasts, particularly in myelodysplastic syndromes in which thrombocytopenia leads to GI blood loss. If coexisting iron deficiency is suspected, a repeat bone marrow examination after iron repletion has failed to correct the anemia reveals the diagnostic ringed sideroblasts.

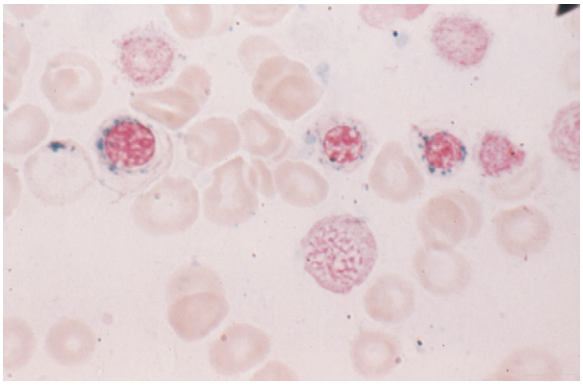

FIGURE 162-4. Sideroblastic anemia. Prussian blue iron stain of the bone marrow shows ringed sideroblasts, which are nucleated red blood cell precursors with perinuclear rings of iron-laden mitochondria.

TREATMENT

Treatment of Underlying Disease

Most forms of sideroblastic anemia lack a specific therapy aimed at the underlying mechanism. Exceptions are those types caused by alcohol or drugs, for which removal of the offending agent usually results in resolution, or at least improvement, of the anemia. Abstinence from alcohol usually reverses the abnormalities in heme biosynthesis in 1 to 2 weeks, as evidenced by the disappearance of ringed sideroblasts in the marrow.

Pyridoxine markedly improves the relatively rare cases of nutritional deficiency, which are usually associated with alcoholism, and some forms of X-linked hereditary sideroblastic anemias in which the binding of pyridoxine by ALAS-2 is defective. Because of its low toxicity in moderate doses, a trial of pyridoxine, 100 to 200 mg/day orally for up to 3 months, is worthwhile in all patients. In responsive cases, reticulocytosis occurs within 2 to 3 weeks, and the hemoglobin level improves over several months. High-dose pyridoxine has been shown to overcome the defect in ALAS-2 activity in some patients with X-linked sideroblastic anemia, but prolonged high-dose therapy can be associated with peripheral neuropathy.

Transfusion

The mainstay of therapy for most severe sideroblastic anemias remains RBC transfusions. Because of the risks of long-term transfusion therapy, treatment should be aimed at achieving a normal performance status rather than a specific target hemoglobin level. Iron stores should be monitored regularly, and iron chelation therapy should be used in the setting of iron overload.

Erythropoietin

Therapy with erythropoietin, with or without granulocyte colony-stimulating factor (G-CSF), benefits a small percentage of patients with acquired sideroblastic anemia due to myelodysplasia. A meta-analysis of 17 studies in which 205 patients were treated with erythropoietin showed an overall response rate of only 16%. However, patients with a diagnosis other than refractory anemia with ringed sideroblasts who were not transfusion dependent had response rates greater than 50%, whereas none of the patients who had refractory anemia with ringed sideroblasts and a serum erythropoietin level greater than 200 U/L responded. Studies using a combination of erythropoietin and G-CSF showed somewhat higher response rates, although none of these studies were large or randomized. Allogeneic bone marrow transplantation (Chapter 181) benefits eligible patients whose myelodysplasia (Chapter 188) has a high risk of evolving into acute leukemia.

PROGNOSIS

As with the underlying pathophysiology, the prognosis in sideroblastic anemias is highly variable. Secondary acquired forms of the disease due to alcohol or toxins respond well to withdrawal of the offending agent, with rapid and often complete normalization of erythropoiesis. The pure sideroblastic anemia variant of myelodysplasia-associated sideroblastic anemia can usually be managed well for many years with transfusions and, if necessary, concordant iron chelation therapy. Other myelodysplasia-related sideroblastic anemias generally have a poor prognosis because of the frequent coexistence of pancytopenia and the relatively high incidence of progression to acute leukemia.

163 AUTOIMMUNE AND INTRAVASCULAR HEMOLYTIC ANEMIAS

ROBERT S. SCHWARTZ

DEFINITION

The immune-mediated hemolytic anemias are a group of disorders in which antibodies, complement, and macrophages, usually acting in concert, cause the patient's red blood cells to die prematurely. In the most common type, the antibodies bind to native constituents of the membrane of the patient's own red blood cells. For this reason, the antibodies qualify as autoantibodies, and the diseases they cause fall under the rubric of autoimmune hemolytic anemia.

There are also less common types of immune-mediated hemolytic anemia. Some drugs elicit antidrug antibodies that can cause hemolytic anemia if the drug plants itself in the erythrocyte membrane, thereby making the red cell a target of the antibodies. A high titer of immunoglobulin (Ig) M antierythrocyte autoantibodies that bind to red blood cells at cold temperatures is the distinguishing serologic feature of cold agglutinin disease. In paroxysmal cold hemoglobinuria, an IgG antibody binds to the erythrocyte at cold temperatures, setting the stage for complement-mediated hemolysis at warm temperatures. Paroxysmal nocturnal hemoglobinuria (PNH), another disease in which complement mediates hemolysis, arises from a somatic mutation in a hematopoietic stem cell that renders erythrocytes susceptible to complement-mediated lysis in the absence of antibody. The hemolytic transfusion reaction (Chapter 180) is another disorder in which complement-mediated destruction of erythrocytes occurs, but in such cases, the recipient's alloantibodies against the donor's red cell antigens trigger lysis of the transfused cells.

AUTOIMMUNE HEMOLYTIC ANEMIAS

Autoimmune Hemolytic Anemia with IgG Autoantibodies

EPIDEMIOLOGY

Autoimmune hemolytic anemia associated with IgG autoantibodies (generally referred to simply as autoimmune hemolytic anemia) accounts for about 75% of all autoimmune hemolytic anemias. It has also been called warm antibody autoimmune hemolytic anemia because the IgG autoantibodies in this disorder react best with red cells at 37° C. Autoimmune hemolytic anemia can be primary (idiopathic), or it can develop in association with another disease (secondary).

Autoimmune hemolytic anemia is uncommon. The estimated overall (not age-adjusted) annual incidence is about 1 case per 100,000 population; after age 60 years, the annual incidence reaches 10 per 100,000. The disorder can occur at any age, but most patients are older than 40 years. About 65% of patients with primary autoimmune hemolytic anemia are women, and almost all cases that complicate systemic lupus erythematosus (Chapter 274) occur in women.

PATHOBIOLOGY

Red Cell Antibodies

IgG anti–red cell autoantibodies mediate the destruction of red blood cells outside the circulating blood in a process called *extravascular hemolysis*. By contrast, when lytic components of the complement system participate in the process, the destruction of red cells usually occurs directly within the circulation (intravascular hemolysis). The participation of lytic complement components in IgG-mediated autoimmune hemolytic anemia is rare.

Structure of IgG Anti–Red Cell Autoantibodies

Chapter 44 reviews the structure and function of immunoglobulins. To understand how autoantibodies cause the destruction of red cells, recall that IgG antibodies consist of two identical heavy chains and two identical light chains (Fig. 163-1A); each kind of chain contains variable and constant

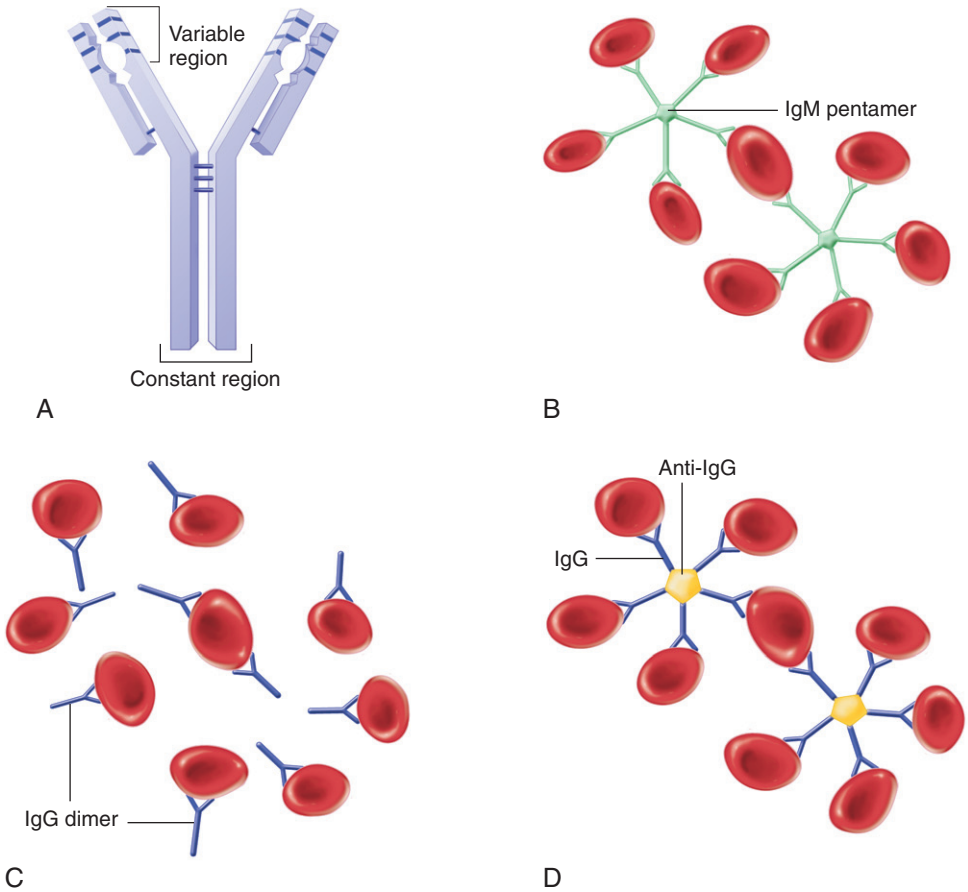

FIGURE 163-1. IgG anti–red cell autoantibodies. A, Structure of an IgG molecule demonstrating its variable and constant regions and the heavy and light chains. **B**, Agglutination of red cells by pentameric IgM antibodies, which can join the cells into a lattice. **C**, Coating of red cells by IgG antibodies. The antibodies are unable to agglutinate the cells. **D**, Agglutination of IgG-coated red cells by an anti-IgG antibody.

regions. The four variable regions of IgG form two identical antigen-binding pockets in the molecule. Disulfide bonds hold the constant regions of the heavy and light chains together and give the molecule its characteristic Y shape. An individual B cell produces a monoclonal antibody, a single kind of antibody with a structurally unique antigen-binding pocket, whereas polyclonal antibodies arise from a mixed population of B cells. The constant region (Fc) of the antibody consists of the constant regions of the two heavy chains.

There are two variants of the constant region of light chains: κ and λ. By contrast, the nine heavy chain constant region genes allow nine types of heavy chains: μ (IgM), δ (IgD), γ3 (IgG3), γ1 (IgG1), α1 (IgA1), γ2 (IgG2), γ4 (IgG4), ε1 (IgE1), and α2 (IgA2). These various constant regions determine the isotype of the antibody.

During the immune response, B cells produce IgM antibodies at first; later, under the influence of antigen-activated helper T cells ($CD4^+$), they switch to the production of an IgG, IgA, or IgE isotype. In autoimmune hemolytic anemia, the autoantibodies are a mixture of IgG κ and IgG λ molecules. Such a polyclonal population of antibodies marks the participation of activated $CD4^+$ T cells.

Red Cell Destruction

Birth and Death of a Normal Erythrocyte

The blood of a normal adult contains about 2000 mL of erythrocytes, which arise in the bone marrow from hematopoietic precursors with a commitment to the red cell lineage. Under the primary influence of erythropoietin, these precursors differentiate, synthesize hemoglobin, and emerge from the marrow 3 days after they become proerythroblasts (Chapter 159). The earliest red cells in the blood are reticulocytes. They lose the blue-staining remnants of cytoplasmic RNA and ribosomes in a little more than a day to become mature oxygen-transporting erythrocytes. Its biconcave shape, the lack of a nucleus, and the lipid bilayer arrangement of its membrane give the red cell the flexibility it needs for the 100-mile journey it makes through the circulatory system during its lifespan of 4 months.

Normally, production and destruction of erythrocytes are matched. To maintain the steady state, the marrow of a 70-kg adult produces about 25 mL of red blood cells (2×10^{11} erythrocytes) daily. About 1% of the circulating red cells die every day, mainly because worn-out water pumps of the aged erythrocyte can no longer prevent intracellular water overload. The excessive water transforms red cell discs into spheres. These spherocytes constitute 1% of the erythrocytes in blood, a figure equal to the percentage of reticulocytes in blood. In sinusoids of the spleen, lymph nodes, and liver, where blood flow is sluggish, macrophages ingest spherocytes and break down their hemoglobin into bilirubin and amino acids.

In an adult, dead erythrocytes release 6 to 7 g of hemoglobin daily, mostly within macrophages. About 10% of dying spherocytes empty hemoglobin directly into the blood stream, where it binds with high affinity to haptoglobin. The haptoglobin-hemoglobin complexes turn plasma red (whereas in myoglobinuria—the result of massive muscle destruction—the plasma is pale amber because myoglobin does not bind to haptoglobin). Macrophages rapidly engulf the hemoglobin-haptoglobin complexes through the macrophage scavenger receptor (CD163), then catabolize the protein constituents of the complex and deliver the heme iron to transferrin. If massive intravascular hemolysis overwhelms the haptoglobin disposal mechanism, the kidneys excrete unbound (free) hemoglobin into the urine. Renal tubular cells take up and convert urinary hemoglobin into bile pigments and retain most of the heme iron. These tubular cells stain with Prussian blue; the blue cells and the cola-colored urine (hemoglobinuria) are diagnostic of chronic (or massive) intravascular hemolysis. Table 163-1 lists the causes of black or brown urine.

Melanin (metastatic malignant melanoma)
Alkaptonuria
Methemoglobinuria

FIGURE 163-2. Electron micrograph of a macrophage that has ingested two spherocytes (dark circular structures within the cytoplasm) and is pinching off bits of membrane from antibody-coated red cells in contact with the surface of the macrophage. (From Jandl JH. Blood. In: *Textbook of Hematology,* 2nd ed. Boston: Little, Brown; 1996:432.)

Mechanism of Antibody-Mediated Red Cell Destruction

IgG anti–red cell autoantibodies are opsonins; when bound to autoantigens on red cell membranes, they instigate phagocytosis of the cells by macrophages. Using its Fcγ receptors, the macrophage can ingest the entire IgG-coated erythrocyte or transform it into a spherocyte by nibbling away its surface (Fig. 163-2). Antibody-coated spherocytes cannot resist osmotic forces and ultimately surrender to macrophages, especially in the splenic sinusoids, where blood flows sluggishly.

Macrophages bind to structures in the constant regions of all four subclasses of IgG by means of Fcγ receptors. When IgG or IgM antibodies bind to an antigen, their Fc regions expose a binding site for C1q, the first component of the complement system (Chapter 49). The bound C1q, which resembles a bouquet of polypeptides, initiates activation of the classical complement pathway to its final step—formation of the lytic membrane attack complex. Macrophages display receptors for the later-acting C3b and C4b components of complement (CR1 receptors), and these components cooperate with the corresponding Fcγ receptors to hasten destruction of the red cell by acting as opsonins. In autoimmune hemolytic anemia, the complement system rarely proceeds to the late lytic components because molecules on the red cell surface can block generation of the membrane attack complex. The density and mobility of target antigens on the erythrocyte membrane are important because binding of C1q to the constant region of the anti–red cell antibody requires two closely adjacent Fcγ structures on the red cell membrane.

The Hemolytic Rate

The rate of hemolysis in autoimmune hemolytic anemia depends on the amount of autoantibody on the red cell surface, the affinity and avidity of autoantibodies for the red cell autoantigen, and the number of macrophages in the environment of the antibody-coated erythrocyte. Populations of autoantibodies with high avidity cause a higher rate of red cell destruction than populations with low avidity. Free (monomeric) IgG competes with the interaction of antibody-coated red cells with the Fc receptors of macrophages, but the IgG in plasma has only a minor influence on the hemolytic rate. The importance of the subclasses of IgG is unclear, but IgG3 antibodies seem more potent than IgG1 antibodies in promoting phagocytosis.

The degree of anemia in autoimmune hemolytic anemia depends not only on the rate of red cell destruction but also on the ability of marrow to generate a compensatory increase in erythrocyte production. With an adequate supply of nutrients and growth factors, the marrow can increase red cell production by six to eight times the normal rate. In such cases, there is erythroid hyperplasia in the marrow, and reticulocytes leave the marrow at an accelerated pace and in increased numbers; in some severe cases, even nucleated red cells enter the blood. Anemia does not appear until the half-life of the circulating red cell population drops to about 10 days (the half-life of a population of normal red cells is about 30 days). A half-life of 5 or 6 days is not unusual in autoimmune hemolytic anemia.

Causes of Autoimmune Hemolytic Anemia

The cause of autoimmune hemolytic anemia is unknown. In about a third of cases, the autoantibodies have specificity for an antigen in the Rh system. In another third, the antibodies target proteins in membrane glycoproteins (glycophorins) of the red cell; in other cases, the antibodies have specificity for antigens in the Kell or Duffy blood group system (very rarely for ABO antigens) or for structures in the membrane that are not blood group antigens (e.g., band 3). In all these cases, the patient's own erythrocytes display the relevant antigen.

During fetal life, the thymus deletes lymphocytes with receptors that can bind to autoantigen. This effect, one of the mechanisms of immunologic tolerance of endogenous ("self") antigens, prevents the development of autoantibodies against blood group antigens. The extreme rarity of autoimmune hemolytic anemia secondary to anti-A or anti-B antibodies indicates that the deletion occurs early in ontogeny, because the embryo begins to synthesize A and B substances at 5 weeks of gestation.

A population of $CD4^+/CD25^+$ T cells that express the transcription factor Foxp3 restrains immune responses against autoantigens. There is evidence that a deficiency of these regulatory T cells plays a role in the pathogenesis of autoimmune hemolytic anemia, but how this deficiency arises is unknown.

The anti–red cell autoantibodies in autoimmune hemolytic anemia constitute a polyclonal population of IgG antibodies—a typical feature of an antigen-driven immune response. Evidence that cultured T cells from patients with autoimmune hemolytic anemia proliferate in the presence of certain synthetic Rh peptides supports the idea that the patient's own Rh antigens, or exogenous cross-reactive antigens, drive the autoimmune response. These peptides are cryptic—they reside in regions of the Rh protein that are not normally exposed on the red cell surface. By contrast, T cells from Rh-negative persons who were alloimmunized by transfusion of Rh-positive blood respond to peptides in exposed regions of the Rh protein. The weak response of T cells from normal subjects to allogeneic Rh peptides suggests that cross-reactive environmental antigens may prime T cells for an anti-Rh response.

T cells from patients with chronic lymphocytic leukemia (Chapter 190) complicated by autoimmune hemolytic anemia also respond in vitro to self-Rh proteins. Notably, the leukemic B cells are highly effective in presenting Rh protein to T cells. In some cases of chronic lymphocytic leukemia with autoimmune hemolytic anemia, the leukemic cells display surface immunoglobulins with light chain isotypes that differ from those of the patient's anti–red cell autoantibodies, indicating that the source of the autoantibodies in these patients is not the leukemic clone.

Drug-Induced Immune Hemolytic Anemia

Many drugs or drug metabolites have the potential to elicit antidrug antibodies. Drugs that form covalent bonds with proteins in the red cell membrane can bind antidrug antibodies to the red cell surface, causing a positive direct antiglobulin test (see later) and, in some cases, initiating antibody-mediated destruction of red cells. Other drugs, such as the cephalosporins, can bind to red cell membranes and take up IgG nonspecifically from plasma. In these cases, there is no antidrug antibody. The diagnosis of drug-induced immune-mediated hemolytic anemia should be considered if the patient has a history of taking a suspected medication, there is acute complement-mediated hemolysis, only complement components are detectable on the red cell surface, or the patient's serum reacts with red cells in the presence of the suspected drug.

Some drugs can induce true autoantibodies against red cells. Fludarabine, a purine nucleoside analogue used in the treatment of chronic lymphocytic leukemia, and monoclonal antibodies against tumor necrosis factor-α (infliximab and adalimumab), T cells (alemtuzumab), α4 integrin (natalizumab), and interleukin-2 receptor (daclizumab) also have this property, the cause of which is unknown. Notably, there is no sure way of distinguishing drug-induced autoimmune hemolytic anemia from primary autoimmune hemolytic anemia.

CLINICAL MANIFESTATIONS

Autoimmune hemolytic anemia usually unfolds insidiously, but in some cases it begins abruptly with overt symptoms of severe anemia. When the disease is secondary to chronic lymphocytic leukemia (Chapter 190), systemic lupus erythematosus (Chapter 274), or some other disorder, the primary condition generally brings the patient to the physician.

The symptoms are nonspecific and varied. They depend on the age of the patient; the presence of comorbid conditions, especially cardiovascular disease; whether the autoimmune process is primary or a complication of another disorder; and the degree of anemia. In primary autoimmune hemolytic anemia, symptoms of anemia predominate; asthenia and easy fatigue are typical. Dyspnea suggests coexisting heart disease; angina or myocardial infarction can occur in patients with severe anemia and coronary artery disease.

DIAGNOSIS

History

The history can provide clues that help in the differential diagnosis of hemolytic anemia (Table 163-2). The patient's medical history is the key to the diagnosis of drug-induced hemolytic anemia. It is essential to question the patient about both prescribed and over-the-counter medications, because drug-induced hemolytic anemia can be confused with autoimmune hemolytic anemia, and management of the two conditions differs. It is also important to inquire about comorbid conditions; for example, symptoms of cardiovascular disease will influence management.

Autoimmune hemolytic anemia is a well-known complication of chronic lymphocytic leukemia (Chapter 190) and non-Hodgkin's B-cell lymphomas (Chapter 191). It can also occur occasionally in ulcerative colitis (Chapter 143), rheumatoid arthritis (Chapter 272), and various carcinomas. Autoimmune hemolytic anemia occurs in about 10% of cases of systemic lupus erythematosus (Chapter 274); it may be the initial clinical manifestation of the disease or occur later. It may also complicate the antiphospholipid antibody syndrome; such cases constitute a subset of systemic lupus erythematosus. In most diseases with autoimmune hemolytic anemia as a secondary feature, the primary disorder is at the center of the clinical problem.

Physical Examination

There are no diagnostic findings on physical examination. The combination of pallor, jaundice, and a palpable spleen (Chapter 171) points strongly to hemolytic anemia, but not necessarily to autoimmune hemolytic anemia. Pallor is often difficult to gauge; examination of the palmar creases, buccal mucosa, and subconjunctival membranes, as well as side-by side comparison of the examiner's nail beds with the patient's, can be revealing. More than half of patients have a palpable spleen. The tip of the spleen rarely descends more than 6 cm below the costal margin, except in the presence of lymphoma or chronic lymphocytic leukemia. Hepatomegaly is also frequent; a firm, nontender edge is easily palpable in about 50% of patients.

The examiner should search for an underlying disease because the differences between primary and secondary autoimmune hemolytic anemia influence management and prognosis. The malar rash of systemic lupus erythematosus and the enlarged lymph nodes of lymphoma or chronic lymphocytic leukemia should not be overlooked. A very large spleen also raises the possibility of coexisting lymphoma or chronic lymphocytic leukemia.

Laboratory Findings

The blood smear reflects the marrow's attempt to compensate for accelerated hemolysis and the effects of the interaction between antibody-coated red cells and macrophages. Two populations are evident: large, blue-tinged red cells, which correspond to reticulocytes, and small, dark red spherocytes (microspherocytes) (Fig. 163-3). Such a dimorphic population is characteristic of hemolytic anemia but is not diagnostic of any particular type of hemolytic anemia.

The white blood cell count is often moderately elevated, a reflection of a bone marrow stressed by severe hemolytic anemia. In uncomplicated cases, platelet counts are normal or occasionally increased slightly. Platelet counts may be low in systemic lupus erythematosus or in Evans syndrome, a rare combination of autoimmune hemolytic anemia and immune thrombocytopenia (Chapter 175).

The characteristic finding in bone marrow is erythroid hyperplasia. However, examination of marrow is necessary only if there are unexpected findings or suspicion of lymphoma.

Elevated serum levels of prehepatic (indirect) bilirubin and lactate dehydrogenase (LDH) and a reduced serum haptoglobin concentration are signs of hemolytic anemia. The indirect bilirubin in hemolytic anemia usually does not exceed 4.0 mg/dL unless there is coexisting liver disease. Serum LDH can be useful, especially in cases with intravascular hemolysis, but neither LDH nor the haptoglobin level is specific for hemolytic anemia. Moreover, the presence of inflammation negates the value of measuring haptoglobin,

which is an acute phase protein. Oral contraceptives, estrogen replacement therapy, and tamoxifen all increase haptoglobin levels. Laboratory signs of intravascular destruction of red blood cells (hemoglobinemia, hemoglobinuria, and hemosiderinuria; see later) are unusual in autoimmune hemolytic anemia.

The Antiglobulin (Coombs) Test

The antiglobulin test is central to the diagnosis of autoimmune hemolytic anemia and to an understanding of the antibody-mediated mechanism of red blood cell destruction in this disorder (Fig. 163-1B to D).

The terms *complete* and *incomplete antibodies* refer to the ability (or inability) of antibodies to cross-link adjacent red cells, thereby building the lattice needed for the macroscopic clumping of red cells. The strong negative charge of red blood cells suspended in saline keeps them apart, even if they have a coating of antibodies—the average distance between cells is 24 nm. IgM antibodies, being pentamers, are efficient agglutinins; with five antigen-binding sites, they can bridge this distance. In contrast, bivalent IgG antibodies usually cannot cause the clumping of saline-suspended erythrocytes.

The test that reveals antibody-coated red blood cells is the direct Coombs (antiglobulin) test. The indirect Coombs test was devised to seek the presence of incomplete antibodies in the patient's serum. As presently used, the standard antiglobulin reagent contains antibodies against all four classes of IgG and components of complement (usually C3 and C4).

A positive Coombs test requires cautious interpretation when there are no other features of autoimmune hemolytic anemia. False-positive test results are not unusual. The reported incidence of positive antiglobulin tests in normal blood donors and general populations of hospitalized patients varies widely—from 1 in 100 to 1 in 15,000. Differences in the technique used to perform the test account for this variation. The usual reason for a false-positive direct antiglobulin test is nonspecific, low-avidity adherence of IgG to red cells. In rare cases, however, the result is not a false-positive but a harbinger of the development of autoimmune hemolytic anemia. False-negative direct antiglobulin tests are usually due to low-affinity autoantibodies that spontaneously elute from the red cell in vitro or to amounts of erythrocyte-coating antibodies that are below the limit of detection by the antiglobulin test. The distinction between a true-positive and a false-positive direct antiglobulin test can be made by eluting the antibody from the red cells and testing its ability to bind to normal red cells. In a false-positive reaction, the eluted antibody does not bind to normal red cells, whereas binding does occur in a true-positive test.

TREATMENT Rx

There are no controlled trials of the treatment of autoimmune hemolytic anemia. A corticosteroid, usually prednisone, is the standard initial treatment. Splenectomy is indicated in patients who fail to attain or sustain a remission. If splenectomy does not result in improvement, one or more immunosuppressive agents can be tried. The physician should not withhold red cell transfusions from symptomatic patients.

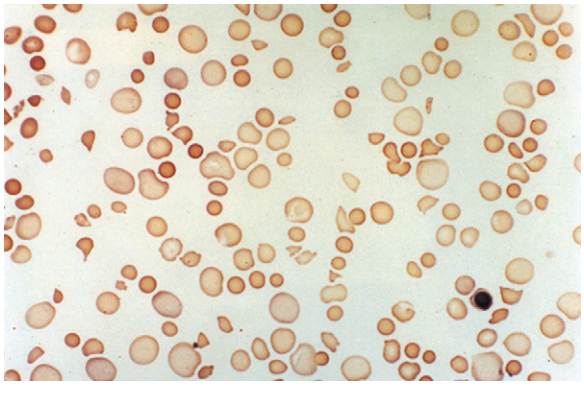

FIGURE 163-4. Microangiopathic hemolytic anemia. A peripheral smear shows fragmental red blood cells or schistocytes in a variety of shapes and sizes.

Initial Therapy

Corticosteroids

In the initial management of the disease, the standard of practice is to administer prednisone at a dose of 1.0 to 1.5 mg/kg/day. The duration of treatment at this dose is an unsettled question, but a response—manifested by a rise in the hematocrit and a fall in the reticulocyte count—is usually evident within 3 to 4 weeks. A patient who fails to improve within this time is unlikely to respond to further treatment with prednisone. In a patient who does respond, slow reduction of the dose of prednisone is essential to avoid a relapse. The usual tapering schedule is a weekly reduction of the initial dose by 10 mg/day to a dose of 30 mg/day, followed by a weekly reduction of 5 mg/day to 15 mg/day. Thereafter, slow, cautious tapering over at least 4 months is the rule. A rise in the reticulocyte count or a fall in the hematocrit should prompt an increase in the dose, usually to the previous level.

About 25% of patients treated with corticosteroids in this manner enter a stable, complete remission; half of patients require continuous, low-dose prednisone; and the remaining 25% respond only transiently or not at all or are unable to tolerate continuous corticosteroid treatment. There is no reliable evidence that alternate-day maintenance treatment is superior to daily treatment, but some patients tolerate this schedule better than daily prednisone. Very high doses of intravenous methylprednisolone have been advocated for stubborn cases, but such treatment is risky and should be considered experimental.

Transfusion

Red blood cell transfusions (Chapter 180) are indicated in patients with disabling symptoms of anemia: marked fatigue, reduced exercise tolerance, or an inability to work. These symptoms often develop when the hemoglobin concentration falls below 10 g/dL, but the decision to administer red cell transfusions should not depend primarily on laboratory tests—the patient's clinical status is the dominant factor. Some patients can tolerate a stable hemoglobin level as low as 8 g/dL; however, symptoms of coronary artery disease or heart failure may force the decision to transfuse before the hemoglobin level falls below 10 g/dL. Regardless of the patient's clinical status, rapid transfusion of large volumes of red cells can have serious adverse consequences. The blood should be administered at a rate that does not exceed 1 mL/kg/hour.

The risk of reactions to blood transfusions (Chapter 180) in patients with autoimmune hemolytic anemia is always present because of the destruction of transfused blood by the patient's autoantibodies. This hazard is increased if the patient also has alloantibodies that were induced by pregnancy or previous transfusions. For these reasons, the blood bank should be alerted to the diagnosis and should be informed if the patient was ever pregnant or has ever had transfusions.

It is important for the managing physician to understand that no patient with symptomatic autoimmune hemolytic anemia should be denied blood transfusions because of an "incompatible crossmatch." The patient's positive antiglobulin test always interferes with compatibility testing. Communication and cooperation between the patient's physician and specialists in transfusion medicine (Chapter 180) are essential in reducing the risks associated with transfusion in patients with autoimmune hemolytic anemia.

Splenectomy

Because the spleen is the major site of red cell destruction in autoimmune hemolytic anemia, splenectomy should be considered for patients who have not responded to corticosteroids or who have maintained a stable but corticosteroid-dependent remission. A complete, durable remission follows splenectomy in one half to two thirds of cases. Attempts to predict responsiveness to splenectomy by measuring the splenic sequestration of ^{51}Cr-labeled erythrocytes have not been reliable. The only way of determining the effectiveness of splenectomy in a given patient is to perform the procedure. Laparoscopic splenectomy, a safe method of removing the organ, is now the preferred surgical technique.

A major risk is post-splenectomy sepsis secondary to encapsulated bacteria, particularly pneumococci and especially in children. Splenectomy also increases susceptibility to babesiosis, ehrlichiosis, and malaria. Preoperative immunization with polyvalent pneumococcal and *Haemophilus influenzae* vaccines reduces the risk of post-splenectomy sepsis. In children, a prophylactic antibiotic, generally penicillin or amoxicillin, is essential after splenectomy. Evidence for the effectiveness of (or need for) prophylactic antibiotics in splenectomized adults is inconclusive. Education of the patient concerning the risk for serious infection after splenectomy is also important.

A rise in the platelet count occurs in almost all patients after splenectomy. The increase rarely exceeds 500,000/mL and usually subsides within 3 to 5 months. The low risk for thromboembolism related to post-splenectomy thrombocytosis argues against the need for routine antithrombotic prophylaxis.

Therapy in Refractory Patients

Rituximab

Rituximab is a chimeric monoclonal antibody with a high affinity for the CD20 antigen on the surface of normal and malignant B lymphocytes (Chapter 35). The antibody consists of murine variable region sequences and human constant region sequences. The usual dose is 375 mg/m^2 by intravenous infusion once a week for four or eight doses, but it may be continued weekly or biweekly if necessary. Rituximab rapidly depletes the circulation and lymphoid tissue of B cells; it can cause allergic reactions and increase the risk for infection.

Other Monoclonal Antibodies

Monoclonal antibodies against components of the immune system or cytokines have been used in the treatment of autoimmune hemolytic anemia, but most of the literature on this topic consists of small, uncontrolled series. Among the monoclonal antibodies that have been used are alemtuzumab (anti-CD52, a T-cell marker) and natalizumab (α4 integrin). These and similar monoclonal antibodies should be reserved for experimental use in refractory, transfusion-dependent cases.

Immunosuppressive Drugs and Other Modalities

Immunosuppressive drugs other than corticosteroids can be useful in stubborn cases of autoimmune hemolytic anemia, but no head-to-head trials have compared the efficacy of these drugs. The choice usually depends on safety and familiarity with the agent. Azathioprine has the least toxicity; cyclosporine is nephrotoxic; and cyclophosphamide damages the bone marrow, ovaries, and bladder and impairs spermatogenesis. Mycophenolate has also been tried, with some success in refractory cases. In general, these drugs should be administered only by specialists and should be reserved for patients who have failed to respond to splenectomy or who, because of comorbidities, are not suitable candidates for splenectomy.

A variety of other treatments have been used in refractory cases of autoimmune hemolytic anemia, including plasma exchange, vinca alkaloids, danazol (a synthetic androgen), and intravenous IgG. None of these forms of therapy is reliably effective, and none of them has been tested for efficacy in a randomized trial.

Cold Agglutinin Disease

DEFINITION AND EPIDEMIOLOGY

Of the two types of cold agglutinin disease, the acute form is a complication of infection, usually by *Mycoplasma pneumoniae* (Chapter 325) or Epstein-Barr virus (infectious mononucleosis [Chapter 385]). The onset in these cases is abrupt and generally appears during recovery from the infection. The acute disease, which almost always affects young adults, is rare, is self-limited, and seldom requires treatment. The usual type of cold agglutinin disease is a chronic disorder of older patients, many of whom have a B-cell lymphoma (Chapter 191), chronic lymphocytic leukemia (Chapter 190), or Waldenström's macroglobulinemia (Chapter 193). In these cases, the cold agglutinin is a monoclonal IgM antibody, in contrast to the polyclonal IgM cold agglutinins of postinfectious cold agglutinin disease.

PATHOBIOLOGY

Cold Agglutinins

Cold agglutinins are IgM autoantibodies that react with erythrocytes at temperatures below 37° C. Normal serum contains low titers of cold agglutinins, which are usually not detectable in a dilution higher than 1 : 10; in chronic cold agglutinin disease, however, the titer can exceed 1 : 10^5. The temperature at which cold agglutinins react with red cells in vitro—the thermal amplitude of the antibodies—varies considerably, but in almost all cases, red cells agglutinate readily at 4° C and quickly disaggregate at 37° C. The temperature-dependent reversibility of the reaction reflects the weak affinity of cold agglutinins for red cell antigens.

Most cold agglutinins react with polysaccharides on the red cell surface. The principal targets are the i antigen (a straight-chain paragloboside) and the I antigen (a branched paragloboside with the same composition as the i antigen). Less common are the Pr glycoproteins and sialylated polysaccharides. The erythrocytes of almost all adults are I$^+$ and lack the i antigen. The i antigen is characteristic of newborns, because the enzyme that converts i to I becomes active only after birth. Cold agglutinins associated with *M. pneumoniae* infection have anti-I specificity, whereas cold agglutinins related to infectious mononucleosis have anti-i specificity. In chronic cold agglutinin disease, the cold agglutinins are almost always monoclonal IgM, anti-I antibodies with a VH4-34 heavy chain; the shape of the antigen-binding surface of this heavy chain favors attachment to polysaccharides. About 10% of B cells from normal subjects display the VH-34 heavy chain; these cells are probably the source of the cold agglutinins in normal serum. Anti-Pr cold agglutinins tend to have a similar κ light chain variable region; presumably, the binding surface of this light chain promotes attachment of the agglutinins to red cell glycoproteins.

Erythrocyte Destruction in Cold Agglutinin Disease

The basis of red cell destruction in cold agglutinin disease is the ability of IgM antibodies to fix complement. Unlike IgG antibodies, each IgM molecule has two binding sites for C1q. An inhibitor on the red cell surface (the membrane inhibitor of reactive lysis) stops the complement cascade before lytic components can be activated, leaving behind C3b and C4b fragments. This step prepares the erythrocyte for engulfment by phagocytic cells with receptors for C3b and C4b. If such coated cells escape into the circulation, enzymes degrade the C3b and C4b fragments to harmless peptides (C3dg and C4d).

Blood cools sufficiently in the hands and feet to allow cold agglutinins to bind red cells. The adherent IgM attracts C1q, which initiates the generation of C3b and C4b on the erythrocyte's surface. On entering the warmer visceral circulation, the red cell releases the cold agglutinin, but the C3 fragments remain engaged to the CR1 of macrophages, thereby enabling phagocytosis of the red cell. The efficiency of this process depends on the amount of cold agglutinin on the red cell surface and the thermal amplitude of the cold agglutinin. An antibody that binds only at very low temperatures causes little harm, whereas an antibody that binds at a temperature close to 37° C can cause severe hemolytic anemia. These variables account for the widely different degrees of severity of cold agglutinin disease.

CLINICAL MANIFESTATIONS

Most cases of chronic cold agglutinin disease occur between the ages of 50 and 70 years. Anemia causes the main symptoms, which can worsen in cold weather. The degree of anemia, which is usually not severe, can remain static without treatment for many months because of the action of an inhibitor of C3b in serum.

In a patient with high-affinity cold agglutinins, exposure to cold can precipitate an attack of acrocyanosis by inducing massive agglutination of red cells in the capillary circulation of the hands, feet, or both. In such a case, intravascular hemolysis with hemoglobinuria and, rarely, acute renal failure can also occur. The acrocyanosis is neither Raynaud's phenomenon (white, blue, and red digits caused by vasospasm [Chapter 80]) nor the vasculitis of cryoglobulinemia (Chapter 193). Enlargement of the spleen is uncommon unless there is an associated B-cell neoplasm.

DIAGNOSIS

Agglutination of the patient's red cells at room temperature or, more often, on chilling of the blood, followed by disaggregation on warming the blood to 37° C, is typical. Hemagglutination causes red cell clumping in the blood smear and may interfere with automated blood counts. Spherocytosis is not prominent; the reticulocyte count is proportional to the degree of anemia.

The titer of cold agglutinins is often $1:10^5$ or higher, and the direct antiglobulin test is positive if the cold agglutinin has a high thermal amplitude. A monoclonal cold agglutinin indicates the presence of a B-cell lymphoma.

TREATMENT Rx

Cold agglutinin disease, whether postinfectious or chronic, often requires no treatment. Postinfectious cold agglutinin disease is self-limited and generally mild. When chronic cold agglutinin disease is stable, its management requires mainly avoidance of the cold. Safe transfusion is possible; there is no agreement concerning the need for transfusion with warmed blood.

In chronic cold agglutinin disease, prednisone, usually at a dose of 1.0 to 1.5 mg/kg/day for 3 to 6 weeks, can be tried, but it is rarely effective. The use of immunosuppressive drugs such as azathioprine or cyclophosphamide is not recommended. Splenectomy generally fails to induce a remission because the liver is a major site of destruction of C3b-coated red cells. Rituximab (375 mg/m^2 by intravenous infusion once a week for four or eight doses) has been used successfully in some cases. In patients with chronic cold agglutinin disease and a B-cell neoplasm, treatment should be directed against the tumor.

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria is a rare form of immune-mediated hemolytic anemia in which C1q bound to an IgG autoantibody attaches to red cells at low temperatures. The target antigens are globoside and a glycosphingolipid. The antibody dissociates from red cells at 37° C, but C1q remains on the membrane; at the warmer temperature it triggers progression of the complement cascade to its lytic components. The result is intravascular hemolysis.

An unsolved problem is how the lytic components of complement are generated on the red cell surface in paroxysmal cold hemoglobinuria but not in cold agglutinin disease. With the waning of late syphilis in modern times, the so-called Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria is encountered most often during convalescence from a viral infection, usually a childhood exanthem.

The Donath-Landsteiner autoantibody has no clinical effects unless the patient is exposed to cold temperatures. With cold exposure, even of just an arm or a leg, intravascular hemolysis begins soon after the return to a warm temperature. Chills, fever, back pain, abdominal cramps, and hemoglobinuria are typical. Urticaria is common, acute renal failure is rare, and anemia is an inevitable consequence of severe intravascular hemolysis. The attack is self-limited, lasting only 1 or 2 days.

A positive Donath-Landsteiner test is diagnostic, but the test is relatively insensitive. The procedure should demonstrate hemolysis in the test tube when the patient's blood is chilled and then warmed to 37° C. Addition of normal serum as a source of complement is often necessary to bring out the hemolytic phase of the reaction.

Treatment is generally unnecessary, and spontaneous recovery can be expected within weeks or a few months.

Paroxysmal Nocturnal Hemoglobinuria

DEFINITION

PNH is an acquired form of hemolytic anemia in which a somatic mutation in a hematopoietic stem cell renders erythrocytes susceptible to the lytic components of complement, thereby causing intravascular hemolysis in the absence of an anti–red blood cell antibody.

EPIDEMIOLOGY

PNH can occur at any age but is most common between 10 and 50 years. The median age at diagnosis is about 40 years; median survival after diagnosis is approximately 20 years. It is a rare disorder with an estimated prevalence in the population of 1 in 10^5 to 1 in 10^6. There is no sex preference, and a family history of PNH is unusual.

PATHOBIOLOGY

Genetics

PNH is due to a somatic mutation that causes a defect in the red cell membrane. The disease begins in a single hematopoietic stem cell when the *PIGA* gene on the short arm of the active X chromosome acquires a mutation. The *PIGA* gene encodes PIG-A, an enzyme that is essential for the synthesis of glycosylphosphatidylinositol (GPI). The location of *PIGA* on the X chromosome allows a single mutation in the gene to affect GPI synthesis. This lipid forms a peptide link with the C-terminal amino acid of numerous proteins, anchoring them to the red cell membrane. Molecular genetic studies indicate that the PNH clone upregulates genes that make the PNH clone resistant to apoptosis and immune attack.

The mutation in a hematopoietic stem cell affects PIG-A in blood cells of all lineages. Almost 150 different mutations of *PIGA* have been identified. Most of them inactivate PIG-A and cause total loss of GPI in the descendents of the carrier stem cell. Red cells with complete deficiency of GPI are termed PNH III erythrocytes, and those with partial deficiency are called PNH II erythrocytes. The coexistence of PNH III and PNH II red cells in the same patient indicates the presence of two mutant clones.

A small number of hematopoietic stem cells in normal people bear the *PIGA* mutation; they have no proliferative advantage and persist in small numbers. In normal blood, the frequency of PIG-A–deficient cells is about 1 : 50,000 red cells. In contrast to those with PNH, however, the deficient cells in normal subjects arise from committed hematopoietic cells. The presence of PIG-A–deficient cells in normal subjects suggest that PNH involves not only the *PIGA* mutation but also a second step, perhaps a mutation, that allows expansion of the mutated clone.

Functional Consequences of Deficiency of GPI

The membrane inhibitor of reactive hemolysis (CD59, or protectin) and CD55, an inhibitor of C3 convertase, are two of the many proteins that GPI anchors to the red cell. They prevent polymerization of C9, the final step in assembly of the membrane attack complex that begins with cleavage of C5 to C5b. The deficiencies of CD59 and CD55 allow unimpeded assembly of the membrane attack complex on the erythrocyte surface, thereby initiating intravascular hemolysis. A variety of nonspecific factors, such as a reduction in the pH of blood, can activate complement. The morning hemoglobinuria of PNH is probably the result of subtle acidification of blood during sleep.

CLINICAL MANIFESTATIONS

Classically, a patient with PNH arises in the morning and passes urine the color of a cola beverage. During the ensuing hours, the color of the urine gradually returns to yellow. The typical paroxysms of hemoglobinuria occur on a background of chronic, low-grade intravascular hemolysis, the cause of constant hemosiderinuria in PNH. About a third of cases evolve into aplastic anemia (Chapter 168). Transformation to acute myelogenous leukemia is a rare event. Abdominal pain, dysphagia, and erectile dysfunction are additional clinical features. The basis of these symptoms is probably scavenging by free plasma hemoglobin of nitric oxide, a regulator of vasomotor and smooth muscle tone. In about a third of cases, venous thrombosis occurs and can cause Budd-Chiari syndrome (Chapter 145) by obstructing the hepatic veins. Splenomegaly is uncommon; hepatomegaly and ascites point to the complication of hepatic vein thrombosis. Petechiae and susceptibility to infection are indications of bone marrow failure. Hemosiderinuria is the result of chronic intravascular hemolysis. Subtle or overt signs of bone marrow damage (leukopenia and thrombocytopenia) are frequent.

The extent of red cell destruction in PNH depends on the number of PNH red cells in blood, the level of GPI on the red cell membrane (PNH III cells are devoid of GPI), and the activation of complement. The anemia is often aggravated by iron deficiency caused by chronic urinary iron loss in the form of hemosiderinuria. The basis of the tendency to develop venous thrombosis is unclear; hypercoagulability caused by the release of prothrombotic materials in red cell and platelet membranes (which are also abnormal in PNH) and impaired fibrinolysis have been implicated. Nitric oxide scavenging by free plasma hemoglobin may also damage endothelial cells and cause aggregation of platelets.

DIAGNOSIS

Often, the clinical picture is virtually diagnostic. The diagnosis can be established by demonstrating, by flow cytometry, a deficiency of CD59 on erythrocytes. Another reagent with utility in flow cytometry is aerolysin, a bacterial protein that binds to the GPI anchor. Flow cytometry can also measure the proportions of PNH III and PNH II red cells in blood, providing information on the severity of the disease. Laboratory tests that depend on the sensitivity of PNH red cells to complement, such as the Ham acidification test, are insensitive and have largely been abandoned.

TREATMENT Rx

Eculizumab, a humanized monoclonal antibody against C5, which is essential for formation of the membrane attack complex, can reduce the signs of intravascular hemolysis, the requirement for transfusions, and the tendency to thrombosis. In a randomized trial, the dose of the antibody was 600 mg every week for 4 weeks, followed 1 week later by a 900-mg dose, and then by 900 mg every other week through week 26. A thrombotic event is a strong indication for eculizumab treatment. Warfarin can also be used in patients with a history of a thrombotic event. Oral iron can correct the iron deficiency; treatment with iron does not exacerbate the hemolysis. Transfusions are helpful in supportive care. Aplastic anemia has been treated successfully with immunosuppressive agents (antithymocyte globulin, usually at a dose of 1.5 mg/kg/day for 7 to 14 days) or cyclosporine (3 to 5 mg/kg for at least 3 months). Bone marrow transplantation is risky but can be curative.

Hemolytic Transfusion Reactions

The cause of hemolytic transfusion reactions (Chapter 180) is intravascular lysis of the donor's red cells by antibodies (alloantibodies or isoantibodies) in the recipient that bind to one or more blood group antigens on the transfused cells. The recipient's isoantibodies can be natural anti-A or anti-B antibodies, or they can be induced by previous transfusions or pregnancy. Whether IgM or IgG, the isoantibodies trigger the assembly of lytic complement components on the surface of the donor's red cell. The rapid formation of large amounts of C3a and C5a fragments causes hypotension and bronchial and smooth muscle spasm. Renal failure is a consequence of severe, prolonged hypotension; the main renal lesion is renal cortical ischemia secondary to shunting of blood away from the kidneys. Hemoglobin itself is not nephrotoxic.

The signs and symptoms of a hemolytic transfusion reaction are nonspecific and include fever, back pain, urticaria, dyspnea, hypotension, and

TABLE 163-3 CAUSES OF EXTRAVASCULAR AND INTRAVASCULAR HEMOLYSIS

DIC = disseminated intravascular coagulation; G6PD = glucose-6-phosphate dehydrogenase; HELLP = hemolysis, elevated liver enzymes, low platelet count.

evidence of disseminated intravascular coagulation. These nonspecific signs appear and worsen during administration of the transfusion. Immediate steps must be taken to stop the transfusion, submit the transfused blood and a sample of the patient's blood to the blood bank, and order tests of plasma and urine for free hemoglobin. Hydration is necessary to ward off renal failure; intravenous fluid, usually normal saline, should be started at once, together with a diuretic (usually furosemide) in amounts to keep urine flow at a rate of at least 100 mL/hour.

OTHER CAUSES OF INTRAVASCULAR HEMOLYSIS

Conditions in which vascular abnormalities, toxins, infections, or drugs damage red blood cells and cause them to lose pieces of membrane and ultimately fragment into hemoglobin-containing bits should be considered in the differential diagnosis of intravascular hemolysis (Table 163-3; see also Table 163-2). Most of these conditions are readily apparent from the history and physical examination. Treatment focuses on the underlying cause of the hemolysis (see Table 163-3).

HEMOLYTIC ANEMIAS: RED CELL MEMBRANE AND METABOLIC DEFECTS

PATRICK G. GALLAGHER

The mature erythrocyte differs from all other cells in the body. Lacking a nucleus, DNA, RNA, and ribosomes, it cannot synthesize RNA, DNA, or protein. It does not divide, it has no mitochondria, it cannot perform the Krebs cycle, and it lacks an electron transport system for oxidative phosphorylation. After enucleation, the reticulocyte, the precursor of the mature erythrocyte, leaves the marrow and enters the circulation equipped with a full complement of enzymes, transporters, signaling molecules, and all other proteins necessary to perform the essential functions of the red cell during its life span.

The erythrocyte membrane accounts for only about 1% of the total weight of a red cell, yet it plays a critical role in the maintenance of normal red cell homeostasis through a number of mechanisms. These include retention of vital compounds and removal of metabolic waste, regulation of erythrocyte metabolism and pH, and import of iron required for hemoglobin synthesis during erythropoiesis. The membrane maintains a slippery exterior so that erythrocytes do not aggregate or adhere to endothelial cells. The membrane skeleton, a network of proteins on the inner surface of the red cell, provides the strength and flexibility needed to maintain the normal shape and deformability of the erythrocyte.

The principal functions of erythrocyte metabolism in the mature erythrocyte include maintenance of adequate supplies of adenosine triphosphate (ATP), production of reducing substances to act as antioxidants, and control of oxygen affinity of hemoglobin by production of adequate amounts of 2,3-diphosphoglycerate (2,3-DPG). Because the mature erythrocyte has lost its ability to perform oxidative phosphorylation, its energy is supplied by anaerobic glycolysis though the Embden-Meyerhof pathway, by oxidative glycolysis through the hexose monophosphate (HMP) shunt, and through nucleotide salvage pathways.

This chapter reviews the structure and function of the erythrocyte membrane and its disorders as well as the principal metabolic processes of the erythrocyte and their disorders.

THE ERYTHROCYTE MEMBRANE

The erythrocyte membrane, because of its easy accessibility, is one of the best studied biologic membranes. Composed of a lipid bilayer and an underlying cortical membrane skeleton (Fig. 164-1), the membrane provides the erythrocyte the deformability and stability required to withstand its travels through the circulation. In one circulatory cycle throughout the body, the erythrocyte is subjected to high sheer stress in the arterial system, dramatic size and shape changes in the microcirculation with capillary diameters as small as 7.5 μm, and marked fluctuations in tonicity, pH, and Po_2.

Membrane Lipids

Red cell membrane lipids are asymmetrically distributed across the bilayer membrane, reflecting a steady state involving a constant exchange of phospholipids between the two bilayer hemileaflets. Glycolipids and cholesterol are intercalated between the phospholipids in the bilayer with their long axes perpendicular to the bilayer plane. Glycolipids, located in the external half of the bilayer with their carbohydrate moieties extending into the aqueous phase, carry several important red cell antigens and serve other important functions. Phospholipids are asymmetrically organized, with the choline phospholipids, phosphatidylcholine and sphingomyelin, primarily in the outer half of the bilayer, and the amino phospholipids, phosphatidylethanolamine and phosphatidylserine (PS), in the inner half of the bilayer. In pathologic states, such as thalassemia, sickle cell disease, and diabetes, loss of phospholipid asymmetry with externalization of PS leads to activation of blood clotting through conversion of prothrombin to thrombin and facilitates macrophage attachment to erythrocytes, marking them for destruction. Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol de novo and depend on lipid exchange and fatty acid acylation as mechanisms for phospholipid repair and renewal.

Membrane Proteins

The red cell membrane contains about a dozen major proteins and hundreds of minor ones. Membrane proteins are classified as *integral*, penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or *peripheral*, interacting with integral proteins or lipids at the membrane surface but not penetrating into the bilayer core. Integral membrane proteins include the glycophorins, the Rh proteins, Kell and Duffy antigens, and transport proteins such as band 3 (AE1, anion exchanger 1, SLC4A1), Na^+, K^+-ATPase, Ca^{2+}-ATPase, and Mg^{2+}-ATPase. Numerous membrane receptors and antigens are present on integral membrane proteins. Peripheral membrane proteins are on the cytoplasmic membrane face and include enzymes such as glyceraldehyde 3-phosphate dehydrogenase and the structural proteins of the spectrin-actin–based membrane skeleton.

Integral Membrane Proteins

Band 3, the major integral protein of the red cell, has two primary functions: ion transport and maintenance of protein-protein interactions. Band 3 mediates chloride-bicarbonate exchange and provides a binding site for glycolytic enzymes, hemoglobin, and the skeletal proteins ankyrin, protein 4.1, and protein 4.2. A single *N*-glycan chain attached to an Asn in the membrane spanning domain of band 3 is composed of *N*-acetyl-D-lactosamine units arranged in an unbranched, linear fashion in fetal erythrocytes (i antigen) and in a branched fashion in adult cells (I antigen).

The glycophorins are the next most abundant family of integral membrane proteins. They provide most of the negative surface charge required by red cells to avoid sticking to each other and to the vascular wall. They are involved in transmembrane signaling and carry receptors for *Plasmodium falciparum*, a number of viruses and bacteria, and several blood group antigens. Other integral proteins include the Rh proteins, Kell antigen, the glucose transporter, the urea transporter, Na^+, K^+-ATPase, Ca^{2+}-ATPase, Mg^{2+}-ATPase, various kinases and phosphatases, acetylcholinesterase, decay accelerating factor, complement proteins, and receptors for transferrin, insulin, insulin-like growth factors, thyroid hormone, parathyroid hormone, α-adrenergic agonists, cholinergic agents, diphtheria toxin, ceruloplasmin, and opiates.

Peripheral Membrane Proteins

Spectrin is the major component of the membrane skeleton. It is composed of two subunits, α and β spectrin, that are structurally related but functionally distinct. These subunits intertwine around each other in an antiparallel fashion to form heterodimers, which in turn self-associate head-to-head to form tetramers—slender, twisted wormlike molecules that extend to a total length of about 100 nm. Spectrin is highly flexible and assumes a variety of conformations, an unusual property that may be critical for normal membrane pliancy. The spectrin-based membrane skeleton is linked to the plasma membrane through the actin-protein 4.1 junctional complex, through spectrin-ankyrin interactions, and through binding of a multiprotein complex containing Rh proteins, Rh-associated glycoproteins, CD47, LW, glycophorin B, and protein 4.2 to ankyrin. Protein 4.1, a protein necessary for normal membrane stability, interacts with spectrin, actin, and other proteins of the red cell membrane. Ankyrin serves as the primary linkage protein for the high-affinity binding of spectrin to the inner membrane through interactions with the cytoplasmic domain of band 3. Protein 4.2 is a peripheral membrane protein that helps link the skeleton to the lipid bilayer through interactions with ankyrin and band 3. Other integral proteins include actin and the actin-associated proteins, the adducins, dematin, myosin, tropomyosin, and tropomodulin.

Erythrocyte membrane disorders result from alterations in the quantity or quality (or both) of individual proteins and their dynamic interactions with each other. Disruption of the vertical protein-protein interactions of the membrane, that is, the spectrin-ankyrin–band 3 linkage or the band 3–protein 4.2 interaction, leads to uncoupling of the membrane skeleton from the lipid bilayer. This leads to membrane instability with loss of lipids and some integral membrane proteins, resulting in loss of membrane surface area and the phenotype of spherocytosis. Disruption of the horizontal interactions of membrane skeleton proteins, including perturbation of spectrin self-association or junctional complex protein-protein interactions, leads to membrane instability, altered membrane deformability and mechanical properties, and the phenotype of elliptocytosis.

DISORDERS OF THE ERYTHROCYTE MEMBRANE

Hemolytic anemias due to defects in the erythrocyte membrane comprise an important group of hereditary anemias. Hereditary spherocytosis (HS),

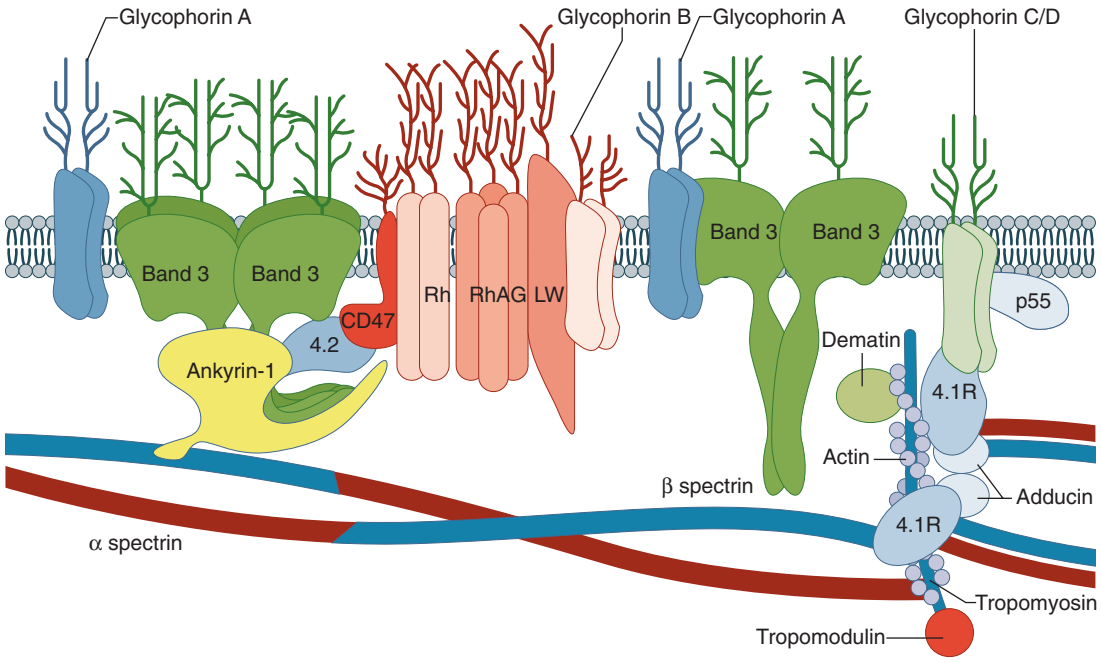

FIGURE 164-1. The erythrocyte membrane. A model of the major proteins of the erythrocyte membrane is shown: α and β spectrin, ankyrin, band 3 (the anion exchanger), 4.1 (protein 4.1) and 4.2 (protein 4.2), actin, and glycophorin. (From Perrotta S, Gallagher PG, Mohandas N. Hereditary spherocytosis. *Lancet*. 2008;372: 1411-1426.)

hereditary elliptocytosis (HE), and hereditary pyropoikilocytosis (HPP) are the most common disorders among this group. Detailed clinical studies carried out years ago have now been complemented by biochemical and genetic studies, providing both a better understanding of the pathogenesis of these disorders and a better understanding of the normal biology of the erythrocyte membrane.

Hereditary Spherocytosis

DEFINITION

HS refers to a group of disorders characterized by spherical erythrocytes on the peripheral blood smear. Clinical, laboratory, and genetic heterogeneity characterize this group of disorders.

EPIDEMIOLOGY

HS affects approximately 1 in 2000 to 3000 individuals of northern European ancestry. Found worldwide, it is much more common in whites than individuals of African ancestry.

PATHOBIOLOGY

The primary defect in HS is the loss of erythrocyte membrane surface area due to defects in erythrocyte membrane proteins including α spectrin, β spectrin, ankyrin, band 3, and protein 4.2. Qualitative or quantitative defects of one or more of these membrane proteins lead to membrane instability, which, in turn, leads to membrane loss. In approximately two thirds of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is nondominant owing to a de novo mutation or autosomal recessive inheritance. Cases with autosomal recessive inheritance are due to defects in either α spectrin or protein 4.2. Rare cases of homozygous HS have been reported, resulting in fetal death or severe hemolytic anemia. In most cases, HS mutations are "private," that is, each individual has a unique mutation, implying that there is no selective advantage to HS.

The spleen plays a critical, albeit secondary, role in the pathophysiology of HS. Splenic destruction of poorly deformable spherocytes is the primary cause of hemolysis experienced by HS patients. Abnormal erythrocytes are trapped in the splenic microcirculation and ingested by phagocytes. Moreover, the splenic environment is hostile to erythrocytes, with low pH, low glucose, and low ATP concentrations and high local concentrations of toxic free radicals produced by adjacent phagocytes, all contributing to membrane damage.

CLINICAL MANIFESTATIONS

The clinical manifestations of the spherocytosis syndromes vary widely. The classic triad of HS is anemia, jaundice, and splenomegaly. Rarely, patients may suffer from severe hemolytic anemia presenting in utero or shortly after birth, continuing through the first year of life. These patients may require multiple blood transfusions, and in some cases, splenectomy in the first year of life. Many HS patients escape detection throughout childhood. In these patients, the diagnosis of HS may not be made until they are being evaluated for unrelated disorders later in life or when complications related to anemia or chronic hemolysis occur. Although the life span of the erythrocyte in these patients may be shortened to only 20 to 30 days, they adequately compensate for their hemolysis with increased marrow erythropoiesis.

Chronic hemolysis leads to the formation of bilirubinate gallstones, the most frequently reported complication in HS patients. Although gallstones have been observed in early childhood, most appear in adolescents and young adults. Routine interval ultrasonography to detect gallstones should be performed, even if patients are asymptomatic.

Other complications of HS include aplastic, hemolytic, and megaloblastic crises. Aplastic crises occur after virally induced bone marrow suppression and present with anemia, jaundice, fever, and vomiting. The most common etiologic agent in these cases is parvovirus B19 (Chapter 379). Hemolytic crises, usually associated with viral illnesses and occurring before 6 years of age, are generally mild and present with jaundice, increased spleen size, and a decrease in hematocrit. Megaloblastic crises occur in HS patients with increased folate demands, such as the pregnant patient, growing children, or patients recovering from an aplastic crisis.

Uncommon manifestations of HS include skin ulceration, gout, chronic leg dermatitis, cardiomyopathy, spinal cord dysfunction, movement disorders, and extramedullary erythropoiesis. In patients with untreated severe HS, poor growth and findings attributable to extramedullary hematopoiesis, such as hand and skull deformities, may be found.

DIAGNOSIS

Patients with HS may present at any age, usually with anemia, hyperbilirubinemia, or an abnormal blood smear. In evaluating a patient with suspected HS, particular attention should be paid to the family history, including questions about anemia, jaundice, gallstones, and splenectomy. Initial laboratory investigation should include a complete blood count with a peripheral smear, reticulocyte count, direct antiglobulin test (Coombs' test), and serum bilirubin. When the peripheral smear or family history is suggestive of hereditary spherocytosis, an incubated osmotic fragility test (discussed later) should be obtained. Rarely, additional, specialized testing is required to confirm the diagnosis.

Overall, laboratory findings in HS are heterogeneous. Erythrocyte morphology is distinctive but not diagnostic (Fig. 164-2A). Typical HS patients have blood smears with easily identifiable spherocytes lacking central pallor. Some patients present with only a few spherocytes on peripheral smear, whereas others present with numerous small, dense spherocytes and bizarre erythrocyte morphology. Specific morphologic findings have been identified

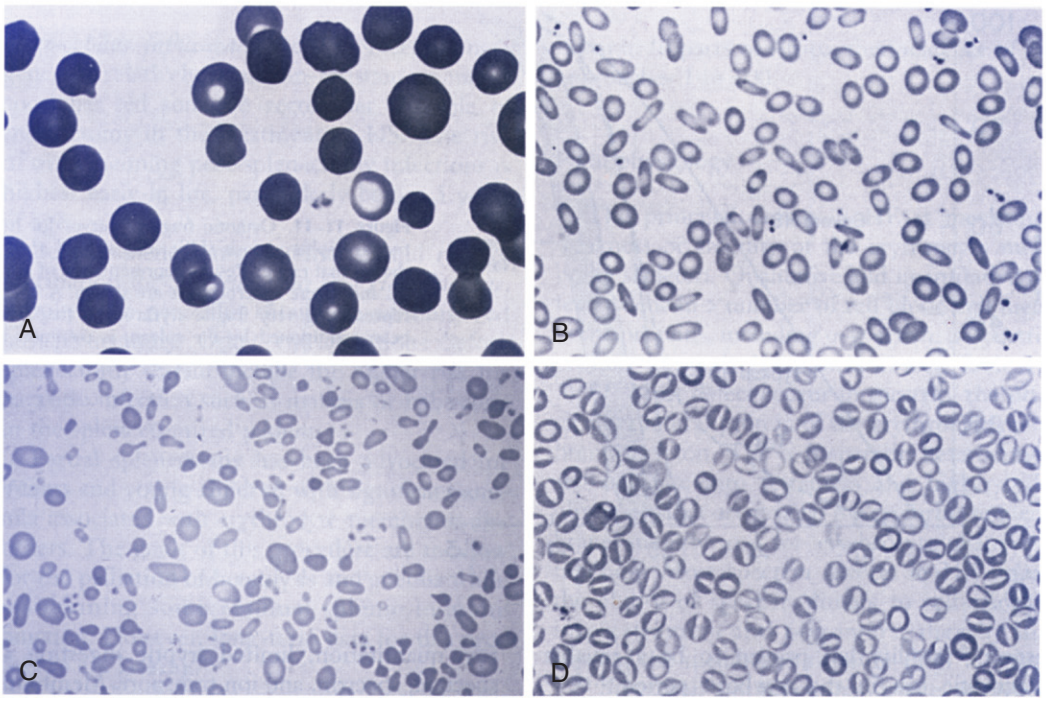

FIGURE 164-2. Peripheral blood smears in disorders of erythrocyte shape. A, Hereditary spherocytosis. Characteristic spherocytes lacking central pallor are seen. **B,** Hereditary elliptocytosis. Smooth, cigar-shaped elliptocytes are seen. **C,** Hereditary pyropoikilocytosis. Pronounced microcytosis, poikilocytosis, fragmentation of erythrocytes and elliptocytes are seen. **D,** Hereditary stomatocytosis.

in patients with certain membrane protein defects such as pincered erythrocytes (band 3) or spherocytic acanthocytes (β spectrin). When examining a smear in a case of suspected spherocytosis, it is important to have a high-quality smear with the erythrocytes well separated and some cells with central pallor in the field of examination because spherocytes are a common artifact on peripheral blood smears. The presence of spherocytosis on peripheral blood smear is not diagnostic of HS. Other disorders with spherocytes on peripheral blood smear are listed in Table 164-1.

The mean corpuscular hemoglobin concentration (MCHC) is increased (between 34.5 and 38) owing to relative cellular dehydration. The mean corpuscular volume (MCV) is usually normal or slightly decreased. Technicon and Advia (Siemens Diagnostics, Deerfield, Ill) blood counters provide a histogram of MCHCs claimed to be accurate enough to identify nearly all HS patients.

In the normal erythrocyte, a redundancy of cell membrane gives the cell its characteristic discoid shape and provides it with abundant surface area. In spherocytes, there is a decrease in surface area relative to cell volume, resulting in their abnormal shape. This change is reflected in the increased osmotic fragility found in these cells. Osmotic fragility is tested by adding increasingly hypotonic concentrations of saline to red cells. Normal erythrocytes are able to increase their volume by swelling, but spherocytes, which are already at maximal volume for surface area, burst at higher saline concentrations than normal. Approximately one fourth of HS individuals will have a normal osmotic fragility on freshly drawn red blood cells, with the osmotic fragility curve approximating the number of spherocytes seen on peripheral smear. However, after incubation at 37° C for 24 hours, HS red cells lose membrane surface area more readily than normal because their membranes have become leaky and unstable. Thus, incubation accentuates the defect in HS erythrocytes and brings out the defect on osmotic fragility, making incubated osmotic fragility the standard test in diagnosing HS. When the spleen is present, a subpopulation of very fragile erythrocytes that have been conditioned by the spleen form the tail of the osmotic fragility curve. This tail disappears after splenectomy. The osmotic fragility test suffers from poor sensitivity, with as many as 20% of mild cases of HS missed after incubation. It is unreliable in patients who have small numbers of spherocytes and in patients who have been recently transfused. It is abnormal in other conditions in which spherocytes are present.

Other tests, such as the autohemolysis test and the acidified glycerol test, suffer from lack of specificity, are cumbersome to perform, and are not widely used. Eosin-5-maleimide (EMA) binding to erythrocyte membranes, a flow cytometry–based method reflecting relative amounts of band 3 and Rh-related proteins, has been used as a screening test for HS. Like osmotic fragility testing, EMA binding is not specific and detects other erythrocyte abnormalities, especially those associated with abnormal band 3, including congenital dyserythropoietic anemia, and abnormalities of erythrocyte hydration and viscosity, including sickle cell disease and cryohydrocytosis. Samples for EMA binding must be processed quickly, because storage may alter tests results.

Specialized testing is available for studying difficult cases or cases in which additional information is desired. Useful tests for these purposes include structural and functional studies of erythrocyte membrane proteins, such as protein quantitation, limited tryptic digestion of spectrin, spectrin, and ion transport. Membrane frigidity and fragility may be examined using an ektacytometer. Complementary DNA and genomic DNA analyses are available when a molecular diagnosis is desired.

Other laboratory manifestations in HS are manifestations of ongoing hemolysis. Increased serum bilirubin, increased lactate dehydrogenase, increased urinary and fecal urobilinogen, and decreased serum haptoglobin reflect increased erythrocyte destruction.

After diagnosing a patient with HS, family members should be examined for the presence of HS. This can be of great epidemiologic importance, particularly for very old and very young patients. Prenatal diagnosis of HS has been made in a few cases, but this is rarely necessary.

TABLE 164-1 DISORDERS WITH SPHEROCYTES ON PERIPHERAL BLOOD FILM

Hereditary spherocytosis
Autoimmune hemolytic anemia
Thermal injuries
Microangiopathic and macroangiopathic hemolytic anemias
Hepatic disease

Poisoning with certain snake, spider, and Hymenoptera venoms
Severe hypophosphatemia
Heinz body anemias
ABO incompatibility (in neonates)

TREATMENT AND OUTCOME

Rx

Splenic sequestration and destruction is the primary determinant of erythrocyte survival in HS patients. Splenectomy cures or alleviates the anemia in most patients, reducing or eliminating the need for transfusions. The risk for cholelithiasis is also decreased to nearly background levels. After splenectomy, spherocytes remain in the peripheral blood, but their life span becomes near normal.

In the past, splenectomy was routinely performed in all HS patients. However, the risk of overwhelming postsplenectomy infection, the emergence of penicillin-resistant pneumococci, and the growing recognition of the increased risk of postsplenectomy cardiovascular disease, particularly thrombosis and pulmonary hypertension, have led to reevaluation of the role of splenectomy in the treatment of HS. In addition, with growing globalization, the important role of the spleen in protection of individuals living in or traveling to geographic regions where parasitic diseases such as malaria or babesiosis occur has re-emerged. When splenectomy is considered, health care providers, the patient, and family members must review and weigh the benefits of splenectomy against the immediate and long-term risks of the procedure. Considering the risks and benefits, a reasonable approach is to splenectomize all patients with severe spherocytosis and all patients suffering from significant signs or symptoms of anemia, including growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors. Other candidates for splenectomy are older HS patients suffering from vascular compromise of vital organs. Whether patients with moderate HS and compensated, asymptomatic anemia should undergo splenectomy is controversial. Patients with mild HS and compensated hemolysis can be followed and referred for splenectomy if clinically indicated. Treatment of patients with mild to moderate HS and gallstones is debatable, particularly because new treatments for cholelithiasis, including laparoscopic cholecystectomy, lower the risk of this complication.

When splenectomy is indicated, laparoscopic splenectomy has become the method of choice. This technique results in less postoperative discomfort, a quicker return to preoperative diet and activities, shorter hospitalization, decreased costs, and smaller scars. Even massive spleens can be removed laparoscopically because the spleen is placed in a large bag, diced intraoperatively, and eliminated through suction catheters. Partial splenectomy, initially advocated for infants and young children with significant anemia associated with erythrocyte membrane disorders to allow for palliation of hemolysis and anemia while maintaining some residual splenic immune function, is now being suggested by some for most HS patients.

Before splenectomy, patients should be immunized with vaccines against pneumococcus, *Haemophilus influenzae* type B, and meningococcus. Postsplenectomy care includes counseling of patients or parents to seek prompt medical care in case of febrile illness. Use of early antibiotic therapy for splenectomized febrile children has led to a decrease in the incidence of severe postsplenectomy infection. Use of routine antibiotics after splenectomy for prevention of pneumococcal sepsis is controversial. Data are lacking to indicate or refute their prescription. Before splenectomy and, in severe cases, after splenectomy, HS patients should take folic acid (1 mg/day orally) to prevent folate deficiency.

Hereditary Elliptocytosis and Related Disorders

DEFINITION

HE is characterized by the presence of elliptical or oval cigar-shaped erythrocytes on peripheral blood smears of affected individuals (see Fig. 164-2B).

EPIDEMIOLOGY

HE has been estimated to occur in approximately 1 in 2000 to 4000 individuals. The true incidence of HE is unknown because its clinical severity is heterogeneous and many patients are asymptomatic. It is common in African Americans and people of Mediterranean ancestry, presumably because elliptocytes confer some resistance to malaria. In parts of Africa, the incidence of HE approaches 1 in 100.

PATHOBIOLOGY

The principal defect in HE is mechanical weakness or fragility of the erythrocyte membrane skeleton. Qualitative and quantitative defects in a number of red cell membrane proteins have been described in HE, including α spectrin, β spectrin, protein 4.1, and glycophorin C. Most defects occur in spectrin, the principal structural protein of the erythrocyte membrane skeleton. αβ Spectrin heterodimers self-associate into tetramers and higher-order oligomers that are critical for erythrocyte membrane stability as well as erythrocyte shape and function. Most spectrin defects in HE impair the ability of spectrin dimers to self associate into tetramers and oligomers, thereby disrupting the membrane skeleton. Structural and functional defects of protein 4.1 appear to disrupt the spectrin-actin contact in the membrane skeleton. Glycophorin C variants are also deficient in protein 4.1. The precise pathobiology of how elliptocytes are formed in these syndromes is unclear.

Genetically, HE is heterogeneous with multiple genetic loci. A wide variety of mutations have been described in the α spectrin, β spectrin, protein 4.1, and glycophorin C genes, including point mutations, gene deletions and insertions, and messenger RNA processing defects. Several mutations have been identified in a number of individuals on the same genetic background, suggesting a "founder effect" for these mutants, which supports the hypothesis that there has been genetic selection for elliptocytosis because these red cells confer some resistance to malaria. Most cases of HE are inherited in an autosomal dominant pattern, with rare cases of de novo mutations.

CLINICAL MANIFESTATIONS

The clinical presentation of HE is heterogeneous, ranging from asymptomatic carriers to patients with severe, life-threatening anemia. Most HE patients are asymptomatic and are diagnosed incidentally during testing for unrelated conditions. Asymptomatic carriers have been identified who posses the same molecular defect as an affected HE relative but who have normal peripheral blood smears. The erythrocyte life span, normal in most patients, is decreased in only about 10% of patients. It is this subset of HE patients with decreased erythrocyte life span who experience hemolysis, anemia, splenomegaly, and intermittent jaundice. Many of these patients have parents with typical HE and thus are homozygotes or compound heterozygotes for defects inherited from each of the parents. Symptoms may vary among members of the same family; indeed, they may vary in the same individual at different times.

Hereditary Pyropoikilocytosis

HPP is a rare cause of anemia with distinctive erythrocyte morphology on peripheral blood smear (see Fig. 164-2C) and has a picture similar to that seen in patients suffering severe burns. Patients typically present in infancy with severe anemia and peripheral blood smear findings of elliptocytosis, poikilocytosis, pyknocytosis, and fragmentation. Microspherocytosis is common, and the MCV is usually very low (50 to 70 fL). The incubated osmotic fragility is increased. Most patients are of African ancestry, and at least one third of HPP patients have a parent or sibling with typical HE. Patients with HPP tend to experience severe hemolysis and anemia in infancy that gradually improves, evolving toward typical HE later in life.

DIAGNOSIS

Cigar-shaped elliptocytes on peripheral blood smear are the hallmark of HE (see Fig. 164-2B). These normochromic, normocytic elliptocytes vary in number from a few to 100%, with the likelihood of hemolysis not correlating with the number of elliptocytes present. Ovalocytes, spherocytes, stomatocytes, and fragmented cells may also be seen. In some cases, pyknocytes may be prominent. Elliptocytes may be seen in association with other disorders, including megaloblastic anemias, hypochromic microcytic anemias (iron deficiency anemia and thalassemia), myelodysplastic syndromes, and myelofibrosis; however, elliptocytes generally make up less than one third of red cells in these conditions. History and additional laboratory testing usually clarify the diagnosis of these disorders. In typical cases, the incubated osmotic fragility is normal, whereas in severe HE and HPP, osmotic fragility is increased.

Other laboratory findings in HE are similar to those found in other hemolytic anemias and are nonspecific markers of increased erythrocyte production and destruction. The reticulocyte count generally is less than 5% but may be higher when hemolysis is severe.

Like HS, specialized laboratory procedures are available to study the erythrocyte membranes of HE and HPP patients. These studies are not routinely required to make the diagnosis of HE or HPP, but they may be helpful in studying problematic cases and in elucidating the underlying molecular defects.

TREATMENT

Rx

Therapy is rarely needed in patients with HE. In rare cases, occasional red blood cell transfusions may be required. In cases of severe HE and HPP, splenectomy has been palliative because the spleen is the site of erythrocyte sequestration and destruction. Many practitioners think that the same indications for splenectomy in HS should be applied to patients with symptomatic HE or HPP. Postsplenectomy patients with HE or HPP experience increased hematocrits, decreased reticulocyte counts, and improvement in clinical symptoms.

Patients should be followed for signs of decompensation during acute illnesses. Interval ultrasonography to detect gallstones should be performed. In patients with significant hemolysis, folate should be administered daily.

Hereditary Stomatocytosis Syndromes

Red cell hydration is primarily determined by the intracellular concentration of monovalent cations. A net increase in sodium and potassium ions causes water to enter, forming *stomatocytes* (see Fig. 164-2D) or *hydrocytes,* whereas a net loss of sodium and potassium produces dehydrated red cells, or *xerocytes*. Numerous descriptions of congenital or familial hemolytic anemias associated with abnormal cation permeability and, in some cases, disturbed red cell hydration have been reported. These span the range from severe hydrocytosis to severe xerocytosis. In most cases, the molecular bases of this group of disorders are unknown. An unusual characteristic of the stomatocytosis syndromes is a predisposition to thrombosis after splenectomy. Acquired stomatocytosis has been associated with acute alcoholism and hepatobiliary disease, vinca alkaloid administration, neoplasms, and cardiovascular disease. Stomatocytosis is also sometimes observed as a processing artifact.

OVERHYDRATED HEREDITARY STOMATOCYTOSIS (HYDROCYTOSIS)

This group of disorders is characterized by stomatocytes, erythrocytes with a mouth-shaped (stoma) area of central pallor on peripheral blood smear (see Fig. 164-2D), severe hemolysis, macrocytosis (110 to 150 fL), elevated erythrocyte sodium concentration, reduced potassium concentration, and increased total Na^+ and K^+ content. The excess cations elevate cell water, producing large, osmotically fragile cells with a low MCHC (24 to 30%). The clinical severity of overhydrated hereditary stomatocytosis is variable; some patients experience hemolysis and anemia, whereas others are asymptomatic.

DEHYDRATED HEREDITARY STOMATOCYTOSIS (XEROCYTOSIS)

Blood smears from patients with dehydrated hereditary stomatocytosis exhibit contracted and spiculated red cells, dessicytes, a variable number of stomatocytes, and target cells. Most patients have nearly normal erythrocyte morphology, with only a few target cells and an occasional echinocyte or stomatocyte. The MCHC and MCV (95 to 115 fL) are increased, and the osmotic fragility is decreased (i.e., resistance to osmotic lysis). The characteristic biochemical abnormality is a reduced potassium concentration and total monovalent cation content.

INTERMEDIATE SYNDROMES AND HEREDITARY STOMATOCYTOSIS VARIANTS

Hydrocytosis and xerocytosis represent the extremes of a spectrum of red cell permeability defects. A number of families with features of both conditions have been reported. Some patients with severe permeability defects have little or no hemolysis. The proportion of stomatocytes and the degree of sodium influx do not correlate with each other, and neither correlates with the amount of hemolysis or anemia.

ERYTHROCYTE METABOLISM

The primary functions of the erythrocyte, gas transport and exchange, are maintained without a net change in energy state. However, several critical functions of the erythrocyte depend on the production and expenditure of energy. These include initiation and maintenance of glycolysis, pumping of cations against electrochemical gradients, maintenance of membrane phospholipids, maintenance of hemoglobin in its functional reduced ferrous state, synthesis of glutathione and other antioxidants, protection of hemoglobin from oxidative damage, and nucleotide salvage reactions. As erythrocytes age, glucose utilization and ATP levels fall, leading to decreased membrane deformability and, ultimately, shortened life span. Lower potassium levels, higher sodium levels, and decreased membrane lipids are also seen in ATP-deficient, aging erythrocytes.

Erythrocytes do not undergo oxidative phosphorylation and do not store glycogen; thus, they must constantly catabolize glucose from the blood stream through the Embden-Myerhof pathway and the hexose monophosphate shunt as a source of energy (Fig. 164-3). Erythrocytes incorporate glucose from the plasma through facilitated transfer, with erythrocyte glucose levels rapidly equilibrating with changes in blood glucose levels. Glucose is the preferred carbohydrate of the red cell, but fructose and mannose are metabolized almost as readily. Inside the erythrocyte, glucose is converted to glucose-6-phosphate or to fructose by sorbitol. Glucose-6-phosphate follows one of three pathways: (1) most (~90%) enters the Embden-Meyerhof pathway, where it is converted into lactate, pyruvate, and ATP; (2) some (~5 to 10%) enters the hexose monophosphate shunt to produce reduced

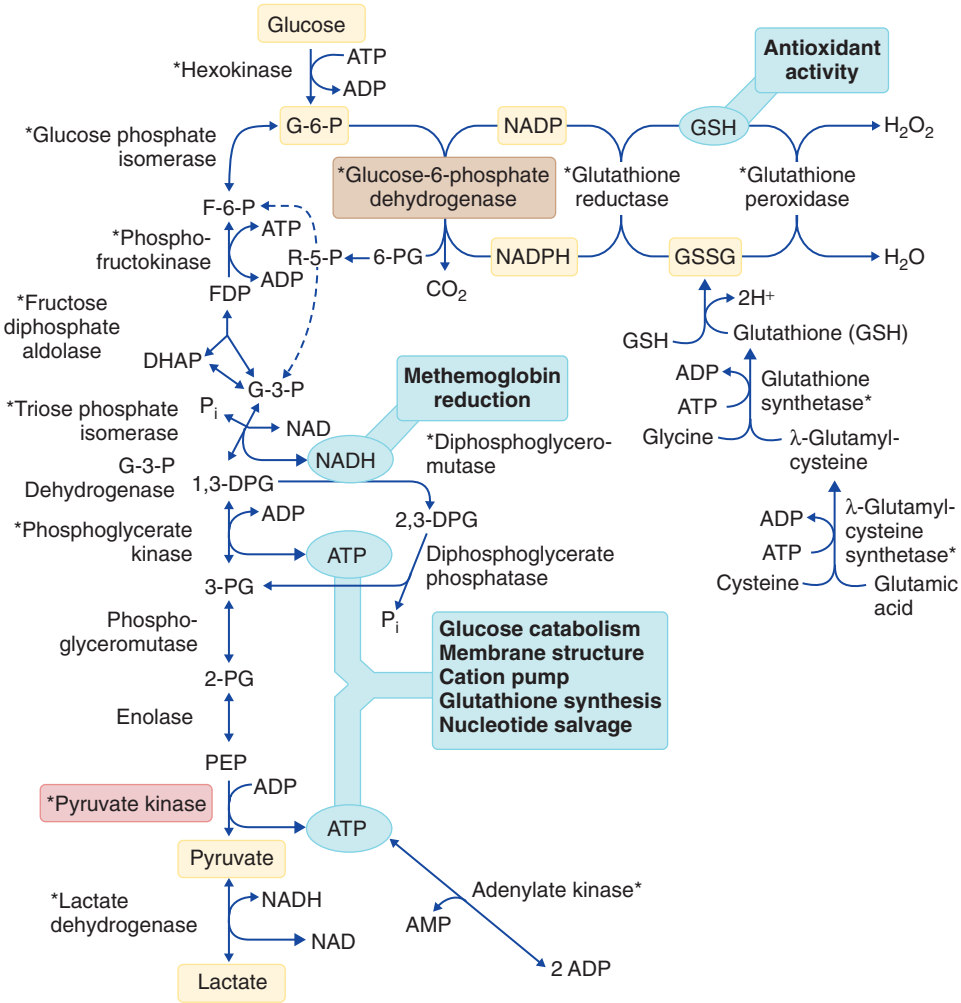

FIGURE 164-3. Pathways of energy metabolism in the erythrocyte. Glucose 6-phosphate may be degraded anaerobically to lactate through the Embden-Meyerhof pathway, or oxidatively through the hexose monophosphate shunt. Pentose phosphates (R-5-P) can reenter anaerobic glycolysis as fructose 6-phosphate (F-6-P) and glyceraldehyde 3-phosphate (G-3-P) after conversion by enzymes of the terminal pentose phosphate pathway or as a product of adenosine or inosine degradation. 2,3-Diphosphoglycerate (2,3-DPG) may be generated instead of adenosine triphosphate (ATP) through diversion of triose through the Rapoport-Luebering shunt. Glutathione may be synthesized directly from constituent amino acids; its cycling from oxidized (GSSG) to reduced forms (GSH) depends on reduced pyridine cofactor (NADPH) generation. ADP = adenosine diphosphate; DHAP = dihydroxyacetone phosphate; FDP = fructose 1,6-diphosphate; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = nicotinamide adenine dinucleotide phosphate, reduced form; PEP = polyestradiol phosphate.

intermediates and ribulose 5-phosphate, the latter of which eventually enters the Embden-Meyerhof pathway; and (3) a tiny fraction (<1%) is converted to glucose-1-phosphate and then to glycogen.

Embden-Meyerhof Pathway

The Embden-Meyerhof pathway of glycolysis is the primary source of ATP, 2,3-DPG, and nicotinamide adenine dinucleotide, reduced form (NADH) in the erythrocyte (see Fig. 164-3). Most of the energy generated by erythrocytes is through the Embden-Meyerhof pathway, followed by storage as high-energy phosphates such as ATP or as reducing energy in the form of glutathione or pyridine nucleotides (NADH and nicotinamide adenine dinucleotide phosphate, reduced form [NADPH]). This pathway metabolizes about 90% of erythrocyte glucose with the catabolism of 1 mole of glucose yielding 2 moles of ATP and 2 moles of lactate. Two moles of ATP per mole of metabolized glucose seems insignificant compared with the Krebs cycle of intermediary metabolism, in which 1 mole of glucose metabolized produces 38 moles of ATP. However, this ATP production is adequate to renew 150 to 200% of the total red cell ATP every hour.

The Embden-Meyerhof pathway is also the primary source of NADH, a necessary cofactor for NADH methemoglobin reductase, which maintains heme iron in the reduced state. Without this reaction, heme iron would be oxidized to methemoglobin, which is not a functional oxygen transporter.

Finally, the Rapoport-Luebering shunt of the Embden-Meyerhof pathway (see Fig. 164-3) produces 2,3-DPG, a compound found in high concentrations in erythrocytes, but in low concentrations in other cells. Once formed, under physiologic conditions of pH and solute concentrations, 2,3-DPG binds reversibly to tetramers of deoxyhemoglobin with greater affinity than it does to oxyhemoglobin. By binding to deoxyhemoglobin, it allosterically upregulates the release of the remaining oxygen bound to the hemoglobin, enhancing the ability of erythrocytes to release oxygen near tissues that need it most.

Hexose Monophosphate Shunt (Pentose Phosphate Pathway)

In the HMP shunt (see Fig. 164-3), glucose-6-phosphate undergoes oxidation followed by a series of reactions to yield fructose-6-phosphate and glyceraldehyde-3-phosphate, intermediates in the glycolytic pathway. The HMP shunt is the primary source of erythrocyte NADPH, with 2 moles of NADPH produced for each mole of glucose metabolized. NADPH is required for the reduction of oxidized glutathione and some protein sulfhydryl groups.

Mature erythrocytes synthesize large amounts of reduced glutathione (GSH). GSH protects erythrocytes from oxidants, including hydrogen peroxide (H_2O_2), superoxide anions (O_2^-), and hydroxyl radicals (OH), which are produced as byproducts of the oxidation of heme by oxygen. Oxidants are also produced by activated phagocytes (e.g., during infection) and by erythrocytes after exposure to certain agents. When oxidants accumulate, they damage cellular proteins and lipids. Detoxification of H_2O_2 is significantly enhanced by glutathione peroxidase. GSH is converted to oxidized glutathione (GSSG) and to mixed disulfides with protein thiols. GSH levels are restored by glutathione reductase. In this process, NADPH is oxidized to nicotinamide adenine dinucleotide phosphate (NADP), which stimulates the HMP shunt to regenerate NADPH. After oxidant stress, hypoxia, or acidosis, erythrocytes can increase the amount of glucose metabolized through the HMP shunt up to 10- to 20-fold to generate increased amounts of reduced glutathione. The tight coupling of glutathione metabolism with the HMP shunt protects the mature erythrocyte from oxidative stress.

The HMP shunt also produces ribose 5-phosphate, a constituent of the purine nucleotides, adenosine diphosphate (ADP) and ATP, and the pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and NADP. Although the mature erythrocyte cannot synthesize purines or pyrimidines de novo, it can form some nucleotides through salvage pathways. Ribose 5-phosphate participates in these salvage pathways.

DISORDERS OF ERYTHROCYTE METABOLISM

Congenital nonspherocytic hemolytic anemia (CNSHA) traditionally includes erythrocyte disorders not due to defects of the red cell membrane or hemoglobin, immune-mediated disease, or other diseases such as paroxysmal nocturnal hemoglobinuria. CNSHA is a heterogeneous group of disorders associated with various metabolic abnormalities of the erythrocyte, including enzymopathies of glucose, glutathione, and nucleotide metabolism. Like the membrane disorders, clinical, biochemical, and genetic heterogeneity are typical within the enzymopathies. Hemolysis may develop as a result of either enzyme or antioxidant deficiency or dysfunction (e.g., abnormal substrate or cofactor binding), altered activation or inhibition characteristics, or decreased stability or specific activity.

Peripheral blood smears in CNSHA, with the exception of pyrimidine 5′-nucleotidase deficiency, are unremarkable. Osmotic fragility of fresh erythrocytes is normal. Response to splenectomy is variable. Inheritance is heterogeneous. A thorough family history is important and may be of assistance in determining the diagnosis. Manifestations of the metabolic defect are usually confined to the erythrocyte but may occasionally involve nonerythroid cells.

Definitive diagnosis of metabolic abnormalities of the red cell depend on qualitative or quantitative assays of specific enzyme activity or identification of the specific genetic mutation by DNA analysis. Results of enzyme assays should be interpreted with caution because (1) they only sample surviving red cells in the peripheral blood, and the metabolic milieu of these cells is not necessarily comparable to cells already hemolyzed; (2) in vitro enzyme assay conditions may not accurately reflect the in vivo environment; (3) transfusions before the assay may obscure the underlying metabolic defect, and (4) leukocyte contamination may lead to spurious results. Finally, average enzyme activity may not accurately reflect activity in subpopulations of erythrocytes. This is particularly true when there is reticulocytosis, which may yield artificially elevated mean enzyme activity owing to higher enzyme levels found in reticulocytes.

Disorders of the Embden-Meyerhof Pathway

Defects of the Embden-Meyerhof pathway are inherited in an autosomal recessive fashion, and usually hemolysis is seen only in homozygotes or compound heterozygotes. Heterozygotes, whose erythrocytes contain less than normal amounts of mutant enzyme, are clinically normal.

An exception is phosphoglycerate kinase deficiency, an X-linked disorder with hemolysis found only in males. In this group of disorders, hemolysis is chronic, is not typically influenced by drugs or other inciting agents, and is attributed to insufficient levels of erythrocyte ATP. Splenomegaly from trapping of mutant erythrocytes is common. The hostile splenic environment contributes to the shortened erythrocyte life span. When performing specific diagnostic enzyme assays, measurement of glycolytic intermediates may assist in diagnosis because concentrations of intermediates is increased upstream of a defect and decreased downstream of a defect.

PYRUVATE KINASE DEFICIENCY

Pyruvate kinase (PK) deficiency accounts for approximately 90% of inherited defects of the Embden-Meyerhof pathway and is the second most common inherited erythrocyte enzymopathy associated with anemia after glucose-6-phosphate dehydrogenase (G6PD) deficiency (see later). PK deficiency is found worldwide, but it is most common in individuals of northern European descent.

PATHOBIOLOGY

PK catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate, generating ATP. Deficient or defective PK leads to decreased levels of erythrocyte ATP, disturbing many cellular processes such as signaling and maintenance of water and ion content, leading to energy failure and dehydration. Upstream catabolites accumulate in the erythrocyte, including 2,3-DPG, which shifts the oxygen dissociation curve to the right, enhancing tissue oxygenation and ameliorating some of the physiologic effects of anemia. Early PK-deficient reticulocytes retain the ability to utilize oxidative phosphorylation to produce ATP, bypassing their defect. This ability is lost as reticulocytes mature and is markedly dampened in the hypoxic environment of the spleen.

PK deficiency is inherited in an autosomal recessive manner. Affected individuals are homozygous or compound heterozygotes for PK defects. Heterozygotes are clinically normal or exhibit very minimal hemolysis.

CLINICAL MANIFESTATIONS

Clinical manifestations in PK deficiency are heterogeneous, ranging from asymptomatic to transfusion-dependent hemolytic anemia. More severely affected patients present in infancy or early childhood with anemia, jaundice, and splenomegaly. Occasionally, patients may escape detection until later in life when complications related to anemia and chronic hemolysis occur such as cholelithiasis or aplastic crisis or when the diagnosis is made during evaluation of the patient for another condition.

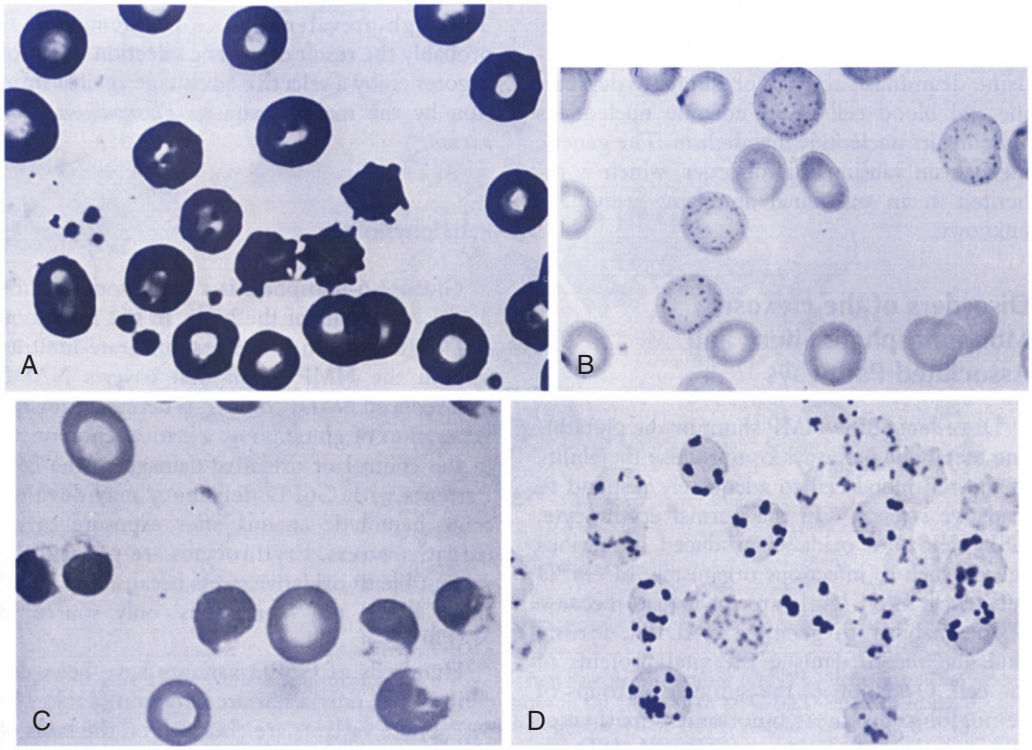

FIGURE 164-4. Peripheral blood smears in erythrocyte enzymopathies. A, Pyruvate kinase deficiency. **B,** Pyrimidine 5′-nucleotidase deficiency; **C,** Glucose-6-phosphate dehydrogenase (G6PD) deficiency. **D,** Heinz bodies in G6PD deficiency. (**B** from Paglia DE. Disorders of erythrocyte glycolysis and nucleotide metabolism. In: Handin RI, Lux SE, Stossel TP, eds. *Blood: Principles and Practice of Hematology.* Philadelphia: JB Lippincott; 1995:1877-1896.)

DIAGNOSIS

Peripheral blood smear demonstrates normocytic, normochromic erythrocytes, sometimes with spiculations (Fig. 164-4A). Poikilocytes and acanthocytes may also be seen. Reticulocytosis is common. Osmotic fragility of fresh erythrocytes is usually normal. Occasional patients exhibit a population of osmotically fragile cells after incubation.

NADH fluorescence under ultraviolet light is a commonly used screening test for PK deficiency. PEP and NADH are mixed with the patient's blood, incubated, and spotted on filter paper, and fluorescence is measured. Direct enzyme assay, which uses PEP as substrate for PK, can be performed on leukocyte-free hemolysate to confirm abnormal fluorescence tests. Leukocytes must be carefully depleted from the samples because they contain over 300 times the PK activity of erythrocytes.

TREATMENT Rx

Most patients require only expectant management, with only rare transfusions, such as during an aplastic episode. In severe cases, patients may be transfusion dependent. In these cases, splenectomy typically lessens hemolysis and ameliorates the anemia. After splenectomy, some patients develop marked reticulocytosis, up to 50 to 70%. This paradoxical reticulocytosis is attributed to increased reticulocyte survival after removal of the hostile splenic environment.

OTHER DISORDERS OF THE EMBDEN-MEYERHOF PATHWAY

Other abnormalities of the Embden-Meyerhof pathway have been described. Hexokinase deficiency is quite uncommon, with great phenotypic variability in reported cases. Severely affected patients have suffered from anemia beginning in infancy and may require blood transfusion. Glucose phosphate isomerase (GPI) deficiency is the third most common hemolytic enzymopathy. GPI deficiency usually presents in infancy or early childhood with moderate to severe hemolytic anemia. Phosphofructokinase deficiency may involve erythrocytes, muscle, or both. Presentation is usually in adolescence with exertional myopathy. Hemolytic anemia has been described in isolated cases of 2,3-bisphosphoglycerate mutase deficiency and phosphoglycerate kinase deficiency.

Disorders of Nucleotide Metabolism

Mature erythrocytes lack the ability to synthesize purine and pyrimidine nucleotides de novo. However, they are able to form some nucleotides through salvage pathways.

PYRIMIDINE 5′-NUCLEOTIDASE DEFICIENCY

Pyrimidine 5′-nucleotidase (P5N) degrades the pyrimidine nucleotides of RNA to cytidine and uridine, which can diffuse out of the cell. When P5N is deficient, nondiffusible, partially degraded RNAs accumulate, leading to the marked basophilic stippling characteristic of P5N-deficient erythrocytes (see Fig. 164-4B). These accumulated pyrimidine nucleotides inhibit the transport of GSSG out of red cells, leading to high levels of erythrocyte glutathione. Clinically, there is mild to moderate hemolytic anemia and splenomegaly. The etiology of the hemolysis remains cryptic. Typically, splenectomy does not ameliorate the hemolysis and anemia.

Disorders of the Hexose Monophosphate Shunt (Pentose Phosphate Pathway) and Associated Pathways

Disorders of the HMP shunt or of the glutathione metabolic pathways (see Fig. 164-3) compromise the ability of the red cell to respond adequately to oxidative stress. In the normal erythrocyte, GSH detoxifies oxidants produced by various agents and infection. In G6PD-deficient erythrocytes, because of the inability to generate NADPH, GSH levels are inadequate, leaving the cell susceptible to oxidant stress. Oxidation of hemoglobin sulfhydryl groups leads to the production of methemoglobin and intracellular hemoglobin precipitates called Heinz bodies. Heinz bodies (see Fig. 164-4D), usually visualized on peripheral blood smears with supravital stains such as methyl violet, attach to and damage the erythrocyte membrane. They induce clustering of immunoglobulins and band 3 protein, marking the erythrocyte for opsonization by phagocytes and eventual removal from the circulation. *Heinz bodies* are "pitted" from circulating cells by the spleen and are commonly seen on smears of patients after splenectomy. *Bite cells*, erythrocytes with localized invaginations, possibly at the site of Heinz body injury or removal, are seen during acute hemolytic episodes. In addition to damage from Heinz body formation, GSH-deficient erythrocytes also undergo peroxidation of membrane phospholipids and oxidative cross-linking of spectrin, decreasing membrane deformability and further promoting splenic trapping.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency is the most common inherited disorder of erythrocyte metabolism, affecting more than 400 million people worldwide. The high prevalence of G6PD deficiency is thought to be due to genetic selection because G6PD-deficient erythrocytes have a selective advantage against invasion by the malaria parasite *Plasmodium falciparum*.

EPIDEMIOLOGY AND PATHOBIOLOGY

G6PD is the initial and rate-limiting step in the HMP shunt (see Fig. 164-3), which converts NADP into NADPH. NADPH is required for the generation of glutathione, a critical constituent in the prevention of oxidative damage to the cell. G6PD-deficient patients may develop acute hemolytic anemia after exposure to oxidative stress. Although G6PD is a ubiquitous enzyme, erythroid cells are particularly susceptible to oxidative stress because the HMP shunt is their only source of NADPH.

Hundreds of G6PD variants have been described, but only a few are common. Variants are classified on the basis of biochemical characteristics, electrophoretic mobility, ability to use substrate analogue, Km for NADP and G6PD, pH activity profile, and thermal stability. The normal enzyme, Gd^{B}, is present in 99% of white Americans and 70% of African Americans. A normal variant, Gd^{A+}, found in 20% of African Americans, has a faster electrophoretic mobility than Gd^{B}. Gd^{A-}, the most common variant associated with hemolysis, is found in about 10% of African Americans and in many Africans. Gd^{A-} has decreased catalytic ability compared with Gd^{A+}. Gd^{Med}, the second most common variant associated with hemolysis, is common in the Mediterranean area, in India, and in southeast Asia, with a prevalence of up to 5 to 50%. Gd^{Med} exhibits markedly decreased catalytic activity. Gd^{Canton}, a variant common in Asian populations, produces a clinical syndrome similar to Gd^{A-}.

Gd^{B} activity decreases as normal cells age, with a half-life of approximately 60 days. Despite very low levels of or no active G6PD, older erythrocytes maintain the ability to produce NADPH and maintain a GSH response to oxidative stress. Gd^{A-} variant has a half-life of only 13 days, so young cells have a normal amount of enzyme activity whereas older red cells are grossly deficient. Because of this heterogeneity in G6PD levels, individuals with the Gd^{A-} variant experience only limited hemolysis after oxidant exposure.

More than 100 mutations in the *G6PD* gene, localized to Xq28, have been described. Most mutations are amino acid substitutions that influence enzyme kinetics, stability, or both, with a few rare deletions and splicing mutations described. Because it is X-linked, G6PD deficiency primarily affects males. Males have only one G6PD allele and express only one G6PD type. Females can express one or two G6PD types. The Lyon hypothesis specifies that only one X chromosome is active in any given cell; thus, any given cell in a heterozygous female is either normal or deficient. In females who are heterozygous for G6PD deficiency, average G6PD activity may be normal or mildly, moderately, or severely reduced, depending on the degree of lyonization. G6PD-deficient erythrocytes in heterozygous females are susceptible to the same oxidant stress as G6PD-deficient cells in males, but, typically, the overall degree of hemolysis is less because there is a smaller population of vulnerable cells.

CLINICAL MANIFESTATIONS

G6PD deficiency is divided into five classes based on clinical severity and degree of enzyme deficiency. Class I is characterized by CNSHA without precipitating cause and severe G6PD deficiency. Class II is characterized by intermittent hemolysis and severe G6PD deficiency. Class III is characterized by hemolysis after oxidant stress and mild G6PD deficiency. Classes II and III together represent more than 90% of G6PD variants. Classes IV and V are clinically asymptomatic. The most clinically significant syndromes of G6PD deficiency are acute hemolytic anemia (AHA), neonatal jaundice (NNJ), and rarely, CNSHA.

AHA is the most dramatic clinical presentation of G6PD deficiency with acute intravascular hemolysis after exposure to an oxidative stress. Oxidative stresses include ingestion of certain drugs such as primaquine or sulfa-containing compounds, exposure to naphthalene (mothballs), ingestion of fava beans, or infection, the latter being the most common cause of hemolysis. Table 164-2 lists drugs that should be avoided in G6PD-deficient patients. Presenting symptoms include irritability, fever, nausea, abdominal pain, and diarrhea within 48 hours of oxidant exposure. Hemoglobinuria, jaundice, and anemia ensue. The spleen and liver may be enlarged and tender. Cases with severe anemia may precipitate congestive heart failure. Laboratory findings include a normochromic, normocytic anemia with anisocytosis and reticulocytosis. Poikilocytes and bite cells may be seen. Heinz bodies, a classic finding in G6PD deficiency, may be seen but are an inconsistent finding because these damaged cells are rapidly cleared from the circulation in the spleen. Additional laboratory findings include hemoglobinuria and the presence of free hemoglobin in the blood.

TABLE 164-2 AGENTS TO BE AVOIDED BY GLUCOSE-6-PHOSPHATE DEHYDROGENASE–DEFICIENT PATIENTS*

ANTIMALARIALS
Primaquine (people with the African A⁻ variant may take it at reduced dosage, under surveillance)
Pamaquine
Chloroquine (may be used under surveillance when required for prophylaxis or treatment of malaria)
SULFONAMIDES AND SULFONES
Sulfanilamide
Sulfapyridine
Sulfadimidine
Sulfacetamide (Albucid)
Acetyl sulfisoxazole (Gantrisin)
Salicylazosulfapyridine (Salazopyrin)
Dapsone
Sulfoxone
Glucosulfone sodium (Promin)
Sulfamethoxazole-trimethoprim (Septrin)
OTHER ANTIBACTERIAL COMPOUNDS
Nitrofurans—nitrofurantoin, furazolidone, nitrofurazone
[Nalidixic acid]
Chloramphenicol
p-Aminosalicylic acid
ANALGESICS
Acetylsalicylic acid (aspirin): moderate doses can be used
Acetophenetidin (Phenacetin)
Safe alternative: Paracetamol
ANTHELMINTICS
β-Naphthol
Stibophen
Niridazole
MISCELLANEOUS
Vitamin K analogues (1 mg of menaphthone can be given to babies)
Naphthalene (moth balls)
Probenecid
Dimercaprol (BAL)
Methylene blue
Arsine†
Phenylhydrazine†
Acetylphenylhydrazine†
Toluidine blue
Mepacrine

*Drugs in bold print should be avoided by people with all forms of glucose-6-phosphate dehydrogenase (G6PD) deficiency. Drugs in normal print should be avoided, in addition, by G6PD-deficient people of Mediterranean, Middle Eastern, and Asian origin. Items in normal print and within square brackets apply only to people with the African A⁻ variant.
†These drugs or chemicals may cause hemolysis in normal people if given in large doses. Many other drugs may produce hemolysis in certain individuals.

Another clinically significant syndrome of G6PD deficiency is NNJ. Jaundice is seldom present at birth, and the peak incidence of onset is between days 2 and 3 of life. The severity of hyperbilirubinemia is variable. It may be severe, resulting in kernicterus or even death. In most cases, however, hyperbilirubinemia is adequately treated with phototherapy. In NNJ, it is important to note that the anemia is very rarely severe. The etiology of NNJ remains controversial. It has been suggested that decreased hepatic elimination of bilirubin is the critical determinant of NNJ. Others suggest that hemolysis is the cause of the jaundice. However, jaundice persists in some cases even when there is no contact with causative agents. NNJ is increased in G6PD-deficient infants who also carry a polymorphism of the uridine diphosphoglucuronyl transferase *(UDPGT1)* gene associated with Gilbert syndrome.

Chronic nonspherocytic hemolytic anemia is associated with uncommon variants of G6PD deficiency, usually mutant enzymes unable to maintain basal NADPH production. Presentation may be in the neonatal period when NNJ is accompanied by anemia in a male. The degree of chronic anemia in CNSHA due to G6PD deficiency has been variable. Some patients have compensated hemolysis, whereas others require intermittent transfusions. Transfusion dependence occurs in the most severe cases.

DIAGNOSIS

The G6PD reaction (glucose-6-phosphate + $NADP^+ \rightarrow$ 6-phosphogluconolactone + NADPH + H^+) reduces $NADP^+$ to NADPH. Formation of NADPH and NADH can be observed directly because they fluoresce in the visible spectrum when illuminated with long-wave ultraviolet light. Based on this observation, several simple screening tests performed using inexpensive long-wave ultraviolet light have been devised. These tests are semiquantitative, categorizing a sample as normal or deficient. They are unreliable after an acute hemolytic episode and do not typically detect female heterozygotes. Positive screening tests should be confirmed by spectrophotometric assay or DNA studies.

Definitive assay of the enzyme depends on direct spectrophotometric measurement of NADPH production. Although more sensitive than screening tests, this still requires 20 to 30% G6PD-deficient cells to obtain an abnormal result. Sensitivity can be increased by comparing the level of G6PD deficiency to levels of other age-dependent erythrocyte enzymes, especially when testing is temporally in close proximity to an acute hemolytic episode. The cyanide-ascorbate test measures the ability of erythrocytes to prevent the oxidation of hemoglobin by ascorbate. Employing intact erythrocytes, as few as 10 to 15% deficient cells can be detected, making this test useful for detecting female heterozygotes and males following a hemolytic episode. This test also detects other perturbations of the HMP shunt or glutathione metabolism.

TREATMENT

Rx

The best treatment for the individual with AHA is careful prescription of medications and avoidance of inciting agents (see Table 164-2). Outside of acute hemolytic episodes, these patients do not require any special therapy. AHA episodes are managed with particular attention to hematologic, cardiopulmonary, and renal complications of hemolysis. Management of NNJ does not differ from that recommended for other causes of neonatal hyperbilirubinemia. In CNSHA, management is expectant. Exposure to oxidant stresses should be avoided. Blood transfusions may be necessary during acute hemolytic episodes. In severe cases of CNSHA, splenectomy may ameliorate the anemia.

Disorders of Glutathione Metabolism

Defects of glutathione metabolism may be associated with hemolysis. Erythrocytes from patients lacking glutathione synthetase or γ-glutamylcysteine synthetase, enzymes involved in glutathione synthesis, have very low levels of GSH. Clinically, these disorders resemble G6PD deficiency. There is mild to moderate chronic hemolytic anemia with increased susceptibility to oxidant stress.

165 THE THALASSEMIAS

MARIA DOMENICA CAPPELLINI

DEFINITION

The thalassemias—or, more comprehensively, the thalassemia syndromes—are a heterogeneous group of inherited hemolytic anemias characterized by deficient or absent production of one of the globin chains of hemoglobin. This leads to imbalanced globin chain synthesis, which is the hallmark of all the thalassemia syndromes.

EPIDEMIOLOGY

Taken together, the thalassemias are the most common single gene disorder in the world population. The estimated number of carriers exceeds 270 million, and more than 300,000 children are born each year with one of the thalassemia syndromes or one of the structural hemoglobin variants. The extremely high frequency of hemoglobin disorders compared with other monogenic diseases reflects natural selection mediated by the relative resistance of carriers against *Plasmodium falciparum* malaria. Other factors that may be involved include the widespread practice of consanguineous marriage and increased maternal age in poorer countries, and gene drift and founder effects. For these reasons, the thalassemias are most frequent in southeastern and southern Asia, the Middle East, the Mediterranean countries, and northern and central Africa. However, as a result of the mass migration of African populations from high-prevalence areas, thalassemias are now encountered worldwide.

PATHOBIOLOGY

The normal adult red cells contain 97% adult hemoglobin (HbA: $\alpha_2\beta_2$), with approximately 2.5% of the minor component HbA_2 ($\alpha_2\delta_2$) and a small amount of fetal hemoglobin (HbF: $\alpha_2\gamma_2$). Because the stable tetramer $\alpha_2\beta_2$ is the major component of hemoglobin after birth, there are two main forms of thalassemia: α-thalassemia and β-thalassemia. Because β-chain synthesis is fully activated only after birth, it follows that the β-thalassemias are not expressed as diseases in intrauterine life; they manifest as γ-chain synthesis declines during the first year of life. In contrast, because α chains are shared by both fetal and adult hemoglobin, α-thalassemias manifest in both fetal and adult life.

As knowledge about their genetic basis and pathophysiologic mechanisms has evolved, the thalassemia syndromes can now be classified at genetic and clinical levels (Table 165-1).

Genetics

Six different types of globin chains (α, β, γ, δ, ε, ζ) are found in normal human hemoglobin at different stages of development. In the very early embryo, hemoglobin synthesis is restricted to the yolk sac and to the production of Hb Gower 1 ($\zeta_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$). Subsequently, at about 8 weeks of gestation, the fetal liver takes over, synthesizing predominantly HbF ($\alpha_2\gamma_2$) and a small amount (<10%) of HbA. Between about 18 weeks and birth, the liver is progressively replaced by bone marrow as the major site of red cell production. This is accompanied in the later stages of gestation with a reciprocal switch in the production of HbF and HbA; this continues until, by the end of the first year of life, HbF production has dropped to less than 2%. The globin genes are encoded in separate gene clusters. The α cluster (ζ, α_2, α_1) lies at the telomere of chromosome 16, and the β cluster (ε, $^{G}\gamma$ and $^{A}\gamma$, δ, β) lies at chromosome 11p15.5. In both clusters the genes are aligned 5′ to 3′ in the order in which they are expressed during development. Both sets of genes are under the regulation of enhancer-like elements (hypersensitive site [HS]-40 for α cluster, and locus control region [LCR] for β cluster) that lie some distance away at the 5′ end of the cluster. Deletion of these enhancer elements results in inactivation of any related globin gene. There are two α genes/alleles (α_2 and α_1) that differ by a few nucleotides in intron 2 and the 3′ untranslated region but produce identical protein products. The output of the α_2 gene exceeds that of the α_1 gene by two- to three-fold. The α cluster also contains pseudo-ζ and pseudo-α genes that are not translated into protein products. The region around a DNase I

TABLE 165-1 GENETIC AND CLINICAL CLASSIFICATIONS OF THE THALASSEMIAS

	GENETIC	CLINICAL
α-Thalassemias	α^0 α^+ Deletion (−α) Nondeletion (α^T)	α-Minor HbH disease Hydrops fetalis
β-Thalassemias	β^0 β^+ Variant with high HbA_2 Normal HbA_2 Silent Dominant Unlinked to β-gene cluster	β-Minor Thalassemia intermedia Thalassemia major
δβ-Thalassemia	$(\delta\beta)^0$ $(\delta\beta)^+$ $(^{A}\gamma\delta\beta)^0$	δβ-Minor Thalassemia intermedia
HPFH	Deletion Nondeletion Unlinked to β-gene cluster	Silent increase in HbF

HbA = adult hemoglobin; HbF = fetal hemoglobin; HbH = hemoglobin H; HPFH = hereditary persistence of fetal hemoglobin.

HS at 40 kb upstream of the ζ-globin gene (HS-40) is the major regulator of α-globin gene expression. The β cluster contains a single pseudo-β gene; the β-cluster "enhancer" consists of five elements marked by erythroid-specific DNase I HSs lying 6 to 20 kb upstream of the ε-globin gene, each of which contains several binding sites for erythroid-specific and other transcription factors. All together, these elements are known as the LCR, and each element contributes to the overall LCR activity. In addition, there is an erythroid-specific HS approximately 20 kb downstream of the β-globin gene; when the cluster is activated, the upstream and downstream HSs are brought into close proximity with the gene promoters to activate their transcription. The individual globin genes share many general features: they consist of three coding sequence exons separated by two introns in identical positions but of variable length, for a total length of approximately 1500 nucleotides. This structure has been highly conserved throughout evolution. The upstream regions flanking the first exon contain a number of sequence motifs that are necessary for specifying correct transcriptional initiation. A TATA box is found at 30 base pairs upstream of the initiation site, together with one or more CCAAT sites at 70 base pairs upstream. The gene promoters also contain a CACCC or CCGCCC box that binds erythroid Krüppel-like factor (EKLF)-1, and some have binding sites for erythroid transcription factor GATA-1. In model systems, mutations introduced into such sequences lead to a reduction in the level of transcription.

All the thalassemias have a similar pattern of inheritance: in most cases, the gene defects are transmitted in a mendelian autosomal fashion. Thus the severe, symptomatic varieties usually result from the interaction of more than one genetic determinant. The inheritance of α-thalassemia is more complicated because it involves the products of the linked pairs of α genes (αα) (see Clinical Manifestations).

Molecular Basis

The α- and β-thalassemias are divided into disorders in which no chains are produced from the affected chromosomes (α^0 and β^0) and those in which the chain output is reduced (α^+ and β^+).

For the α-thalassemias, the most common molecular defects are deletions of one or both α genes, which are designated –α and ––, respectively. The single α gene is believed to have arisen by crossover between two misaligned α genes on the homologous chromosome, which can give rise to chromosomes with either single (–α) or triplicated (ααα) α-globin genes. Depending on the point of crossover, deletions may remove between 2.5 and 5.3 kb of sequence, with the loss of 3.7 ($-\alpha^{3.7}$) or 4.2 ($-\alpha^{4.2}$) kb being most prevalent. Full duplication of the α-globin gene locus, including the upstream regulatory element, has also been reported in subjects of different ancestries, suggesting that this type of homologous genetic recombination occurs relatively frequently in globin loci. To date, more than 20 different deletions that involve both α genes, resulting from illegitimate or nonhomologous recombination, have been reported. The lengths of deletion vary from 5.2 to more than 40 kb, with the most common being those from Southeast Asia, the Mediterranean, and the Philippines, designated $--^{SEA}$, $--^{MED}$, and $--^{FIL}$, respectively. Nondeletion types of α-thalassemia (α^T) are much less common than the deletion forms, and in most cases they result from single oligonucleotide mutations at regions of the α gene sequence that are critical for normal expression. Because expression of the α_2 gene is two to three times greater than that of the α_1 gene, it is not surprising that most of the nondeletion mutants affect predominantly expression of the α_2 gene. The mutations may affect the initiation codon or splicing signals, cause frameshifts, or introduce premature stop codons. At least five single-nucleotide variants affect the natural termination codon (TAA) of the α_2-globin gene. Among these, Hb Constant Spring ($\alpha^{CS}\alpha$) is the most common and extensively studied. Finally, there are several α-globin variants that are so unstable that they undergo very rapid, postsynthetic degradation. In such situations, β chains remain in excess within the red cell, and patient carriers of these α-chain variants, by definition, have α-thalassemia. To date, 17 unstable α variants have been shown to produce the phenotype of α-thalassemia to a greater or lesser extent.

As for the α-thalassemias, the β-thalassemias are classified as β^0 thalassemia (in which no β globin is produced) and β^+ thalassemia (in which some β globin is produced, but less than normal). In some cases the defects in β-chain production are so mild that they are designated β^{++}. So far, more than 200 different thalassemic mutations of the β-globin gene have been reported; the vast majority are point mutations within the gene or its immediate flanking sequence. A few β-thalassemia mutations that segregate independently of the β-globin gene cluster have been described, presumably involving transacting regulatory factors. The distribution of alleles is highly variable from one population to another, but within each population, only a few alleles are common. The nondeletion forms of β-thalassemia account for the vast majority of β-thalassemia alleles. An updated list of these mutations is accessible at the Globin Gene Server website: *http://globin.cse.psu.edu*. They include transcriptional mutations, RNA processing mutations, and mutations affecting translation.

Simple deletions of the β-globin gene are rare, ranging in size from 290 base pairs to more than 60 kb. The 619–base pair deletion at the 3′ end of the β gene is relatively common among Sind and Punjabi populations in India and Pakistan. The remaining deletions are restricted to single families and are necessarily β^0 thalassemias; interestingly, they are associated with an unusually high level of HbA_2 in heterozygotes. Large deletions that affect the entire β-globin gene cluster $(\varepsilon\gamma\gamma\delta\beta)^0$ are rare and restricted to single families. Finally, some highly unstable β-chain variants may manifest as a dominant form of β-thalassemia.

The δβ-thalassemias and the hereditary persistence of fetal hemoglobin (HPFH) are the result of deletions affecting various parts of the β-globin locus. These deletions are partially compensated by an increased expression of the γ genes, which raises the level of HbF. The length of deletion accounts for different forms of δβ-thalassemia, including both $^{G}\gamma$ and $^{A}\gamma$ genes or only $^{A}\gamma$, and this length varies from 9 to 100 kb. Hb Lepore is a hybrid of δ and β chains resulting from a crossover between the two misaligned genes; this hemoglobin is synthesized inefficiently and gives rise to a form of δβ-thalassemia. Deletions of δ and β genes are also the molecular basis for many forms of HPFH that usually have higher levels of compensatory HbF production than the δβ-thalassemias. Other forms of HPFH are due to point mutations in the promoter region upstream from the transcription start site in either the $^{G}\gamma$ or $^{A}\gamma$ genes that alter the binding of one or more transcription factors; they are known as nondeletion HPFH. Genetic studies have identified three major quantitative trait loci that account for 20 to 50% of the common variation in HbF levels in patients with β-thalassemia and sickle cell disease, as well as in healthy adults.

CLINICAL MANIFESTATIONS

The clinical manifestations (phenotype expression) of the thalassemia syndromes are extremely variable and depend on the degree of globin chain imbalance.

α-Thalassemias

As previously mentioned, there are two major classes of α-thalassemias: α^0, in which both α genes are inactivated (––/), and α^+, in which only one of the pair is defective owing to either an α deletion or a mutation (–α or $\alpha\alpha^T$). The clinical spectrum of α-thalassemias correlates well with the number of affected α genes—that is, from normal to the loss of all four genes. The inheritance of a normal allele (αα) with one of the α^+ or α^0 alleles results, most frequently, in α-thalassemia minor (––/αα, –α/αα, $-\alpha^T/\alpha\alpha$, $\alpha^T\alpha/-\alpha$, $-\alpha/-\alpha$). In general, carriers of such genotypes have lower levels of total hemoglobin, mean corpuscular volume, and mean cell hemoglobin but a higher than normal red blood cell count. The greatest differences are seen in mean cell hemoglobin, which is usually less than 26 pg. The peripheral blood smear is quite variable, showing different degrees of hypochromia, with some target cells and occasional poikilocytes (Chapter 160). In carriers of α^0-thalassemia (––/αα), it is possible to generate a few red cell HbH inclusions (β_4). The carriers of nondeletional forms ($\alpha\alpha^T/\alpha\alpha$) show slightly more marked hematologic changes than carriers of deletional forms. The hemoglobin constitution of adults carriers of α^+- or α^0-thalassemia is indistinguishable from normal but has slightly lower levels of HbA_2. Traces of Hb Bart's (γ_4) in the neonatal period are detectable in a large proportion of neonates with α-thalassemia, and the levels decline during the first 6 months after birth. The α-thalassemias are common in areas where β-thalassemias are also found at a high frequency. Thus, the coinheritance of α- and β-thalassemia traits may occur and even ameliorate the hematologic parameters. For families in which both α- and β-thalassemias are present, genotype determination is essential to provide genetic counseling. The unstable mutant Hb^{CT} causes a severe reduction in α_2-globin expression from the affected chromosome; therefore, carriers and particularly homozygotes have a more severe phenotype than α-thalassemia minor but not as severe as most cases of HbH disease.

HbH disease most frequently results from the interaction of α^+ and α^0 thalassemia, and not surprisingly, most patients originate from southeastern Asia, the Mediterranean, and the Middle East. HbH disease is a diagnosis attributed to subjects older than 6 months with a sufficient globin imbalance to produce detectable levels of HbH (>1 to 2%) in their peripheral blood,

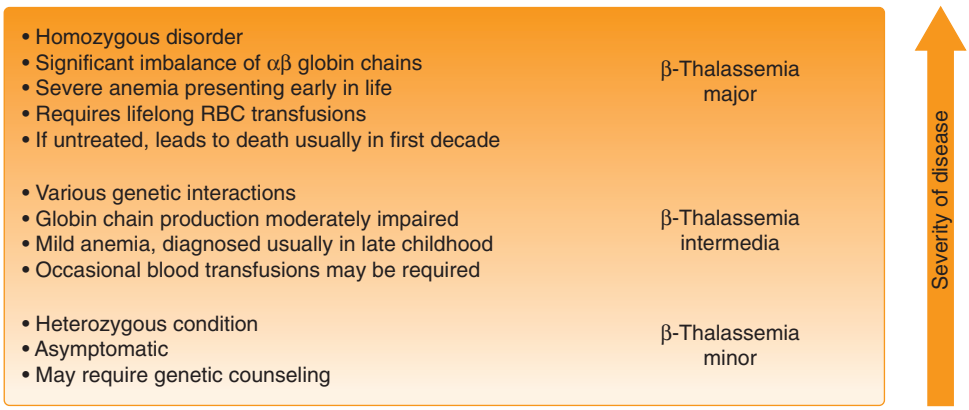
together with inclusion bodies (β_4 tetramers) in their red cells. The clinical phenotypes encompass a wide spectrum, from mild clinical manifestations to thalassemia intermedia. The predominant features are a hypochromic microcytic anemia, with jaundice and hepatosplenomegaly. Because the main mechanism of the anemia is hemolysis rather than dyserythropoiesis, only a few patients have clinical evidence of an expanded erythron. The most common complication is the development of hypersplenism due to severe splenomegaly. Other complications include gallstones, leg ulcers, increased risk of infection, folic acid deficiency, and increased risk of venous thrombosis, mainly following splenectomy. Hemoglobin levels range from 3 to 12 g/dL in different series, and fluctuations may occur after exposure to an oxidant drug, infection, or transient aplasia possibly owing to intercurrent viral infection. Rarely, patients with HbH disease require regular blood transfusions. The anemia is associated with reticulocytosis and typical thalassemic changes of the red cell indices. The relative amount of HbH varies from 1 to 40%. HbA_2 values are always reduced. The peripheral blood film shows hypochromia with variable anisopoikilocytosis, target cells, and basophilic stippling. The characteristic feature of HbH disease is that it is always possible to generate multiple inclusions in the red cells after incubation with brilliant cresyl blue. The bone marrow shows marked erythroid hyperplasia.

The most severe form of α-thalassemia is hydrops fetalis, in which all four α-globin genes are deleted (genotype —/—). It is incompatible with life. In fact, because α-globin chains are absent during gestation, Hb Bart's (γ_4) becomes the dominant hemoglobin. Because of its very high oxygen affinity, Hb Bart's is unable to deliver oxygen to tissues, and the intrauterine consequences are progressive severe anemia, severe ineffective erythropoiesis with marked extramedullary erythropoiesis, massive organomegaly, heart failure, severe albuminemia, and edema. Infants with hydrops fetalis syndrome die either in utero (30 to 40 weeks' gestation) or soon after birth. The hemoglobin levels range from 3 to 20 g/dL; the peripheral blood film is characterized by marked anisopoikilocytosis, large hypochromic macrocytes, and many nucleated red cells. The hemoglobin consists almost entirely of Hb Bart's (80 to 90%), with some remaining HbH and Portland. Mothers of these infants often have a history of previous neonatal deaths. Without medical care, women carrying these fetuses may have delivery and postpartum complications (e.g., retained placenta, eclampsia, sepsis).

There are several reports describing α-thalassemia associated with mental retardation (so-called ATR-16 syndrome). These conditions are mainly owing to large deletions (1 to 2 megabases) of the tip of chromosome 16, including the α-globin gene cluster. However, several cases have no deletions or other apparent abnormalities of the α-globin gene cluster. It has been shown that these patients, with a peculiar phenotype characterized by severe mental retardation, dysmorphic facies, genital abnormalities, and α-thalassemia, have a disorder that maps to the X chromosome (ATR-X syndrome).

β-Thalassemias

The β-thalassemias include a heterogeneous group of disorders of hemoglobin synthesis, all of which are characterized by reduced output of the β chains of adult hemoglobin. The clinical classification includes thalassemia major (TM; transfusion dependent), thalassemia intermedia (TI; intermediate severity), and thalassemia minor (asymptomatic) (Fig. 165-1; see Table 165-1). The severity of the clinical manifestations correlates quite well with the degree of imbalance of the globin chains: depending on the β-globin gene defects and their interaction, the production of β-globin chains is quantitatively reduced to different degrees, whereas the synthesis of α-globin continues as normal, resulting in the accumulation of excess unmatched α-globin chains in the erythroid precursors. The free α-globin chains are unable to form stable tetramers; they therefore precipitate in the erythroid precursors, forming inclusion bodies that damage the red cell membrane, thereby causing premature destruction of erythroid precursors in the bone marrow (ineffective erythropoiesis). Ineffective erythropoiesis leads to a sequence of events



A

	Thalassemia major more likely	Thalassemia intermedia more likely
Clinical		
Presentation (years)	<2	>2
Hb levels (g/dL)	<7	7-10
Liver/spleen enlargement	Severe	Moderate to severe
Hematologic		
HbF (%)	>50	10-50 (may be up to 100%)
HbA_2 (%)	>3.5	<4-4.5
Genetic		
Parents	Both carriers of high HbA_2 β-thalassemia	One or both carriers: high HbF β-thalassemia, borderline HbA_2
Molecular		
Type of β-chain mutation	Severe	Mild/silent
Coinheritance of α-thalassemia	No/rare	Yes
Hereditary persistence of fetal hemoglobin	No	Yes
δβ-thalassemia	No	Yes
Gy XmnI polymorphism	No	Yes

B

FIGURE 165-1. **A,** Clinical classification of β-thalassemias. **B,** Tentative criteria to differentiate thalassemia major from thalassemia intermedia at presentation. HbA = adult hemoglobin; HbF = fetal hemoglobin; RBC = red blood cell.

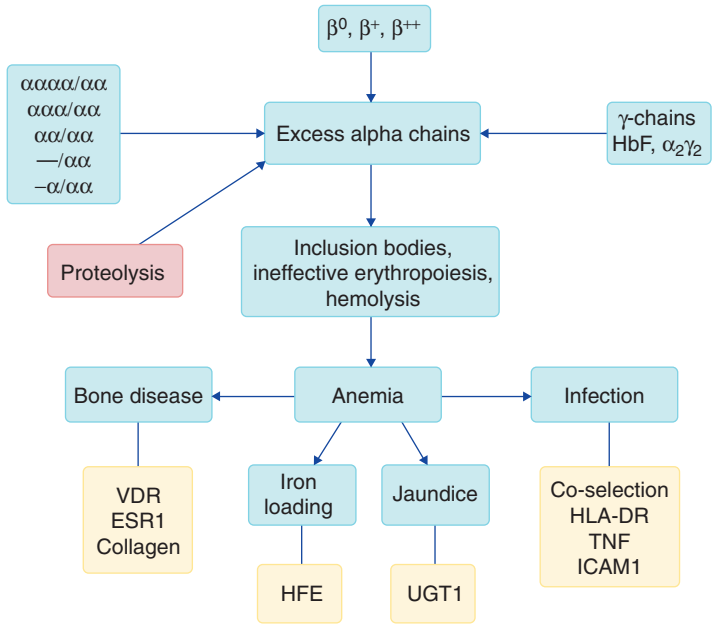


FIGURE 165-2. Pathophysiology of β-thalassemias and modifiers of globin chain imbalance. The severity of ineffective erythropoiesis is dependent on the degree of excess free α chains that result primarily from three different mechanisms: (1) inheritance of severe, mild, or silent β-chain mutations; (2) coinheritance of determinants associated with increased γ-chain production; and (3) coinheritance of α-thalassemia. A phenotype of thalassemia intermedia may result from the increased production of α-globin chains by a triplicated (αααα) or quadruplicated (ααααα) α genotype associated with β heterozygosity. Inheritance of polymorphisms or mutations of genes involved in bone, iron, and bilirubin metabolism, as well as in infection, may contribute to modify the clinical course of the disease. ESR1 = estrogen receptor 1; HbF = fetal hemoglobin; HFE = hereditary hemochromatosis gene; HLA = human leukocyte antigen; ICAM1 = intercellular adhesion molecule-1; TNF = tumor necrosis factor; UGT1 = UDPglucose: glycoprotein glucosyltransferase 1; VDR = vitamin D receptor.

responsible for bone marrow expansion, anemia, hemolysis, splenomegaly, and increased iron absorption. Any factor that reduces the degree of chain imbalance and the magnitude of α-chain excess, such as coinheritance of α-thalassemia or an innate ability to increase HbF, will ameliorate the clinical expression of the disease (Fig. 165-2).

The major forms of β-thalassemia (still sometimes called Cooley's anemia) are disorders in which life can be sustained only by regular blood transfusions. This condition usually results from the homozygous state or from the compound heterozygous state for severe β gene mutations (β^0). The typical forms of TM manifest during the first year of life, during which γ chains are switched off but not replaced by β-chain synthesis. These infants, left untreated, are incapable of maintaining a hemoglobin level above 5 g/dL and show marked bone deformities and growth retardation. They develop thalassemic facies due to frontal bossing of the skull and protrusion of the jaws and cheekbones. The magnitude of the increase in erythropoiesis may result in extramedullary masses usually arising from the sternum and ribs. Progessive hepatosplenomegaly is a constant finding, leading to pancytopenia. The early childhood of untreated or inadequately treated TM patients includes various complications, such as recurrent infections, spontaneous fractures, gallstones, and leg ulcers. The mortality rate in such patients was once very high around puberty. Fortunately, this is no longer the case in children with well-treated TM. Children who are transfused to maintain a hemoglobin level above 9 g/dL have relatively normal growth and development, and their future course depends on whether they receive adequate iron chelation (see Treatment). Many children who are adequately transfused and are fully compliant with iron chelation therapy develop normally, enter puberty, and become sexually mature. At present, we are dealing with an adult population of TM patients who may suffer from the side effects of long-term treatment—namely, transfusion-associated infections (particularly hepatitis B and C and, in some populations, HIV) and organ damage (liver, heart, endocrine glands) due to unsatisfactory long-term iron chelation. The main causes of death in adult TM patients is still cardiac complications. Heart failure in these patients is multifactorial, involving chronic anemia, remaining iron overload, myocarditis, pericarditis, and probably many other mechanisms. Furthermore, in addition to the degree of globin chain imbalance, which is dependent on genetic factors linked to the globin genes (coinheritance of α-thalassemia, innate increased synthesis of HbF), there are many other genetic modifiers that may secondarily impact the outcome of complications. For example, the presence of a polymorphic variant in the UGT1A1 promoter responsible for Gilbert's syndrome (Chapter 149) may increase the predisposition to cholelithiasis, which is already a common complication in thalassemia. Likewise, polymorphisms in genes involved in iron homeostasis or bone metabolism may negatively or positively influence the degree of iron overload or osteopenia and osteoporosis, respectively (see Fig. 165-2). Environmental factors, including social conditions, nutrition, and the availability of medical care, have also been implicated in the variable severity of the clinical manifestations of TM.

TI is a clinical term used to describe patients with anemia and splenomegaly but without the full clinical spectrum of TM. The clinical phenotypes of TI lie between those of thalassemia minor and major, encompassing a wide spectrum. Mildly affected patients are almost completely asymptomatic until adult life, experiencing only mild anemia and spontaneously maintaining hemoglobin levels between 7 and 10 g/dL. Patients with more severe TI generally present between 2 and 6 years of age; although they are able to survive without regular transfusion therapy, growth and development may be retarded. Most TI patients are homozygotes or compound heterozygotes for mild to moderate β gene mutations (β^+/β^+, β^0/β^+); less commonly, only a single β-globin gene is affected. Because the clinical severity of the disease is dictated by the extent of globin chain imbalance, at least three different mechanisms can promote the mild clinical characteristics of TI versus those of TM: inheritance of mild or silent β gene mutations; coinheritance of determinants associated with increased γ-chain production, which contributes to neutralizing the large proportion of unbound α chains; and coinheritance of α-thalassemia, which reduces the synthesis of α chains, thereby reducing the α/non-α chain imbalance.

Three main factors are responsible for the clinical sequelae in TI patients: ineffective erythropoiesis, chronic anemia, and iron overload. The degree of ineffective erythropoiesis depends primarily on the underlying molecular defects (as already mentioned) and is due to the precipitation of free α chains into erythroid precursors in the bone marrow, causing membrane damage and premature cell death in the marrow. The degree of ineffective erythropoiesis is the primary determinant of the anemia of TI; the peripheral hemolysis of mature, circulating red cells and an overall reduction in hemoglobin synthesis are secondary. Hemolysis per se and damaged red cells that expose negatively charged membrane phosphatidyl-serine residues have been linked to the development of the hypercoagulable state and the increased risk of pulmonary hypertension found in the TI population. Chronic anemia and chronic ineffective erythropoiesis lead to an inappropriate increase in gastrointestinal iron absorption, resulting in iron overload. In contrast, in TM, iron loading results mainly from transfusional iron infusion. It has been shown that chronic anemia and ineffective erythropoiesis, which are characteristic of TI, are associated with the reduced expression of hepcidin, a hepatic peptide that plays a central role in iron homeostasis. Moreover, growth and differentiation factor 15 (GDF15), secreted by erythroid precursors and overexpressed in the presence of ineffective erythropoiesis, may suppress hepcidin synthesis. Taken together, ineffective erythropoiesis (leading to increased GDF15) and chronic anemia and hypoxia result in hepcidin suppression, increased dietary iron absorption from the gut, and increased release of recycled iron from the reticuloendothelial system, leading to an iron overload situation that is very similar to that observed in patients with hereditary hemochromatosis syndromes (which are characterized by impaired hepcidin production; Chapter 219). As a consequence of these pathophysiologic processes, several complications have been identified as unique in TI patients, especially in splenectomized naïve patients. Cholelithiasis is much more common in TI than in TM because of ineffective erythropoiesis and peripheral hemolysis. Extramedullary hematopoiesis, as a compensatory mechanism, leads to the formation of erythropoietic tissue masses that primarily affect the spleen, liver, lymph nodes, and vertebrae. These masses may cause neurologic problems such as spinal cord compression and paraplegia and intrathoracic masses. Leg ulcers are rare in well-transfused TM patients but are quite common in adult TI patients; it remains unclear why, at the same hemoglobin and HbF levels, some patients develop leg ulcers and others do not. Thrombotic risk is definitely increased in TI patients. Several studies have collectively shown that the incidence of thromboembolic events is higher in splenectomized TI patients. Although stroke is rare in TI, asymptomatic brain damage, including ischemia, has been documented by magnetic resonance imaging (MRI) and computed tomography

in TI patients. Pulmonary hypertension (Chapter 68) is prevalent in TI patients (approximately 60%) and is thought to be the primary cause of heart failure in this population. Liver disease due to viral infection is less frequent than in TM; however, abnormal liver enzymes are frequently observed in TI patients, primarily owing to hepatocyte damage resulting from iron overload. In some of the oldest patients with TI (>40 years), hepatocellular carcinoma (Chapter 202) has been detected owing to long-term untreated iron accumulation with resultant cirrhosis, as found in genetic hemochromatosis (Chapter 219). Hypogonadism, hypothyroidism, and diabetes mellitus are quite rare. Although patients with TI generally experience puberty late, they have normal sexual development and are usually fertile. Women with TI may have spontaneous successful pregnancies, although complications may occur.

Thalassemia minor is the heterozygous state of β-thalassemia. Subjects with thalassemia minor are "carriers" of a single β-globin gene defect and are usually asymptomatic, except for a mild anemia of pregnancy. The carriers are usually identified as part of a family study, incidentally during an intercurrent illness, or as part of a population survey. The anemia is mild, microcytic, and hypochromic and is associated with an elevated level of HbA_2. The blood smear shows characteristic microcytosis and hypochromia, with some variation in size and shape of the red cells. The presence of target cells is very variable. The hematologic features are remarkably similar among different ethnic groups. Carriers of β-thalassemia with normal HbA_2 have been observed in settings in which an individual with mild TI was found to have one parent with typical β-thalassemia minor with elevated HbA_2 while the other showed either minimal or no hematologic abnormalities and normal HbA_2. Subjects with normal HbA_2 are usually carriers of silent β mutations (β^{++}).

δβ-Thalassemia and Hereditary Persistence of Fetal Hemoglobin

The clinical manifestations of $(\delta\beta)^0$-thalassemias are similar to those of TI, whereas the heterozygotes are distinguished from β-thalassemia heterozygotes by normal levels of HbA_2 and increased HbF levels of 5 to 20%. Homozygotes for Hb Lepore may have phenotypes similar to either TM or TI. Subjects affected by deletion or nondeletion forms of HPFH are usually asymptomatic.

Any of the β-thalassemia defects may be coinherited with β-chain variants (e.g., HbS, HbC, HbE) and cause a clinically relevant β-thalassemia phenotype of differing severity. These variants illustrate that β-thalassemia syndromes have a wide clinical spectrum and that specific therapeutic approaches may completely change the clinical course and natural history of these disorders.

DIAGNOSIS

The diagnosis of thalassemia may be required in a patient with a suspicious clinical picture or to identify a heterozygote subject as part of a family study or population screening program. The general diagnostic approach is common to any form of thalassemia, regardless of presentation. The primary evaluation is based on hematologic changes: the red cell indices obtained by electronic cell counter and the red cell morphology examined on a well-stained blood film are sufficient to direct further investigations. Individuals with a mean corpuscular volume below 80 fL and mean corpuscular hemoglobin below 27 pg with normal iron parameters need further investigation. The number of red blood cells is usually higher than normal. In the presence of anemia with thalassemic red cell changes, the next step is the evaluation of hemoglobin fractions (HbA, HbA_2, HbF, or Hb variants) by electrophoresis on cellulose acetate at alkaline pH or, even better, by high-performance liquid chromatography, which enables the precise measurement of HbA_2, HbF, and HbA and the provisional identification of a large number of Hb variants. An HbA_2 level greater than 3.5% associated with hypochromic microcytic red cells is diagnostic of β-thalassemia minor. HbA_2 values between 3.2 and 3.5% (borderline) should be interpreted with care because they could be due to the interaction of more than one thalassemic defect (α and β), a silent β mutation, or concomitant iron deficiency. If iron deficiency is present, it should be corrected and the HbA_2 estimation repeated. The majority of individuals with thalassemic red cell indices and normal or low HbA_2 and normal HbF are α^0-thalassemia carriers or α^+-thalassemia homozygotes. Carriers of α^0-thalassemia may have a few red cells with HbH inclusions. Microcytosis with low or normal HbA_2 levels and elevated HbF (2 to 20%) indicates heterozygosity for δβ-thalassemia. Patients with HPFH usually have normal red blood cell indices but increased levels of HbF with a different intercellular distribution (homogeneous or pancellular, with the exception of heterocellular HPFH) compared with δβ-thalassemia (uneven or heterocellular). A radioactive method for measuring the α/β-globin synthesis ratio was introduced in the mid to late 1960s and was largely directed at prenatal diagnosis in the pre-DNA era. Although it gives a quantitative assessment of globin production, today its use is limited to difficult cases caused by the interaction of different globin chain defects. Definitive diagnosis of the thalassemia syndromes involves identification of the underlying mutations through DNA analysis. There are several methods available for the diagnosis of any particular mutation, such as polymerase chain reaction (PCR) restriction-enzyme analysis, PCR allele-specific-oligonucleotides, gap PCR, and direct sequencing, which is probably the easiest and most reliable method. For deletion forms of α-thalassemia, multiplex ligation-dependent probe amplification is a useful, recently introduced method.

During their clinical course, patients affected by different forms of thalassemia develop several complications mainly due to iron overload, which must be monitored to direct iron chelation therapy. The principal methods of determining body iron levels (Chapter 219) are measurements of the serum ferritin level and assessment of liver iron concentration from biopsy tissue or, as an alternative noninvasive method, by R2 MRI. High serum ferritin levels (>2500 μg/L) and a high liver iron concentration (>15 g/dry weight) indicate a high risk of significant morbidity and mortality. Cardiac iron can be measured by a recently introduced T2* MRI procedure that allows estimation of the cardiac iron load. MRI T2* less than 10 msec is always associated with severe iron load and a high risk of heart failure within 1 year. MRI T2* greater than 20 msec is considered normal, meaning there is no iron in the heart. Echocardiography may also be useful to evaluate functional changes. For other complications, including endocrinopathies, liver disease, lung disease, thrombophilia, and bone disease, the diagnostic approaches are similar to those used in clinical practice, taking into consideration test cost, performance characteristics, and patient preferences.

TREATMENT Rx

Conventional Treatment

No specific treatment is required for α- or β-thalassemia heterozygotes (carriers, thalassemia minor), but they should receive appropriate genetic counseling. During pregnancy, particularly during the second and third trimesters, thalassemia-carrying women may become more anemic, so they should be followed carefully and supported with folic acid. When real iron deficiency is associated with thalassemia traits, iron supplementation should be provided, while monitoring transferrin saturation and ferritin. Very few cases of in utero blood transfusions have been reported with Hb Bart's hydrops fetalis syndrome; most of these babies have been delivered prematurely by cesarean section, subsequent development has been abnormal, and survivors required regular blood transfusions after birth. HbH patients in general have rather high hemoglobin levels (8 to 9 g/dL) and do not need regular blood transfusion. Supplementation with folic acid (2 to 5 mg/day) is generally recommended, especially in pediatric patients. The major complications in HbH disease are hemolytic crises that may occur during or after acute infections; in such cases, immediate intervention, including blood transfusions and treatment for infection, should be promptly administered.

The clinical management of TM and TI remains the major issue. The lifespan and quality of life of TM and TI patients have been transformed over the last 10 years, with life expectancy increasing well into the third and fourth decades. Nevertheless, prolongation of life is accompanied by several complications, partly due to the underlying disorder and partly as a consequence of treatment with blood transfusions and iron overload. Moreover, we have to deal with aging-related complications in the context of a multiorgan disease that requires management by a team of clinicians with specific knowledge of thalassemias, working together with different specialists and well-trained nurses. The conventional treatment for TM patients includes regular transfusion therapy and iron chelation. Definition of the optimal transfusion and iron chelation regimen has been the most important advance in the management of TM patients, with the primary objective being to control the ineffective erythropoiesis, its consequences, and the iron burden. The optimal regimen involves regular blood transfusions, usually administered every 2 to 5 weeks, to maintain pretransfusion hemoglobin levels above 9 to 10.5 g/dL. The decision to initiate lifelong transfusion therapy should be based on a definitive diagnosis of severe thalassemia, taking into account the molecular defects, the severity of anemia on repeated measurements, the level of ineffective erythropoiesis, and clinical criteria such as failure to thrive or bone changes. It is advisable for TM patients to receive leukoreduced packed red cells to reduce transfusion reactions and pathogen transmission. Adverse reactions to red blood cell transfusions may occur during or after the transfusion, and they can be hemolytic or nonhemolytic. Transfusion-related acute lung injury (TRALI) is a very rare but severe complication and must be managed immediately

(Chapter 180). Many patients with TM require splenectomy because of hypersplenism. However, with optimal clinical management, the need for splenectomy may be delayed or even obviated. Splenectomy should be considered for patients whose annual blood consumption increases progressively and is responsible for significant increases in iron stores, despite good chelation therapy, and in those experiencing symptoms due to spleen enlargement. Clinical problems related to leukopenia or thrombocytopenia due to hypersplenism are other reasons to consider splenectomy. The major complication of splenectomy is severe and sometimes overwhelming infection. Because removal of the spleen may reduce the primary immune response to encapsulated organisms, it is advisable to delay splenectomy until patients are at least 5 years old. The mortality rate for overwhelming post-splenectomy infection in thalassemia patients is approximately 50%, despite intensive supportive care; therefore, preventive measures are mandatory, including immunoprophylaxis (vaccination against *Streptococcus pneumoniae*, pneumococcus, and meningococcus), chemoprophylaxis, and parent and patient education to recognize and report febrile illnesses.

Iron overload is an inevitable and serious complication of long-term blood transfusion therapy and hyperabsorption of dietary iron, and it requires adequate treatment to prevent early death from iron-induced cardiac disease. Optimal chelation therapy extends complication-free survival (Fig. 165-3). For more than 40 years, the standard chelation therapy has been deferoxamine (DFO), given for 10 to 24 hours a day as a continuous subcutaneous infusion 5 to 7 days per week. The long-term efficacy of DFO has been extensively documented in large cohorts of patients in Italy and elsewhere. Unfortunately, compliance with the rigorous daily regimen is a serious limiting factor, and in noncompliant patients, life expectancy is no different from that in the pre-DFO era. This has been the rationale behind the intensive effort to identify alternative, orally effective iron chelators. At present, two oral iron chelators are in the market: deferiprone (DFP) and deferasirox (DFX). DFP is registered in Europe but is not yet available in the United States. Based on the guidelines of the EMEA countries (Europe, Middle East, and Africa), treatment with DFP at doses of 75 to 100 mg/kg/day is restricted to patients unable to use DFO or those with an unsatisfactory response to DFO as judged by serum ferritin levels and liver iron concentrations. Recent studies indicate that DFP may be more effective than DFO in protecting the heart from the accumulation of iron.[1] A potential benefit of combined DFO/DFP therapy has been observed,[2,3] and according to the Thalassemia International Federation, combination DFO/DFP treatment should be considered for patients with very high levels of heart iron or cardiac dysfunction. The new orally effective iron chelator DFX is safe and effective for removing excess iron from different organs, including the heart. DFX is now available in most countries throughout the world as first-line treatment. Iron chelation therapy must be individualized according age, compliance history, and other factors. Monitoring and adjusting iron chelation based on repeated measurements of ferritin, calculation of iron intake by transfusions, and, whenever possible, measuring cardiac and liver iron by MRI (at least once) are mandatory.

The management of TI patients is more complicated owing to the wide heterogeneity of TI phenotypes. A number of options are currently available to treat TI patients, including transfusion therapy, splenectomy, modulation of HbF production, and hematopoietic stem cell transplantation. However, increasing evidence is delineating the benefit of transfusion therapy in decreasing the incidence of complications. Thus, although common practice in the past was to initiate transfusion when complications ensued, it may be worthwhile to start transfusion therapy earlier, as a preventive approach and to help alleviate the increased risk of alloimmunization with the delayed initiation of transfusion. The initiation of iron chelation therapy in patients with TI depends not only on the amount of excess iron but also on the rate of iron accumulation, the duration of exposure to excess iron, and various other factors in individual patients.

Bone Marrow Transplantation and Experimental Therapies

Allogeneic hematopoietic stem cell transplantation (HSCT) in thalassemia syndromes has been increasingly successful during the last 2 decades, mainly in β-thalassemia major. Predictors of poor transplant outcome are hepatomegaly, a history of irregular chelation, and hepatic fibrosis. Patients are categorized into three risk classes. Class 1 patients have none of these adverse risk factors, class 2 patients have one or two adverse risk factors, and class 3 patients have all three. In the most recent update of the Pesaro group's experience, the probability of thalassemia-free survival for patients younger than 17 years at the time of HSCT, receiving the allograft from a human leukocyte antigen (HLA)–identical relative, was 87% in class 1 patients, 85% in class 2 patients, and much lower in young class 3 patients. The progressive adjustment of conditioning therapy in class 3 patients and in adults (older than 17 years) has significantly reduced the incidence of transplant-related mortality. Only 25 to 30% of patients with diseases potentially curable by HSCT have suitable HLA-compatible siblings however, and bone marrow transplantation from unrelated donors significantly increases the incidence of acute and chronic graft-versus-host disease, particularly in thalassemia. A study from the Eurocord cooperative group reported the outcome of 33 class 1 and 2 patients with thalassemia who received cord blood HSCT from HLA-identical siblings: no patient died of transplant-related complications, suggesting that this is a safe procedure for thalassemia patients.

An alternative treatment of β-thalassemia consists of the pharmacologic stimulation of HbF synthesis. In humans, the hemoglobin switch from HbF to

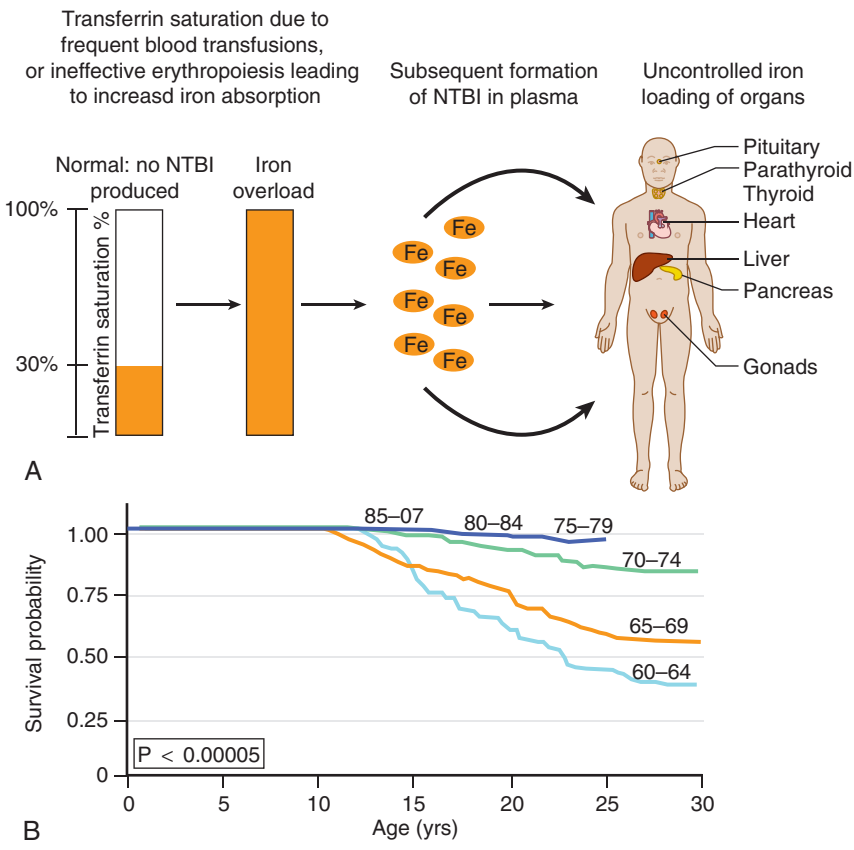

FIGURE 165-3. **A,** Transfusional iron overload and specific organ iron loading. **B,** Survival of Italian thalassemia major patients by cohort of birth: 1960 to 1964, 1965 to 1969, 1970 to 1974, 1975 to 1979, 1980 to 1984, and 1985 to 1997. Survival and complications in patients with thalassemia major treated with transfusion and deferoxamine. *Haematologica.* 2004;89:1187-1193.)

HbA occurs in the period around birth as a result of γ- to β-globin gene switching. A number of pharmacologic agents with the ability to reactivate HbF synthesis have been identified, including hypomethylating agents, histone deacetylase inhibitors, and hydroxyurea. Although the effect of these treatments (particularly hydroxyurea) in sickle cell disease is clear (Chapter 166), their benefit on the clinical course of β-thalassemia is presently limited. This discrepancy in the response to HbF inducers may be related mainly to the higher level of HbF required to achieve clinical results in β-thalassemia compared to sickle cell disease. The limited clinical response to γ-globin inducers observed in the majority of β-thalassemia patients may also be a reflection of the unfavorable effects of these agents on the other globin genes (i.e., increased α-globin synthesis).

Gene therapy is an attractive approach for thalassemia syndromes; however, this strategy poses major challenges in terms of controlling transgene expression, which should be erythroid specific and sustained over time. Treatment of ß-thalassemia, sickle cell disease, and other disorders through lentivirus-mediated gene transfer has been reported in murine and primate models, but few human patients have been treated.

UNSTABLE HEMOGLOBINOPATHIES

More than 80 rare mutant hemoglobins have been reported to cause hemolytic anemia owing to amino acid replacements or deletions that significantly lower solubility. These mutant hemoglobins form intracellular precipitates that can be detected as so-called Heinz bodies when the blood smear is exposed to a supravital stain. Structural abnormalities include mutations that weaken the linkage between heme and globin, disrupt secondary (α-helical) structures, or introduce a charged or polar side group into the hydrophobic interior of the globin subunit.

This disorder, sometimes called congenital Heinz body hemolytic anemia, is inherited in an autosomal dominant manner. Severely affected individuals have jaundice, splenomegaly, and, on occasion, dark brown urine owing to the release of heme and aberrant conversion to dipyroles. The instability of a few of these globin mutants is so extreme that they cannot be detected by routine laboratory methods. This results in a thalassemia phenotype with microcytosis and ineffective erythropoiesis. Like individuals with glucose-6-phosphate dehydrogenase deficiency (Chapter 164), those with unstable hemoglobin mutants often lack clinical symptoms and signs of hemolysis until or unless they develop an infection or are exposed to an oxidant drug.

The diagnosis can be established by the combination of a positive Heinz body preparation and either abnormal hemoglobin electrophoresis or demonstration of a precipitate following exposure of a hemolysate to heat or isopropanol. Some clinics have access to a reference laboratory that can identify the specific mutation by α- and β-globin DNA sequencing.

Most individuals with this disorder do not require treatment. However, some are symptomatic from severe anemia. Splenectomy generally results in a significant increase in red cell mass, but the fraction of Heinz body–positive red cells increases markedly after splenectomy, putting these patients at significant risk of developing pulmonary hypertension and cor pulmonale.

SICKLE CELL DISEASE AND OTHER HEMOGLOBINOPATHIES

MARTIN H. STEINBERG

SICKLE CELL DISEASE

DEFINITION

Sickle cell disease, caused by a mutation in the β-globin gene (*HBB*), consists of a group of chronic hemolytic anemias, all characterized by vaso-occlusive events, hemolytic anemia, vasculopathy, widespread acute and chronic organ damage, and premature mortality.

EPIDEMIOLOGY

The prevalences of the various forms of sickle cell disease and of the sickle cell trait, which is not truly a form of sickle cell disease, vary in the United States and worldwide (Table 166-1; Fig. 166-1). The sickle hemoglobin mutation became prominent in equatorial Africa, the Middle East, and India several thousand years ago, when deforestation, the rise of agriculture, and stagnant pooling of water permitted *Plasmodium falciparum* infection to become endemic. Carriers of the sickle cell trait were more likely to survive to reproductive age and had a selective advantage where falciparum malaria was present. At least five distinct origins of this identical mutation can be distinguished by the accompanying haplotype of the β-globin gene–like cluster. Slave trading and war spread this mutation to the Americas, throughout the Mediterranean basin, and eastward to the Indian subcontinent. In some sites in Africa, half the population carries the sickle hemoglobin gene.

PATHOBIOLOGY

Globin, the protein portion of hemoglobin, harbors the porphyrin heme ring and permits the molecule to operate efficiently in oxygen transport and its other physiologic functions (Fig. 166-2). Mutations can alter the primary amino acid sequence of the globin polypeptide, sometimes resulting in clinically significant diseases called hemoglobinopathies, including sickle cell disease. Sickle hemoglobin (HbS; $\alpha_2\beta_2^S$) is caused by an adenine (A) to thymidine (T) substitution (GAG → GTG) in codon 6 of the β-globin gene, resulting in replacement of the normal glutamic acid residue by a valine (Glu6Val). HbS polymerizes when it is deoxygenated, a property only of hemoglobin variants that have the *HBB* Glu6Val substitution. Critical amounts of HbS polymer within sickle erythrocytes cause cellular injury and lead to the phenotype of sickle cell disease, which is recognized by hemolytic anemia and vaso-occlusion. Other hemoglobin variants, such as HbE and HbC, are also common. More than 1000 hemoglobin mutations are known, and occasionally they can affect the stability and function of hemoglobin and cause hemolytic anemia (Chapter 161), disordered oxygen transport (Chapter 169), or methemoglobinemia (Chapter 161). However, most globin mutations are clinically insignificant. Thalassemias (Chapter 165) are also caused by mutations in globin genes, but these mutations affect globin gene expression so that synthesis of a globin chain is reduced or absent, although the structure of any globin produced is usually normal.

In sickle cell disease, erythrocytes are heterogeneous as a result of membrane damage and the cellular distribution of fetal hemoglobin (HbF). HbF

TABLE 166-1 GENETIC AND LABORATORY FEATURES OF COMMON SICKLE HEMOGLOBINOPATHIES*

GENOTYPE	GENETICS	PREVALENCE AMONG AFRICAN AMERICANS†	HEMATOCRIT (%)	MCV (FL)	HBS (%)	HBA_2 (%)	HBF (%)	SEVERITY‡
Sickle cell anemia (HbSS)	Homozygous HbS	1 : 600	18-28	85-95	>85	2-3	2-15	4
HbSS-α-thalassemia	Homozygous HbS α^+-thalassemia	30% of HbSS patients	25-33	70-85	>85	4-6	2-15	4
HbSC disease (HbSC)	Compound heterozygous HbS, HbC	1 : 800	28-40	70-85	50	2-3	1-8	2
HbS-β^0-thalassemia (HbS-β^0-Thal)	Compound heterozygous HbS, β^0-thalassemia	1 : 1600	20-30	65-75	>85	4-6	5-15	4

Normal (HbAA)	Homozygous HbA	—	38-50	80-90	0	2-3	<1	—

*Many other abnormal globin genes can be found as compound heterozygotes with the HbS gene. The most common of these are α-thalassemia, HbD, HbO (Arabia), HbG (Philadelphia), HPFH, Hb Hope, and Hb Lepore. Average ranges of laboratory values are shown, but these can vary according to patient age.
†These figures differ depending on the prevalence of the involved genes in the population studied. In West and Central Africa, where the disease is most common, approximately 2% of all newborns have sickle cell disease. The prevalence of the HbC trait in African Americans is 3%, and that of the β-thalassemia trait is 1%. About 30% of African Americans carry an α-thalassemia gene, which can alter the phenotype of sickle cell disease by causing microcytosis, reduced cell density, and less hemolysis.
‡Severity of disease compared with sickle cell anemia, clinically the most severe genotype. This is a qualitative ranking of the clinical severity of each genotype; within each genotype, there is great clinical heterogeneity.
§Although this combination is still a rare genotype, the rising Asian population in the United States (HbE is a Southeastern Asian gene) will make it more frequent with time. With few cases reported compared with the other genotypes, the phenotype of HbSE disease is not totally defined. It may resemble HbS-β^+ thalassemia with symptoms appearing mainly in adults.
¶Sickle cell trait should not be classified as a form of sickle cell disease. About 8% of African Americans are carriers of HbS. Carriers are hematologically normal with a normal life expectancy. The few abnormalities traceable to the presence of HbS besides the renal lesions (see Table 166-3) include a four-fold increased risk of pulmonary embolism, an increased risk of splenic infarction at high altitude, and a higher risk of dying during the course of exertional heat illness.
Hb = hemoglobin; HPFH = hereditary persistence of HbF; MCV = mean corpuscular volume.

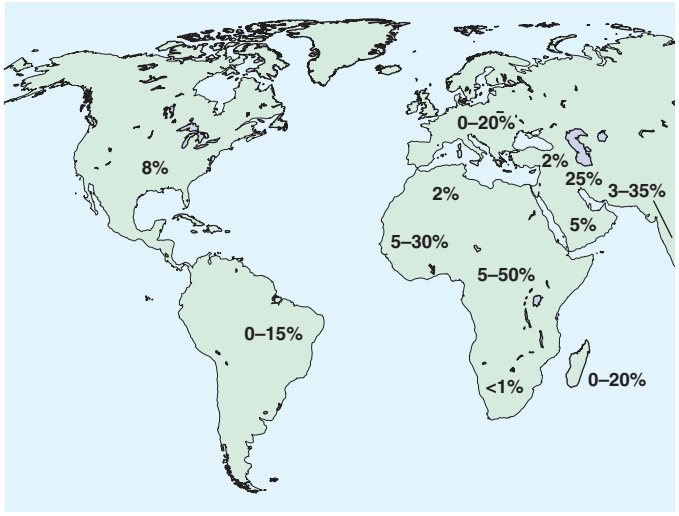

FIGURE 166-1. Worldwide prevalence of the sickle cell trait. Shown are the percentages of individuals with sickle cell trait in regions of the world where the hemoglobin S (HbS) gene is often present. In each geographic area, the prevalence of sickle cell trait can vary markedly according to racial or ethnic group, historical migration patterns, and even from village to village. Not shown is the high concentration of the HbS gene in areas of Europe such as London, Manchester, and Paris, where migrants from Africa or Afro-Caribbean populations have settled.

concentrations vary among patients with sickle cell anemia (homozygosity for HbS) and among erythrocytes of each individual. Because HbF inhibits HbS polymerization (see later discussion), its concentration within each cell and its distribution among all cells influence cell heterogeneity.

Sickle cell anemia is noteworthy for its clinical heterogeneity. Any patient can have almost all known disease complications; some have almost none but die suddenly; some skip one or more phases of the disease but suffer intensely from others. Thus, this prototypical single-gene, mendelian disorder behaves clinically as a multigenic trait with exceptional phenotypic variability. Understanding the vascular and inflammatory components of the disease provides many loci where the disease phenotype can be influenced by modifying genes. These genes potentially affect the pathogenesis of sickle cell anemia by modulating HbF concentration, inflammation, oxidant injury, nitric oxide (NO) biology, vasoregulation, cell-cell interaction, blood coagulation, and hemostasis. Polymorphisms have been noted in candidate genes that affect these functions, and some may be prognostically useful. The sickle mutation is found on several different haplotypes of the β-globin gene–like cluster, reflecting different origins of the mutation in Africa and the Middle East. The Senegal haplotype is often associated with higher HbF levels than other haplotypes and with a more benign clinical course. Conversely, the Bantu haplotype may be associated with more disease complications; however, there is phenotypic heterogeneity even within a particular haplotype group.

Cation homeostasis is impaired in some sickle cells. A reduced capacity of sickle cells to maintain normal potassium (K^+) gradients is mediated by activation of the Gardos and K^+/Cl^- cotransport channels. As a result, sickle erythrocytes vary in their density and deformability. Irreversibly sickled cells (ISCs; Fig. 166-3) always appear deformed because of permanent membrane damage, even though they may not contain HbS polymer. In some dense cells, the mean corpuscular hemoglobin concentration reaches 50 g/dL (normal, 27 to 38 g/dL), and HbS polymer is always present. Individuals with the highest numbers of ISCs and dense cells have the most hemolysis and anemia but not necessarily the highest incidence of acute vaso-occlusive events like painful episodes.

Hemolysis is mainly extravascular owing to erythrophagocytosis by reticuloendothelial cells that recognize the damaged sickle erythrocyte. In most patients, intravascular destruction of sickle erythrocytes liberates excessive amounts of hemoglobin into the circulation, thereby depleting haptoglobin and scavenging NO. This process promotes a vasoconstrictive, proinflammatory phenotype (Fig. 166-4). Certain complications of sickle disease, such as pulmonary hypertension, priapism, leg ulcer, and stroke, are epidemiologically linked to the intensity of hemolysis, whereas other complications, such as painful episodes, acute chest syndrome, and osteonecrosis, are linked to high blood viscosity and the interactions among sickle cells, leukocytes, and the endothelium.

Vaso-occlusive events probably depend on features intrinsic to the sickle erythrocyte, such as polymer content and the degree of cellular damage, interacting with factors in the cell's environment, such as endothelial injury, vascular tone, and other blood cells. In the first hours of a painful episode, the number of dense cells falls; it rises again as pain resolves. These observations suggest the possibility that more deformable, more adherent cells might

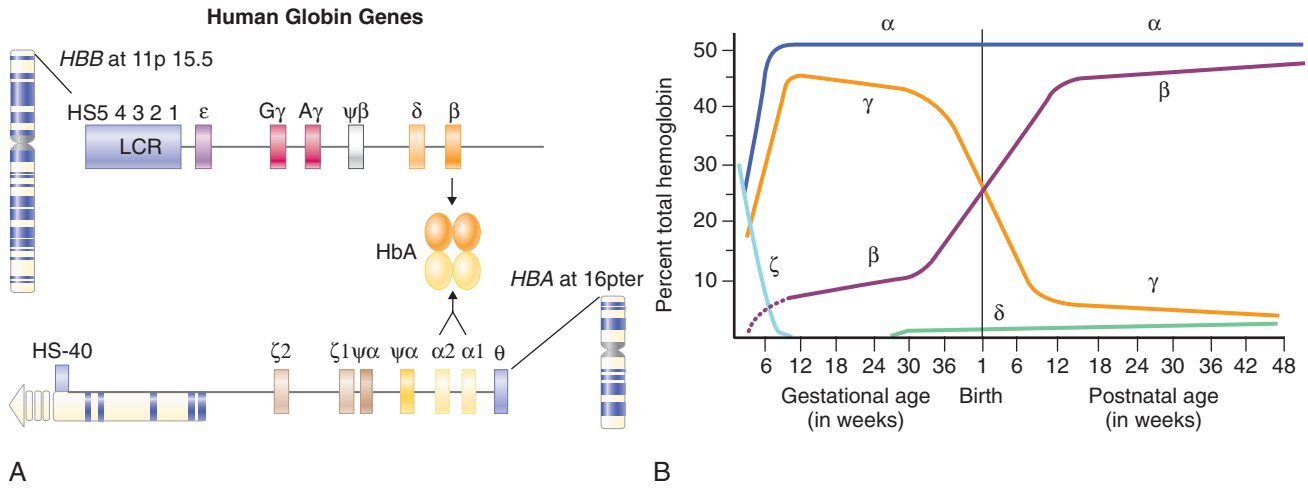

FIGURE 166-2. Human globin genes. A, The β-like globin gene cluster on chromosome 11 is shown above, and the α-like globin gene cluster below. Two β-globin chains and two α-globin chains combine to form the normal hemoglobin A (HbA) tetramer, represented between the globin genes. Each globin chain contains one heme group, and oxygen transport takes place sequentially at the four iron-containing heme groups. Fetal hemoglobin (HbF) is composed of two α- and two γ-globin chains; the minor hemoglobin of adults, HbA_2, contains two α- and two δ-globin chains. Normally present at a level of only 2 to 3%, HbA_2 concentration is increased to 4 to 6% in most carriers of β-thalassemia. The ζ *(HBZ)* and ε *(HBE1)* genes are normally expressed only in the embryo. The 5′ ψα gene has recently been found to be expressed at a very low level and is now called the μ-globin gene *(HBM)*. The θ-globin gene *(HBQ1)* is also expressed at low levels. Neither the θ nor the μ gene has been found in a functional hemoglobin. Any of the globin chains participating in hemoglobin formation may have a mutation altering its amino acid sequence. HbS, HbE, and HbC mutations affect the β-globin gene *(HBB)*. Other mutations can affect the α- *(HBA1, HBA2)*, γ- *(HBG1, HBG2)*, and δ-globin *(HBD)* genes. LCR = locus control region. **B**, Expression of globin genes during development. α-Chains are expressed throughout gestation and adult life, fetal γ-globin chains are expressed predominantly in utero, and the β- and δ-globin genes are expressed mainly postnatally. This switching of gene expression patterns accounts for the different hemoglobins present in the embryo, fetus, and adult. It also accounts for the observation that disorders of α-globin can affect both fetus and adult, whereas β-globin chain diseases usually are not clinically apparent in the first months of life, when HbF levels are still high.

initiate vaso-occlusion, whereas dense cells become sequestered or destroyed in the microvasculature. Endothelial cells are responsive to many biologic modifiers that can be generated during sickle vaso-occlusive episodes and infection. Their activation and damage may be provoked by adherent sickle cells and shear stresses that cause release of oxidant radicals, expression of endothelin, and disturbed NO balance. Cellular damage enables adhesive interactions among sickle cells, endothelial cells, and leukocytes. Reperfusion injury can also induce endothelial activation. The association of sickle and endothelial cells by a variety of adhesion molecules and their ligands may sufficiently delay cellular passage so that HbS polymerization, cell sickling, and vaso-occlusion happen before transit through the microvasculature is complete. Reticulocytes that are prematurely released from bone marrow display adhesive ligands that facilitate erythrocyte-endothelial interactions. Individuals with the greatest amount of hemolysis have the highest reticulocyte counts, and these adherent cells provide another link of hemolysis with vaso-occlusion. Neutrophils, which are modulators of inflammation and tissue damage, are increased in patients who have the acute chest syndrome, priapism, or stroke, and their numbers at baseline are a risk factor for survival.

CLINICAL MANIFESTATIONS

The clinical phenotype of sickle cell disease can be a result of many different genotypes, but most patients have either sickle cell anemia, HbSC disease, or HbS-β-thalassemia (see Table 166-1). Although hemolytic anemia and vaso-occlusive events are found in all genotypes, genotypes with higher cellular concentration of HbS are clinically more severe. Within milliseconds to seconds after HbS deoxygenation, depending on the intracellular concentration of HbS, HbS polymer appears in the sickle erythrocyte. In sickle cell trait (i.e., the simple heterozygote carriage of the HbS mutation), each cell contains only 30 to 40% HbS, so polymer is not found under most conditions (see Fig. 166-3). Therefore, carriers have few complications and a normal life expectancy.

The features of sickle cell anemia change as life advances (Table 166-2). The switch from HbF to HbS underlies the clinical shift in life's first decade. This time is typified by acute problems: high risks of severe life-threatening infection, acute chest syndrome, splenic sequestration, and stroke. Chronic organ damage (renal failure, pulmonary hypertension, and late effects of previous cerebrovascular disease) becomes paramount in adults.

Most patients with sickle cell anemia have moderate anemia with a hematocrit between 25 and 30%. Some patients appear to have more severe hemolysis, with hematocrit less than 20%, marked reticulocytosis, and extreme elevation of serum lactic dehydrogenase (LDH). Patients with the most profound hemolysis appear more likely to have stroke, pulmonary hypertension, priapism, and leg ulcers. Many patients with HbSC disease, especially adult men, have almost normal hematocrits and may have a higher incidence of sickle retinopathy, perhaps owing to their increased blood viscosity. Symptoms of anemia, such as weakness and dyspnea, are not the hallmarks of sickle cell disease, yet hemoglobin concentration can be a prognostic indicator for certain complications (see Table 166-2). Plasma volume in sickle cell anemia may be greatly expanded, making it difficult to predict the red blood cell (RBC) mass based on the hematocrit. Serum erythropoietin levels in sickle cell anemia are inappropriately low for the hematocrit. A consequence of hemolysis is increased turnover of bile pigments, regulated in part by promoter polymorphisms in the uridine diphosphate-glucuronosyltransferase 1A (*UGT1A*) gene, which is also associated with unconjugated hyperbilirubinemia and Gilbert's syndrome (Chapter 149). As a result, more than half of all adults have cholelithiasis (Chapter 158). Hemolytic anemia places patients at risk for acutely developing severe anemia when erythropoiesis is temporarily interrupted by parvovirus B19 infection (Chapter 379), which is the predominant cause of the aplastic crisis. Aplastic crisis is typified by a plummeting hematocrit, reticulocytopenia, and a bone marrow without erythroid precursors. It is a transient process, most common in children, and often requires blood transfusion to maintain circulatory competence until a spontaneous recovery follows. Rarely, if a patient's diet is inadequate, hemolysis-induced accelerated turnover of erythrocytes causes folic acid deficiency and megaloblastic anemia (Chapter 167).

First 20 Years

Although any complication can occur at any age, certain events tend to predominate in different age groups. In life's first decades, the most common sickle cell disease–related clinical events are painful episodes, acute chest syndrome, and stroke. Delayed growth and sexual development, more severe in patients with sickle cell anemia than in those with HbSC disease, become major issues of concern to the adolescent, but sexual maturation is eventually achieved.

Psychosocial problems are common in adolescents with sickle cell disease. Difficulties with medical staff often begin in adolescence and frequently center on issues of pain management and inpatient stay.

The Painful Episode

Pain, presumed to be caused by sickle vaso-occlusion, often starts in young children as the hand-foot syndrome: painful swelling of the hands and feet caused by inflammation of the metacarpal and metatarsal periosteum. Acute painful episodes are the most commonly encountered vaso-occlusive events in patients of all ages, but what triggers an acute painful episode is usually

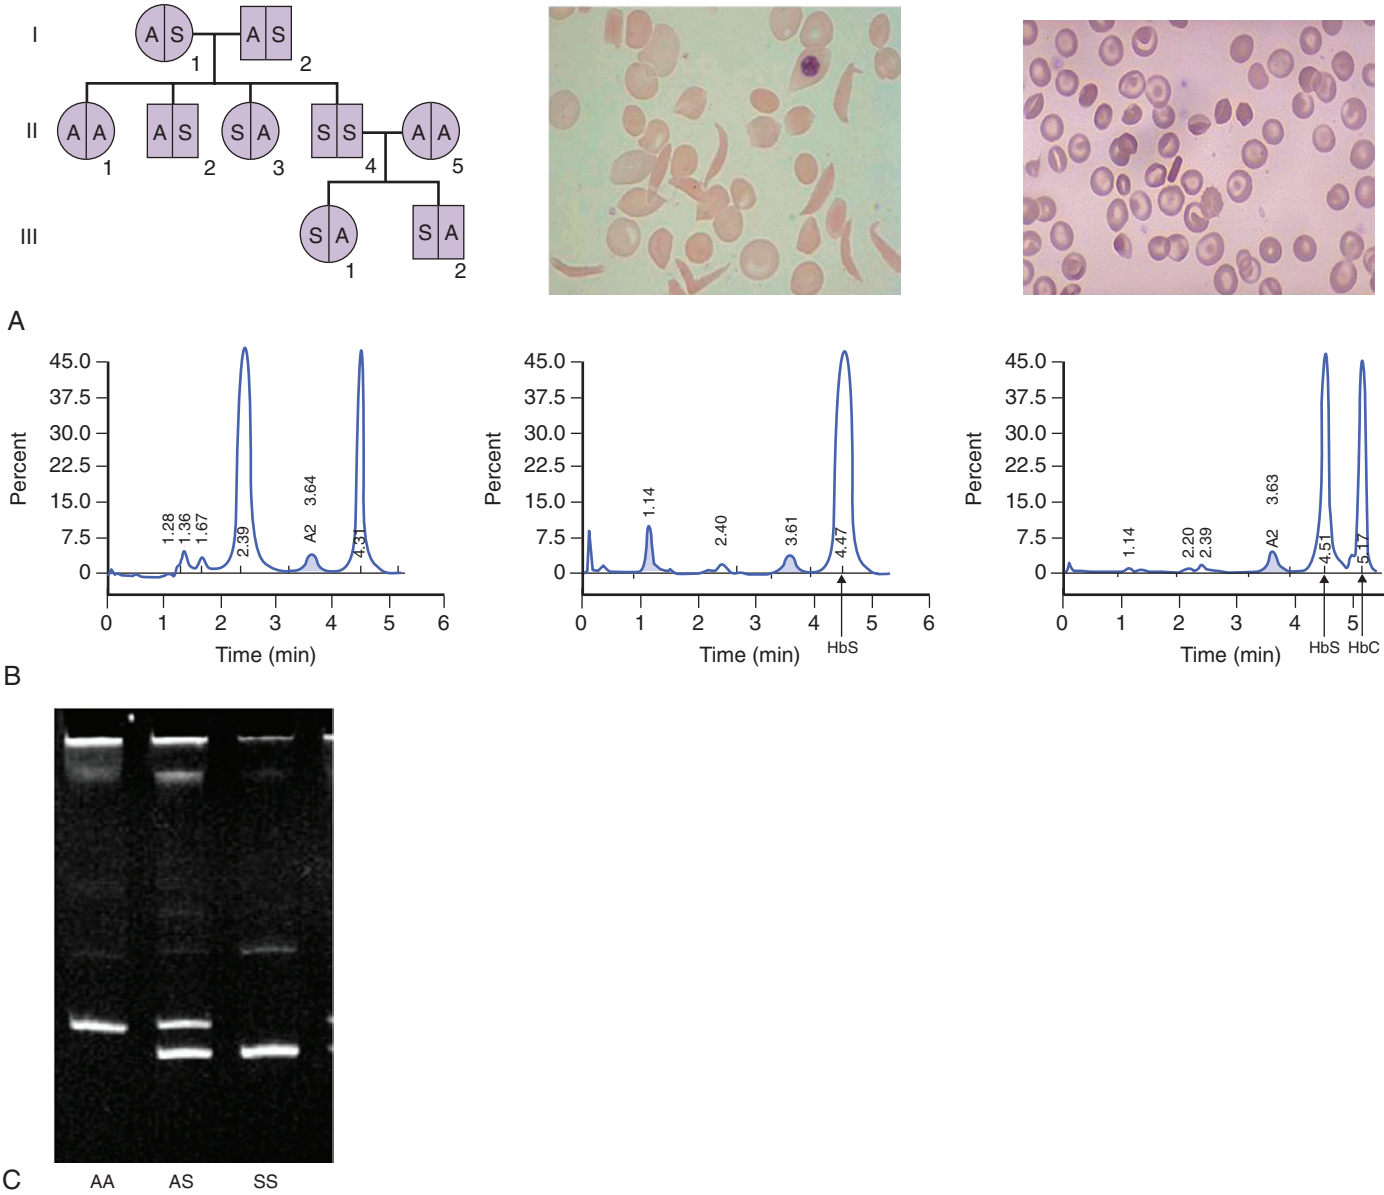

FIGURE 166-3. Diagnosis of sickle cell disease. A, A prototypical family structure in which both parents (I) have sickle cell trait and each offspring (II) has a 25% chance of having sickle cell anemia (SS). Each child of an affected parent (III) will have sickle cell trait (SA) if the other parent has a normal hemoglobin (AA) genotype. The center and right blood films are from patients with sickle cell anemia and HbSC disease, respectively. Note the irreversibly sickled cells (ISCs) in the former and the hemoglobin C (HbC) crystal and target cells in the latter. **B**, High-performance liquid chromatography (HPLC) profiles from patients with sickle cell trait (*left*), sickle cell anemia (*center*), and HbSC disease (*right*). **C**, Amplification refractory mutation system (ARMS)-based separation of the β-globin genes from a normal subject (AA), a carrier of sickle cell trait (AS), and a patient with sickle cell anemia (SS).

unknown. Commonly, painful episodes begin with little warning; some patients, however, may sense one in the offing. These episodes, which last from hours to many days, may wax and wane in intensity and migrate from site to site. No useful laboratory test can tell whether a vaso-occlusive pain episode is occurring, and the history remains the best clue. Sickle cell pain is described as worse than postoperative or traumatic pain. Some women describe the pain of childbirth as paling in comparison with the pain experienced during painful episodes. These agonizing attacks of acute pain must be separated from chronic pain perhaps caused by osteoporosis of the spine, pain associated with osteonecrosis of the hips and shoulders, neuropathic pain, iatrogenic pain, and the milder aches, pains, and soreness that are frequently present between severe episodes.

Patients vary greatly in the number, severity, and frequency of their painful episodes. Painful episodes are often stereotypical, affecting individuals in the same manner from episode to episode. Patients usually know whether the pain they are experiencing is different from their typical painful episode, and the wise physician should heed a patient's advice about the need for hospitalization or the likelihood that the pain has an alternative explanation.

About 40% of patients do not have pain requiring a hospital visit in a given year, whereas 3% have more than six painful episodes per year. Having more than three pain episodes requiring hospitalization per year is associated with increased mortality among patients 20 years and older. Recent studies suggest that pain is present on about half of all days; most episodes are managed at home and not in a medical setting, so hospital visits underestimate the frequency of pain.

HbF levels are inversely related to the frequency of painful episodes. Concurrent α-thalassemia may increase the pain rate because of its effect on the hematocrit. The day-to-day management of sickle cell disease often equates with the management of acute and chronic pain.

The pain accompanying acute chest syndrome, acute cholecystitis, splenic sequestration crisis, splenic infarction, or right upper quadrant syndrome may sometimes be mistaken for uncomplicated pain episodes. Acute painful episodes often herald the acute chest syndrome, and occasionally pain episodes end with multiorgan failure. Unexplained death can occur during acute painful episodes, perhaps as a result of an arrhythmia secondary to unrecognizable myocardial damage or perhaps as a sequela of pulmonary hypertension. Currently, it is not possible to foretell whether a "usual" pain episode will have an unexpected mortal outcome or presage acute chest syndrome, but the presence of atypically severe pain or an uncommonly high leukocyte count or low hematocrit should be cause for extra scrutiny.

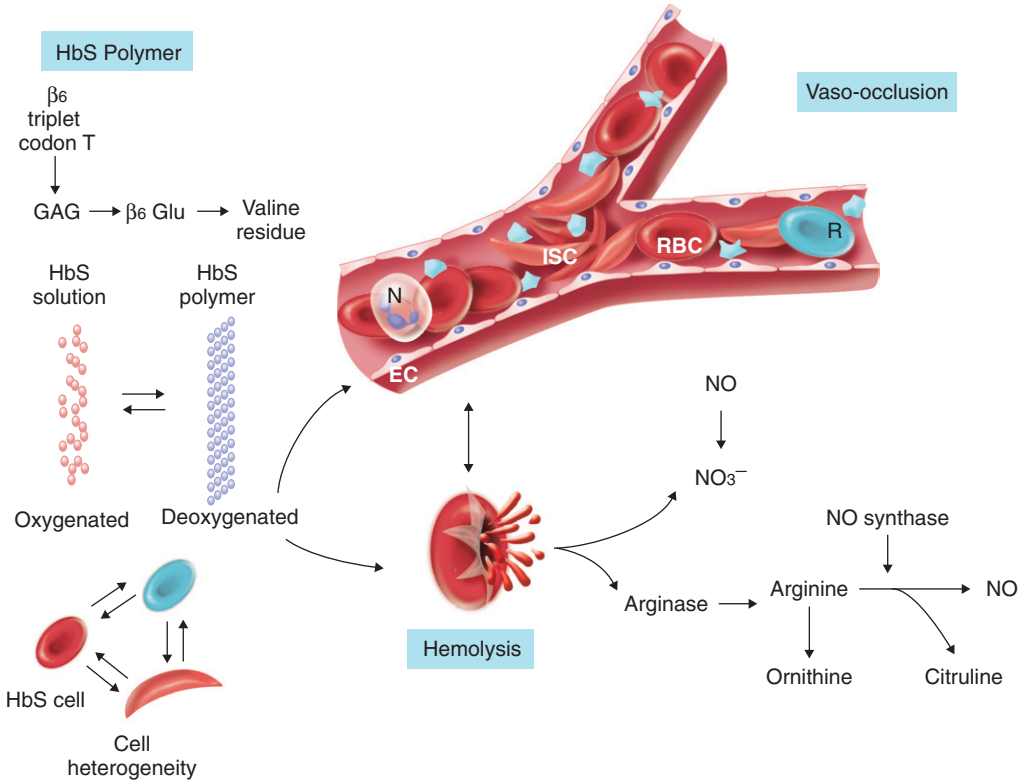

FIGURE 166-4. Pathophysiology of sickle cell disease. An adenine (A) to thymidine (T) transversion (A6T) at codon 6 in the β-hemoglobin gene on chromosome 11 *(HBB)* leads to the substitution of a glutamic acid codon by a valine codon. β^6 valine endows the hemoglobin S (HbS) molecule ($\alpha_2\beta_2^S$) with the property of polymerization when deoxygenated. HbS polymer injures the erythrocyte and leads to a heterogenous population of sickle cells with damaged membrane cytoskeleton, reduced cation and water content, and altered distribution of membrane lipids. In the vasculature, sickle cells interact with endothelium and other blood cells to cause vaso-occlusion. Some damaged erythrocytes hemolyze intravascularly, thereby releasing heme into the plasma to scavenge nitric oxide (NO) and to reduce hemoglobin to methemoglobin and nitrate. NO, by binding soluble guanylate cyclase, converts cyclic guanosine triphosphate (cGTP) to guanosine monophosphate (GMP), thereby relaxing vascular smooth muscle and causing vasodilation. A state of reduced endothelial NO bioavailability in sickle cell disease impairs the homeostatic vascular functions of NO, such as inhibition of platelet activation and aggregation and transcriptional repression of genes transcribing cell adhesion molecules. Hemoglobin, heme, and heme iron catalyze the production of oxygen radicals and protein nitration, potentially further limiting NO bioavailability and activating endothelium. Lysed erythrocytes also liberate arginase, which destroys L-arginine, the substrate for NO production, providing another mechanism for endothelial NO deficiency. The normal balance of vasoconstriction versus vasodilation is therefore skewed toward vasoconstriction as well as endothelial activation and proliferation. EC = epithelial cell; ISC = irreversibly sickled cell; N = neutrophil; R = reticulocyte; RBC = red blood cell.

TABLE 166-2 FEATURES OF SICKLE CELL ANEMIA

Painful episodes: associated with higher hemoglobin
Acute chest syndrome: associated with higher hemoglobin
Stroke: associated with lower hemoglobin
Osteonecrosis: associated with higher hemoglobin
Priapism: associated with lower hemoglobin
Proliferative retinopathy: associated with higher hemoglobin
Splenic infarction and sequestration
Leg ulcers: associated with lower hemoglobin
Gallstones
Aplastic crisis
Osteopenia—bone marrow hyperplasia
Nutritional deficiencies—folic acid, zinc, calories
Pneumococcal disease and sepsis
Placental insufficiency
Some complications are associated with hemoglobin concentration

Stroke

A major complication of sickle cell anemia in early life is stroke caused by stenosis and occlusion of large vessels (Chapter 414). Sickle erythrocytes and anemia-related high blood flow velocity lead to vascular damage. Hemorrhagic stroke is often caused by rupture of aneurysms. Moyamoya disease, a proliferation of small vessels found in sickle cell patients with stenotic lesions, may also cause hemorrhage in adults (Chapter 414). Hemorrhagic stroke is associated with a mortality rate of more than 20%. Stroke is most common among patients with sickle cell anemia, with much lower rates among those with HbSC disease or HbS-β^+-thalassemia. Beyond age 1 year, the incidence of stroke in sickle cell anemia is approximately 0.5 events per 100 patient years until age 40 years. The risk of having a first stroke is 11% by age 20 years, 15% by age 30 years, and 24% by age 45 years. Severe anemia, acute chest syndrome, and elevated systolic blood pressure are associated with ischemic strokes, whereas an elevated leukocyte count is a risk factor for hemorrhagic stroke. α-Thalassemia may protect patients with sickle cell anemia from stroke, perhaps because these patients have less hemolysis and a higher hematocrit. Subclinical neurologic events and silent cerebral infarction are even more common than stroke. The aberrant behavior of some sickle cell patients is most likely a result of otherwise silent cerebral infarction with deteriorating neurocognitive function.

Acute Chest Syndrome

Acute chest syndrome, characterized by fever, chest pain, wheezing, cough, hypoxia, and a new lung infiltrate, is a sometimes lethal complication that affects more than half of all patients with sickle cell anemia. It is the second most common reason for hospitalization and is a frequent cause of death in adults. The syndrome is more frequent in children, in whom its course is often mild, than in adults, in whom it tends to be more severe.

Commonly, acute chest syndrome develops after several days in individuals hospitalized for an acute painful episode (see earlier discussion). Acute chest syndrome also often occurs postoperatively, even when patients are properly prepared with blood transfusion. Other causes include rib infarction with atelectasis and regional hypoxia; fat emboli from the bone marrow (Chapter 98); infection with chlamydia, parvovirus B19, or other viral agents; microvascular or large vessel in situ thrombosis; thromboembolic disease; and vascular injury and inflammation. Fat embolism can be identified by finding lipid within pulmonary macrophages obtained by bronchopulmonary lavage, but this nonstandardized test is not recommended.

In most cases of acute chest syndrome, a cause cannot be found early enough to guide treatment. Elevated concentrations of phospholipase A_2

have been found in patients with sickle cell disease in association with acute chest syndrome and may predict its occurrence, but this test is not used widely.

Acute Anemia

Acute anemia can result from sequestration of blood in the spleen or liver, an aplastic crisis caused by parvovirus B19 infection (Chapter 379), or a severe vaso-occlusive event, such as acute chest syndrome or multiorgan failure. Transfusion may be needed. Megaloblastic arrest of erythropoiesis is uncommon if the diet is adequate in folic acid.

Infection

Because patients with sickle cell anemia are functionally asplenic early in life and hyposplenic later, they are susceptible to infection with encapsulated bacteria. Persistent gross splenomegaly but not normal splenic function is common in patients with sickle cell disease in Africa and is related to endemic malaria. Splenomegaly and splenic function often persist in patients with HbSC disease—hence the reduced incidence of infection but risk of splenic sequestration and infarction in adults. Prevention of mortality from pneumococcal infection is the basis for screening of newborns for sickle cell disease and the use of prophylactic oral penicillin in affected individuals. Pneumococcal vaccines (Chapter 17) are also recommended.

Age 20 to 40 Years

Pregnancy

There is no absolute contraindication to pregnancy for patients with sickle cell anemia, and fertility is probably normal. All approved methods of contraception can be used satisfactorily.

Modern medical management generally achieves good results of pregnancy, but the rates of pyelonephritis, pregnancy-induced hypertension (Chapter 247), and cesarean section are increased, and babies are more likely to have low birthweight. Some obstetricians believe that blood transfusions should be used routinely, but limited data suggest that, with good prenatal care, transfusions do not improve the outcome.

Osteonecrosis and Bone Diseases

Osteonecrosis of the hip and shoulder joints (Chapter 256) affects about half of all patients with sickle cell anemia or HbSC disease. Its onset is insidious but progressive, and most patients with early-stage disease progress to collapse of the femoral head within 2 years. Osteonecrosis of the hip usually manifests with pain in and around the affected joint, or at times with spasm of the surrounding muscles. Patients with higher hematocrits and with sickle cell anemia α-thalassemia have the highest prevalence of osteonecrosis. Osteonecrosis can be detected very early by magnetic resonance imaging, but only more advanced disease is visible on plain radiographs.

Osteomyelitis (Chapter 280) is often difficult to distinguish from bone infarction. Osteomyelitis is usually caused by staphylococcal infection, but salmonella infection is a particular cause of sickle cell osteomyelitis.

Leg Ulcers

About 5 to 10% of patients with sickle cell anemia older than 10 years of age develop leg ulcers, but leg ulcers are rare in HbSC disease or HbS-β^+-thalassemia and in children before age 10 years. In the tropics, leg ulcers are more common. Small and superficial leg ulcers heal spontaneously with rest and careful local hygiene. Control of local inflammation and infection remains the mainstay of treatment. Dressing the ulcer with an Unna boot protects the involved area and is a reasonable method of conservative management. Deep, large, painful ulcers may require large doses of narcotic analgesics, prolonged bed rest, and even surgery.

Priapism

Priapism, a prolonged undesirable painful erection, may be seen in 40% of men with sickle cell anemia. Priapism in sickle cell anemia is usually bicorporeal, with only the corpora cavernosa affected. Venous outflow is obstructed rather than arterial flow increased. In bicorporeal priapism, the glans remains soft, and urination is normal. Recurrent, self-limited attacks of priapism can last for several hours with tolerable discomfort. These episodes have been termed stuttering priapism and usually have a nocturnal onset. Erectile function is usually preserved between attacks. Major episodes of priapism often, but not always, follow a history of stuttering attacks, last for days, and can be excruciatingly painful; they often end in impotency. Affected patients have a higher incidence of stroke, pulmonary hypertension, renal failure, leg ulcers, and premature death than individuals without priapism, perhaps reflecting the severity of vasculopathy.

Digestive Diseases

Sickle hepatopathy, hepatic crisis, and right upper quadrant syndrome are terms applied to sickle cell–associated liver disease. Liver disease may be related to intrahepatic and extrahepatic cholestasis, viral hepatitis (Chapter 150), cirrhosis, hypoxia, infarction, erythrocyte sequestration, iron overload (Chapter 153), or drug reactions (Chapter 152). Differentiation among these potential causes can be difficult. Increased bilirubin levels (Chapter 149) are often the result of unconjugated bilirubinemia and are a manifestation of hemolytic anemia.

Gallstones

Cholelithiasis (Chapter 158), a consequence of the accelerated bile pigment turnover typical of hemolytic anemia, can appear in the first decade of life, and more than half of all adults are affected. Depending on the degree of calcification, pigmented gallstones may be either radiopaque or radiolucent. Ultrasonography is the preferred means of detection, and laparoscopic cholecystectomy is the preferred method of dealing with symptomatic stones. Documented episodes of acute cholecystitis and typical obstructive jaundice are much less frequent than the presence of stones. If stones are asymptomatic or symptoms and laboratory findings suggesting cholecystitis are equivocal, careful observation may be the best course.

Beyond the Fifth Decade

Pulmonary Hypertension

Echocardiographic studies show that 30 to 43% of adults with sickle cell anemia have a tricuspid regurgitant velocity (TRV) of more than 2.5 m/second (Chapter 55), suggestive of pulmonary hypertension (Chapter 68). This is associated with a six- to ten-fold increased risk in mortality. Although it is assumed that many patients with elevated TRV have pulmonary hypertension, pulmonary artery catheterization data in this population are limited, and it is likely that in many instances, an elevated TRV is not synonymous with true pulmonary hypertension. Pulmonary arterial hypertension is present in about half of catheterized patients, but with milder hemodynamics and symptoms compared with idiopathic pulmonary hypertension, particularly early in the course of disease. Increased TRV and the coexistence of relative systemic hypertension, renal disease, and intimal and smooth muscle proliferative changes in conduit vessels suggest the presence of a more widespread vasculopathy, which may be responsible for the observed mortality risk. Increased TRV is also seen in children and in patients with HbSC disease.

Nephropathy

Hyposthenuria is present in almost all patients with sickle cell anemia and even in most carriers of sickle cell trait (Table 166-3). Clinically, the loss of urine concentrating ability is not important unless access to fluid is restricted. Isosthenuria, distal renal tubular acidosis, and impaired potassium excretion are signs of medullary dysfunction.

Glomerular hyperfiltration, increased creatinine secretion, and a very low serum creatinine are characteristic of young patients with sickle cell anemia, so renal dysfunction can be present even with normal serum creatinine values. Glomerulopathy begins very early in life, but an increasing prevalence of renal failure is a hallmark of an aging population of sickle cell anemia patients. About 4% of patients with sickle cell anemia and 2% of those with HbSC develop renal failure, at median ages of 23 and 50 years, respectively. Among sickle cell patients, 60% of those older than 40 years of age have proteinuria, and 30% have renal insufficiency. Nephrotic syndrome is found in 40% of adults with creatinine levels greater than 1.5 mg/dL. Survival time for patients with sickle cell anemia after the diagnosis of sickle renal failure is 4 years, even with dialysis.

Eye Disease

Proliferative sickle retinopathy is present in fewer than 20% of patients with sickle cell anemia but in more than 40% of those with HbSC disease by the third decade of life. Vitreal hemorrhage and retinal detachment can occasionally lead to visual loss, but proliferative lesions may regress spontaneously. Screening for proliferative retinopathy using fluorescence angiography is recommended in patients with HbSC disease to guide possible laser photocoagulation.

TABLE 166-3 RENAL ABNORMALITIES IN SICKLE CELL DISEASE*

DISTAL NEPHRON
Impaired urine concentrating ability
Impaired urine acidification—incomplete renal tubular acidosis
Impaired K^+ excretion
HEMATURIA
PAPILLARY NECROSIS
PROXIMAL TUBULE
Increased phosphate reabsorption
Increased β_2-microglobulin reabsorption
Increased uric acid secretion
Increased creatinine secretion
HEMODYNAMIC CHANGES
Increased glomerular filtration rate
Increased renal plasma flow
Decreased filtration fraction
GLOMERULAR ABNORMALITIES
Proteinuria
Nephrotic syndrome with focal glomerular sclerosis
Chronic renal failure

*In carriers of sickle cell trait, because of its hypertonicity and oxygen content, HbS can polymerize in the renal medulla and lead to hyposthenuria, a possible increased risk of urinary tract infection during pregnancy, papillary necrosis, and hematuria. A rare tumor, medullary carcinoma, arises from distal nephrons and is associated with sickle cell trait.

Cardiovascular Complications

The heart is usually enlarged, with a hyperactive precordium and systolic ejection murmurs. Myocardial infarction is rare and when present suggests small vessel disease. Sudden unexpected and unexplained death is common in adults and may be due to arrhythmias and pulmonary hypertension.

Patients with sickle cell anemia usually have blood pressures that are in the normal range yet inappropriately high compared with controls who have similar levels of anemia. "Relative" hypertension in sickle cell anemia may reflect endothelial cell damage and NO scavenging. Survival is decreased and the risk of stroke is increased as blood pressure rises. Treatment goals of 120/80 mm Hg or less are generally the same as for other patients (Chapter 67).

DIAGNOSIS

Normocytic, microcytic, or macrocytic hemolytic anemia with reticulocytosis, increased levels of lactate dehydrogenase and aspartate aminotransferase, and a compatible clinical history should suggest the presence of sickle cell disease. Nevertheless, because of the multiple genotypes and considerable clinical heterogeneity of each genotype, milder cases may not be diagnosed for many years.

The Blood

In sickle cell anemia, the erythrocytes are normocytic or macrocytic depending on the reticulocyte count. Microcytosis in a suspected case of sickle cell disease can be seen very early in life, when iron deficiency has developed, or when β-thalassemia or α-thalassemia is present. Sickled cells are usually present in the peripheral blood smear in sickle cell anemia and in HbS-β^0-thalassemia (see Fig. 166-3A) but are less common in other forms of sickle cell disease. In HbSC disease, target cells are prominent, and HbC crystalizes in some cells (see Fig. 166-3A). ISC numbers remain relatively constant over time, although their percentage may rise early during a painful episode. Finding ISCs has no value for establishing whether a patient is experiencing a vaso-occlusive episode.

Hemoglobin Composition of the Blood

After 1 year of age, hemoglobin fractions are sufficiently stable to be relied on for diagnosis, but the high HbF concentrations of early infancy often make the results of hemoglobin analysis at that time difficult to interpret. In patients with sickle cell anemia, except in infancy, HbS almost always forms more than 80% of the hemolysate. HbS is best detected by high-performance liquid chromatography (HPLC), which is also the method of choice for quantitation of the hemoglobin fractions in newborns and adults (see Fig. 166-3B), or by isoelectric focusing that provides qualitative information. HPLC provides excellent resolution of hemoglobin fractions, gives quantitative results, and is automated. HbF levels in adults average about 6% but can vary between 1 and 20%. DNA-based methods of detecting HbS are specific but usually are not needed for uncomplicated cases. Nevertheless, they are necessary for antenatal diagnosis and, sometimes, for genetic counseling (see Fig. 166-3C).

Family Studies

The *HBB* gene on chromosome 11 (see Fig. 166-2) is inherited as a codominant trait, implying that both normal and mutant alleles are expressed and are easily detectable. However, the sickle cell phenotype (see Table 166-1) is present only in homozygotes for HbS and in certain compound heterozygotes. Family studies (see Fig. 166-3) can suggest a patient's hemoglobin genotype.

PREVENTION AND TREATMENT Rx

Primary Prevention

In populations with a high prevalence of the HbS gene, heterozygote detection is simple, but there is little proven benefit of a broad screening effort to detect carriers. A preferred approach consists of educational programs about sickle cell disease and sickle cell trait, followed by counseling for couples who are planning families. These couples are offered the choice of testing, after which the risks of having affected fetuses can be discussed and the availability of antenatal diagnosis by chorionic villus sampling or amniocentesis presented.

General Measures

Sickle cell disease is a chronic disorder, for which good nutrition and timely immunizations are critical. Work should be encouraged.

Older children do not routinely need continued antibiotic prophylaxis. Neonatal screening to detect newborns with sickle cell disease allows early administration of prophylactic penicillin[1] and antipneumococcal immunization. These measures reduce the incidence of and mortality from pneumococcal bacteremia in children younger than 5 years of age who have sickle cell anemia.

Because of increased rates of RBC production and inadequate nutrition, folic acid, 1 mg daily, is generally recommended but may not be necessary with a good dietary intake. There is no evidence that high concentrations of inhaled oxygen are of preventive value.

Hydroxyurea

Hydroxyurea, the sole drug approved by the U.S. Food and Drug Administration for treatment of sickle cell anemia, increases HbF in these patients because its cytotoxicity causes erythroid regeneration and perhaps because its metabolism leads to NO-related increases in soluble guanylate cyclase, with a subsequent increase in cyclic guanosine monophosphate (cGMP) that augments γ-globin gene expression. In a multicenter trial in adults with sickle cell anemia, hydroxyurea reduced the incidence of pain and acute chest syndrome by almost 50%,[2] with little risk during more than 17.5 years of observation.[3,4] In follow-up studies, cumulative mortality was reduced almost 40%, and the favorable result was related to the ability of the drug to increase HbF and reduce painful episodes and the acute chest syndrome. Children have a more robust HbF response to hydroxyurea than adults. Cancer and leukemia have been reported in patients with sickle cell disease treated with hydroxyurea, but whether the incidence is higher than in the general population is not known. Hydroxyurea should be used in nearly all adults with sickle cell anemia and HbS-β^0 thalassemia (Table 166-4). However, not all patients who might benefit from this treatment receive it. The clinical benefits of hydroxyurea in HbSC disease are just beginning to be studied.

Red Blood Cell Transfusion

Acute transfusions of packed RBCs can be life-saving, and chronic transfusions reduce the incidence and severity of most complications of sickle cell disease. However, repeated transfusions produce iron overload, alloimmunization, loss of venous access, and viral infection. Whether exchange transfusion is preferable to simple transfusion in the acute chest syndrome, stroke, or other acute complications has not been tested in clinical trials. For severe symptomatic anemia or stroke prophylaxis, simple transfusions are preferred.

Treatment of Common Complications

Painful Episodes

A decision as to whether hospitalization is needed can be made after an assessment of the duration and severity of the pain and the response to treatment. Associated factors such as excessive tachycardia, hypotension, body temperature higher than 38.3° C (101° F), marked leukocytosis, a fall in the hematocrit and platelet count, hypoxia, or a new infiltrate on chest radiography should prompt admission.

TABLE 166-4 HYDROXYUREA TREATMENT IN SICKLE CELL ANEMIA*

BASELINE EVALUATION
Blood counts, RBC indices, HbF level, serum chemistries, pregnancy test, willingness to adhere to all recommendations for treatment, not receiving chronic RBC transfusions
INITIATION OF TREATMENT
Hydroxyurea 10-15 mg/kg/day or, for adults, 500 mg every morning for 6-8 wk
CONTINUATION OF TREATMENT
If counts are acceptable by CBC every 2 wk (granulocytes, ≥2000/mm^3; platelets, ≥80,000/mm^3), escalate dose in increments of 200 to 500 mg every 6-8 wk. When a stable nontoxic dose of hydroxyurea is reached, CBC may be done at 4- to 8-wk intervals. Most good responses require 1000 to 2000 mg/day and a final dose more than 30 mg/kg/day should be the top.
GOALS OF TREATMENT
Less pain, increase in HbF (usually measured every 6-8 wk) or MCV, increased hematocrit if severely anemic, acceptable toxicity. Failure of HbF to increase may be due to biologic inability to respond to treatment or, more often, to poor compliance with treatment. If compliance is documented, the dose can be increased cautiously to 2000-2500 mg/day (maximum dose, 30 mg/kg).

*Special caution should be exercised in patients with compromised renal or hepatic function and in those who are habituated to narcotics. Contraception should be practiced by both men and women. Without chronic RBC transfusions or an intercurrent illness suppressing erythropoiesis, a trial period of 6 to 12 months is probably adequate.
CBC = complete blood count; HbF = fetal hemoglobin; MCV = mean corpuscular volume; RBC = red blood cell.

TABLE 166-5 PULMONARY COMPLICATIONS OF SICKLE CELL DISEASE

ACUTE CHEST SYNDROME
Diagnosis: Chest pain, fever, cough wheezing, new infiltrate on chest radiograph, hypoxemia
Management: simple or exchange transfusions, pain relief, oxygen if hypoxemic, bronchodilators, incentive spirometry, antibiotics (broad coverage)
PULMONARY HYPERTENSION
Diagnosis: Tricuspid regurgitant velocity (TRV) ≥ 2.5 m/sec by echocardiography. May also have an elevated N-terminal pro–brain natriuretic peptide (NT-pro-BNP) (≥160 pg/mL) and a reduced 6-min walk distance (≤350 m).
Management: Screen by echocardiography beginning at age 18 yr, repeat echocardiogram periodically according to symptoms. If TRV > 3.0 m/sec, refer for right heart catheterization. Consider anticoagulation, treatment of iron overload and nocturnal hypoxemia. Optimize hydroxyurea, consider chronic transfusions and pulmonary vasodilator therapy.
ASTHMA
ABNORMAL PULMONARY FUNCTION

Physical examination is usually not helpful, but sometimes there is localized swelling and pain over an involved bone. Low-grade fever and a mild increase in leukocytosis can accompany uncomplicated painful episodes, but higher temperature elevations may point to infection or extensive tissue damage.

The cornerstones of pain management (Chapter 29) are fluid replacement and opioid analgesics. Because almost every patient is hyposthenuric, urinary output in patients with sickle cell anemia may exceed 2 L/day, making them susceptible to dehydration. Pain is often accompanied by reduced fluid intake and increased water losses, so increased fluid intake is essential. Administration of 5% dextrose in water and 0.25 to 0.5 normal saline should be used for initial fluid replacement. Although needs vary and hydration should be monitored closely to avoid iatrogenic heart failure or electrolyte imbalance, the daily fluid intake should be approximately 3 to 5 L for adults and 100 to 150 mL/kg for children. Oxygen should be reserved for patients who are hypoxic or have acute respiratory distress. Infection should always be considered and treated early if present, although bacterial infections are uncommon.

Analgesic management presupposes that other treatments, such as hydration, oxygen, and antimicrobial agents, are used if needed. The key to successful pain management is individualized treatment and dosing, taking into account prior pain management and prior use of opioids. Patient-controlled analgesia and a scheduled regimen of drug dosing are preferable, and PRN analgesics should be avoided. Frequent reassessment of the effects of treatment is paramount so that opioid doses can be titrated for pain relief and tapered when relief is obtained. Meperidine should be avoided because its metabolites (e.g., normeperidine) can cause central nervous system excitation. Pain management (Chapter 29) is complicated by the influence of learned pain behavior, pain memories, and pain therapy–induced pain. Management proves extremely difficult in perhaps 10% of all patients, and often enormous doses of opioids are required for relief.

Stroke

For new strokes, after initial stabilization and transfusion, chronic RBC transfusion reduces the chance of recurrent ischemic stroke. However, it is not known how long chronic transfusions should continue. In practice, transfusions are often stopped after children make the transition from pediatric to adult care. Long-term management of hemorrhagic stroke is unclear, and whether transfusion reduces their recurrence is unknown. Increased intracranial flow velocity, measurable only in children, increases the risk of stroke, but its sensitivity is only 10%, with a far from perfect specificity. Children found to be at risk for stroke by transcranial Doppler flow velocities should be started on chronic transfusions, but it is unclear whether or when such transfusions may be discontinued.

Acute Chest Syndrome

Routine treatments for acute chest syndrome initially include bronchodilators (e.g., albuterol nebulizer 0.25 mL in 2.5 mL normal saline; or albuterol metered-dose inhaler during the acute episode), incentive spirometry, empirical antimicrobial agents as used for community-acquired pneumonia (e.g., ceftriaxone or azithromycin or levofloxacin for 5 to 7 days [Chapter 97]), and supplemental oxygen when hypoxia is noted by continuous or frequent monitoring of blood oxygen saturation. Opioid analgesics (e.g., morphine) are often needed, but their dose should be titrated carefully to avoid respiratory depression and worsening of hypoxia.

Blood transfusion is the cornerstone of treatment when a patient becomes hypoxic, develops respiratory distress, has a clinically significant fall in the hematocrit and platelet count or increase in leukocyte count, or shows any sign of multiorgan failure, such as impaired mentation, rhabdomyolysis, renal failure, or liver failure. Both simple transfusion and exchange transfusions appear to reverse many adverse findings of the acute chest syndrome, but controlled studies have never tested the superiority of either method. Although the death rate in acute chest syndrome is less than 10%, a few patients have a rapidly deteriorating course with sudden development of the acute respiratory distress syndrome (ARDS; Chapter 104), as manifested by increased oxygen requirements, extensive pulmonary opacification, and multiorgan failure. Excessive hydration and fat emboli are potential contributing causes. Successful management of severe acute chest syndrome and ARDS requires close coordination among physicians and nurses. Some patients have repeated episodes of severe acute chest syndrome, and chronic transfusion can reduce the recurrence rate. Hydroxyurea also reduces the rate of acute chest syndrome by about 50%.

Osteonecrosis and Bone Disease

Treatment with reduced weight bearing, nonsteroidal anti-inflammatory drugs (NSAIDs), and physical therapy is the mainstay of conservative management but does not retard progression of osteonecrosis and bone disease. Total hip arthroplasty can be very successful, but about one third of prostheses fail within 4 to 5 years.

Diffuse osteoporosis (Chapter 251) is usually present, and osteomalacia (Chapter 252) due to vitamin D deficiency is common in both children and adults. If vitamin D deficiency is present, treatment with calcium (1000 mg PO daily) and vitamin D (50,000 IU PO every week for 2 months, then 50,000 IU PO every other week) is reasonable.

Priapism

Conservative treatment of priapism includes analgesics, hydration, and transfusions. Aspiration and irrigation of the corporeal bodies should be performed within a 12-hour window from the onset of erection if the episode differs from prior episodes of stuttering priapism. Operative treatment, which should be considered after 24 to 48 hours of priapism, includes the creation of shunts between the corpora cavernosa and spongiosum. For a typical episode of low-flow priapism, a Winter shunt between the glans penis and corpora cavernosa should be performed within 24 to 48 hours. Oral or intracavernous administration of α-adrenergic agonists such as pseudoephedrine and sildenafil treatment are being studied.

Pulmonary Hypertension

Patients with sickle cell anemia should be screened by echocardiography for the presence of pulmonary hypertension because of the prognostic importance of an elevated TRV, although management of patients with few symptoms and minimally elevated TRV is ill defined. For symptomatic individuals, optimization of hydroxyurea, transfusions, sildenafil, bosentan, and epoprostenol have all been used, but controlled trials reporting their effectiveness in sickle cell patients have not been (Table 166-5) reported.

Renal Disease

In a small randomized trial, 6 months' treatment with 25 mg/day of captopril caused a 37% reduction in microalbuminuria, compared with a 17% increase in placebo-treated patients; such treatment would be reasonable in patients with known microalbuminuria, but whether screening or long-term treatment is worthwhile is unknown. NSAIDs reduce the glomerular filtration rate in sickle cell anemia and should be avoided in older individuals with creatinine levels of 1.2 mg/dL or higher. Dialysis and renal transplantation are used in end-stage sickle cell nephropathy, but with outcomes less favorable than in other types of renal failure.

Surgery and Anesthesia

Preoperative blood transfusion should be used for all surgeries requiring general anesthesia and selected other surgeries. Simple transfusion to a hematocrit of about 30% before surgery is as effective in preventing postoperative complications as exchange transfusion and causes fewer transfusion-related complications.■ In some minor surgeries, it is likely that preoperative transfusion is unnecessary.

Implantable infusion ports and catheters have higher risks of complications in sickle cell anemia, including thrombosis of large veins and bacteremia. Low-dose warfarin may retard thrombosis of these devices.

Red Blood Cell Transfusion and Iron Chelation Therapy

The customary level of chronic stable anemia alone is seldom an indication for transfusion. With aging and the onset of renal failure, anemia worsens and can become symptomatic. Transfusion may become necessary, although judicious use of erythropoietin (e.g., darbepoetin, 0.45 μg/kg every 2 weeks, increased as needed) can often restore the hematocrit to prerenal failure levels and should not be higher because of the potential adverse effects of hyperviscosity.

It is advised that patients undergo erythrocyte phenotyping to determine their RBC antigens before embarking on a transfusion program. Otherwise, alloimmunization occurs in about one fourth of frequently transfused patients. In the presence of multiple alloantibodies, it may be difficult to find compatible blood.

With repeated transfusion, iron overload inevitably develops and can result in heart and liver failure and many other complications (Chapter 219). Serum ferritin is an inaccurate means of estimating the iron burden. Liver biopsy might be the most accurate means of determining tissue iron concentration and the response to chelation, but magnetic resonance imaging (FerriScan) correlates very well with this measurement and is noninvasive.

Chelation of excessive iron can be achieved using deferasirox (20 mg/kg orally daily).■ Increases in serum creatinine and proteinuria occur in about 40% of patients. Desferrioxamine is a parenteral chelator and is usually started with 25 to 30 mg/kg given subcutaneously five times per week in 8- to 12-hour infusions (Chapter 219). Side effects include skin reactions, ototoxicity, retinal toxicity, bone and growth abnormalities, and *Yersinia* infection resulting from the sudden mobilization of iron. Another oral chelator, deferiprone, is less potent than deferasirox or desferrioxamine but is useful instead of or in addition to these drugs; at present, it is approved for use in more than 40 countries but not the United States. Side effects requiring discontinuation of deferiprone, seen in 5 to 10% of patients, include agranulocytosis, neutropenia, arthropathy, and gastrointestinal symptoms.

Stem Cell Transplantation

Successful stem cell transplantation (Chapter 181) can cure sickle cell anemia, but only about 10% of patients have suitable donors. Myeloablative stem cell transplantation carries a 5 to 10% mortality rate and is poorly tolerated in adults. A nonmyeloablative regimen that used total-body irradiation and treatment with alemtuzumab and sirolimus led to stable mixed chimerism in 10 adults transplanted with an HLA-identical family donor, with no graft versus host disease observed. If extended to a larger group of patients and to haploidentical transplants, this approach would be a major advance in treating the most severely ill patients.

FUTURE DIRECTIONS

Experimental treatments to induce higher levels of HbF more consistently and to reduce HbS polymer with drugs that may remodel chromosomal structure (e.g., short-chain fatty acids and their derivatives) or affect hypomethylation of the HbF gene promoters (e.g., decitabine) are undergoing clinical trials. Where malaria is endemic, antimalaria prophylaxis reduces episodes of malaria and increases mean hemoglobin levels. Gene therapy trials are slowly progressing.

PROGNOSIS

Average life expectancy for patients with sickle cell anemia in the United States is between 50 and 60 years; patients with HbSC disease typically live 60 to 70 years. Patients with HbS-β^0-thalassemia are likely to have a life expectancy similar to those with sickle cell anemia, and the lifespan for patients with the HbS-β^+ form may resemble that of patients with HbSC disease. Death is often caused by infection, and another 20% of deaths are related to organ failure. However, death in adults often is unexpected, happening in the midst of an acute event such as an acute painful episode, and occurring within the first 24 hours of hospitalization. In areas of the developing world without access to modern medical care, death in childhood is still common.

OTHER HEMOGLOBINOPATHIES

Hemoglobinopathies other than those associated with HbS, HbE, and HbC rarely cause clinically recognizable disorders. HbC (*HBB* Glu6Lys) and HbE (*HBB* Glu26Lys) are common β-globin variants. As with HbS, their high gene frequencies are a result of the positive selective pressure of endemic falciparum malaria. HbC is present in about 2% of African Americans, and HbE is seen in Southeast Asia, where, in some areas, the gene frequency may reach 50%. Heterozygotes with either mutation are asymptomatic, although the blood of HbC trait carriers contains target cells, and HbE carriers may have very mild anemia and microcytosis. Even homozygotes for HbC and HbE have virtually no clinical disease, only mild hematologic abnormalities such as microcytosis, target cells, and mild anemia. Compound heterozygotes for HbE and β-thalassemia usually have the phenotype of transfusion-dependent β-thalassemia, although genotype-phenotype correlations are difficult to make because of the likelihood that other genes affect the expression of disease.

Rare hemoglobinopathies may change the affinity of hemoglobin for oxygen, render it susceptible to oxidation, or cause molecular instability. Amino acid substitutions involving heme-binding residues may lead to irreversible iron oxidation, methemoglobinemia, and cyanosis (Chapter 161). Patients with these conditions have congenital pseudocyanosis but are usually asymptomatic and need no treatment.

Substitutions at contacts between globin subunits may alter the affinity of hemoglobin for oxygen. When hemoglobin-oxygen affinity is increased, less oxygen is available in tissues, erythropoietin production is enhanced, and erythrocytosis results (Chapter 169). Usually, no treatment is required because the erythrocytosis is mild. Hemoglobin-oxygen affinity may also be reduced by some mutations, resulting in anemia or cyanosis. Hemoglobin instability, produced by several molecular mechanisms (including introduction of proline residues into the α-helix, substitutions near the heme ring, and deletion or addition of amino acids) often causes loss of heme from the molecule and hemolytic anemia. Hb Koln is the most common example of this class of hemoglobinopathy, but more than 200 unstable variants have been described. Sometimes, oxidant drugs provoke increased hemolysis. Splenectomy is sometimes effective treatment when the anemia is severe.

167 MEGALOBLASTIC ANEMIAS

AŚOK C. ANTONY

DEFINITION

Megaloblastic anemias, a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells, are commonly due to a deficiency of vitamin B_{12} (cobalamin) or folates. These anemias are globally prevalent and carry a significant burden of morbidity. Folate and cobalamin are both required to sustain one-carbon metabolism, which involves the transfer of one-carbon groups such as methyl-, formyl-, methylene-, methenyl-, and formimino- in enzyme reactions essential for pyrimidine and purine biosynthesis, including the synthesis of three of the four nucleotides of DNA. Thus, a deficiency in cobalamin or folate results in the common biochemical feature of a defect in DNA synthesis, along with lesser alterations in RNA and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. The majority of megaloblastic cells have DNA values between 2 and 4 N because of delayed cell division. This is morphologically expressed as larger-than-normal "immature" nuclei with finely particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater "mature" cytoplasm and cell volume. The microscopic appearance of this nuclear-cytoplasmic asynchrony (or dissociation) is morphologically described as *megaloblastic*. Megaloblastic hematopoiesis commonly presents with anemia, the most easily recognized manifestation of a global defect in DNA synthesis in all proliferating cells (especially of the gastrointestinal and reproductive tracts). Because vitamin replacement is curative, precise identification of the deficient vitamin is essential. In the case of cobalamin, the cause of the deficiency (Table 167-1) dictates the dose and duration of replacement therapy.

EPIDEMIOLOGY

Cobalamin

Nutrition

Cobalamin is a red, water-soluble vitamin with a complex structure that generally resembles the heme molecule, but with cobalt replacing iron in the center of the pyrrole ring. The recommended daily allowance of cobalamin is 2.4 µg for men and nonpregnant women, 2.6 µg for pregnant women, 2.8 µg for lactating women, and between 1.5 and 2 µg for children 9 to 18 years old. Cobalamin is produced in nature only by microorganisms, and humans receive cobalamin solely from the diet. Meat from parenchymal organs is richest in cobalamin (>10 µg/100 g wet weight); fish and animal muscle, milk products, and egg yolks have 1 to 10 µg/100 g wet weight. An average nonvegetarian Western diet with abundant meat, milk and other dairy products, and eggs contains 5 to 7 µg/day of cobalamin, which is adequate to sustain normal cobalamin equilibrium. For vegetarians, the consumption of eggs, milk, and dairy products generally provides less than 0.5 µg/day of cobalamin and cannot sustain cobalamin balance. Other foods, including *nori* (dried seaweed) and *tempeh* (fermented soybean cake), are not reliable sources of cobalamin. Near-vegetarians who consume meat infrequently (usually because of poverty) have a cobalamin status that is only marginally better than that of lacto-ovovegetarians.

Cobalamin is stored exceptionally well in tissues. Of the total body content of 2 to 5 mg in adults, half is in the liver. With a daily loss of 1 µg, dietary cobalamin deficiency can take 5 to 10 years to become apparent. However, it takes about 3 to 4 years to deplete cobalamin stores if dietary cobalamin is abruptly malabsorbed (e.g., ileal resection), thereby interfering with an efficient enterohepatic circulation, which accounts for the turnover of 5 to 10 µg of cobalamin per day and the reabsorption of 75% of cobalamin secreted into bile. Although cobalamin resists high-temperature cooking processes, it is unstable with light exposure and can be converted to inactive analogues.

Folates

Nutrition

Folates are synthesized by microorganisms and plants. Rich food sources include green leafy vegetables (spinach, lettuce, broccoli), beans, fruit (bananas, melons, lemons), yeast, mushrooms, and animal protein (liver, kidney). The recommended daily allowance of folate is 400 µg for adult men and nonpregnant women, 600 µg for pregnant women, 500 µg for lactating women, and 300 to 400 µg for children 9 to 18 years of age. A balanced Western diet can prevent folate deficiency, but the net dietary intake of folate in many developing countries may be insufficient to sustain folate balance and is often less than half of optimum. Folates are susceptible to breakdown during prolonged cooking (>15 minutes), which can destroy 50 to 95% of folate.

PATHOBIOLOGY

Cobalamin

Normal Physiology

Absorption and Transport

Cobalamin in food is usually in coenzyme form (as deoxyadenosylcobalamin and methylcobalamin) and bound to proteins (Fig. 167-1). In the stomach, peptic digestion at low pH is a prerequisite for the release of cobalamin from food protein. Once it is released by proteolysis, cobalamin preferentially binds to a high-affinity cobalamin-binding protein called R protein, which is secreted in salivary and gastric juice. These cobalamin–R protein complexes, along with unbound intrinsic factor, which is produced by gastric parietal cells, pass into the second part of the duodenum, where pancreatic proteases degrade R proteins. This allows the transfer of cobalamin to intrinsic factor.

The stable intrinsic factor–cobalamin complexes then pass through the jejunum to the ileum, where they bind to membrane-associated intrinsic factor–cobalamin receptors (also called *cubam* receptors because they are composed of a complex of two proteins, cubulin and amnionless) on the microvilli of ileal mucosal cells. Within enterocytes, cobalamin is transferred to transcobalamin II, which efficiently binds and delivers cobalamin ultimately to transcobalamin II receptors found on cell surfaces. Another protein, transcobalamin I, which binds approximately 75% of serum cobalamin but does not participate in transport, appears to be a storage protein for cobalamin in blood. A third quantitatively minor protein, transcobalamin III, binds a wide spectrum of cobalamin analogues that are rapidly cleared by the liver into bile for efficient fecal excretion.

Cellular Processing

More than 95% of intracellular cobalamin is bound to two intracellular enzymes: methylmalonyl-coenzyme A (CoA) mutase and methionine synthase. In mitochondria, deoxyadenosylcobalamin is a coenzyme for methylmalonyl-CoA mutase, which converts the product of propionate metabolism, methylmalonyl-CoA, to succinyl-CoA, a form that is easily metabolized. In the cytoplasm, methylcobalamin is a coenzyme for methionine synthase, which catalyzes the transfer of methyl groups from methylcobalamin to homocysteine to form methionine. The methyl group of 5-methyltetrahydrofolate (methyl-THF) is donated to regenerate methylcobalamin, thereby forming the THF that is essential to sustain one-carbon metabolism. The methionine so formed can be adenylated to S-adenosylmethionine, which donates its methyl group in a critical series of biologic methylation reactions involving more than 80 proteins, phospholipids, neurotransmitters, RNA, and DNA. An elevation of methylmalonic acid and homocysteine in the blood can point to cobalamin deficiency.

Pathogenesis of Cobalamin Deficiency

Nutritional Cobalamin Deficiency

Vegetarianism and poverty-imposed near-vegetarianism are the most common causes of nutritional cobalamin insufficiency worldwide in all age groups. In such patient populations, low maternal cobalamin status is associated with adverse pregnancy outcomes (preterm birth, intrauterine growth retardation, very early recurrent miscarriage), neural tube defects, reduced neurocognitive performance in children, accelerated bone turnover, and low bone mineral density with fractures.

Inadequate Dissociation of Cobalamin from Food Protein

Failure to release dietary cobalamin from food protein can lead to cobalamin deficiency despite the presence of intrinsic factor. This is a common cause of

TABLE 167-1 ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF COBALAMIN AND FOLATE DEFICIENCIES

I. Cobalamin deficiency
  A. Nutritional cobalamin deficiency (insufficient cobalamin intake)—vegetarians, poverty-imposed near-vegetarians, breast-fed infants of mothers with pernicious anemia
  B. Abnormal intragastric events (inadequate proteolysis of food cobalamin)—atrophic gastritis, hypochlorhydria, proton pump inhibitors, H_2-blockers
  C. Loss/atrophy of gastric oxyntic mucosa (deficient intrinsic factor molecules)—total or partial gastrectomy, adult and juvenile pernicious anemia, caustic destruction (lye)
  D. Abnormal events in the small bowel lumen
    1. Inadequate pancreatic protease (R factor–cobalamin not degraded, cobalamin not transferred to intrinsic factor)
      a. Insufficient pancreatic protease—pancreatic insufficiency
      b. Inactivation of pancreatic protease—Zollinger-Ellison syndrome
    2. Usurping of luminal cobalamin (inadequate binding of cobalamin to intrinsic factor)
      a. By bacteria—stasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (scleroderma), hypogammaglobulinemia
      b. By *Diphyllobothrium latum* (fish tapeworm)
  E. Disorders of ileal mucosa/intrinsic factor–cobalamin receptors (intrinsic factor–cobalamin not bound to intrinsic factor–cobalamin receptors [a.k.a. cubam receptors])
    1. Diminished or absent cubam receptors—ileal bypass, resection, fistula
    2. Abnormal mucosal architecture or function—tropical/nontropical sprue, Crohn's disease, tuberculous ileitis, amyloidosis
    3. Cubam receptor defects—Imerslund-Gräsbeck syndrome, hereditary megaloblastic anemia
    4. Drug effects—metformin, cholestyramine, colchicine, neomycin
  F. Disorders of plasma cobalamin transport (TCII-cobalamin not delivered to TCII receptors)—congenital TCII deficiency, defective binding of TCII-cobalamin to TCII receptors (rare)
  G. Metabolic disorders (cobalamin not used by cells)
    1. Inborn enzyme errors (rare)
    2. Acquired disorders (cobalamin functionally inactivated by irreversible oxidation)—nitrous oxide inhalation
II. Folate deficiency
  A. Nutritional causes
    1. Decreased dietary intake—poverty and famine, institutionalization (psychiatric facilities, nursing homes), chronic debilitating disease, prolonged feeding of infants with goat's milk, special slimming diets or fad foods (folate-rich foods not consumed), cultural or ethnic cooking techniques (food folate destroyed)
    2. Decreased dietary intake and increased requirements
      a. Physiologic—pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy
      b. Pathologic
        (1) Intrinsic hematologic diseases involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration by malignant disease
        (2) Dermatologic disease—psoriasis
  B. Folate malabsorption
    1. With normal intestinal mucosa
      a. Drugs—sulfasalazine, pyrimethamine, proton pump inhibitors (via inhibition of proton-coupled folate transporters)
      b. Hereditary folate malabsorption (mutations in proton-coupled folate transporters) (rare)
    2. With mucosal abnormalities—tropical/nontropical sprue, regional enteritis
  C. Defective CSF folate transport—cerebral folate deficiency (autoantibodies to folate receptors) (rare)
  D. Inadequate cellular utilization
    1. Folate antagonists (methotrexate)
    2. Hereditary enzyme deficiencies involving folate
  E. Drugs (multiple effects on folate metabolism)—alcohol, sulfasalazine, triamterene, pyrimethamine, trimethoprim-sulfamethoxazole, phenytoin, barbiturates
III. Miscellaneous megaloblastic anemias not caused by cobalamin or folate deficiency
  A. Congenital disorders of DNA synthesis
    1. Orotic aciduria
    2. Lesch-Nyhan syndrome
    3. Congenital dyserythropoietic anemia
  B. Acquired disorders of DNA synthesis
    1. Deficiency—thiamine-responsive megaloblastic anemia (thiamine transporter 1 mutation)
    2. Erythroleukemia; refractory sideroblastic anemias (pyridoxine responsive?)

CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; TCII = transcobalamin II.

cobalamin deficiency in affluent countries and occurs among 30 to 50% of elderly individuals with low cobalamin status. It is about 10-fold more common than pernicious anemia or loss of functional cubam receptors.

Absent Secretion of Acid and Intrinsic Factor

Deficiency of intrinsic factor as a result of gastric parietal cell atrophy is associated with insufficient hydrochloric acid secretion and can be caused by total or partial gastrectomy; autoimmune destruction (chronic atrophic gastritis), as found in classic pernicious anemia; or destruction of gastric mucosa by caustic (lye) ingestion.

Total gastrectomy invariably leads to cobalamin deficiency in 2 to 10 years, thus warranting prophylactic cobalamin (and iron) replacement. After partial gastrectomy, up to a third of patients may have multifactorial cobalamin deficiency from decreased secretion of intrinsic factor, hypochlorhydria, or intestinal bacterial overgrowth of cobalamin-consuming organisms. Morbidly obese patients following bariatric gastric bypass surgery (Chapter 227) also have food-cobalamin malabsorption, as do those on long-term H_2-blockers or proton pump inhibitors.

In pernicious anemia, the primary event is autoimmune destruction and atrophy of the gastric parietal cell mucosa, leading to the absence of intrinsic factor and hydrochloric acid, which causes severe cobalamin malabsorption and deficiency. The autoimmune gastritis that eventually leads to chronic atrophic gastritis involves the gastric fundus and body. Intrinsic factor antibodies are found in the serum of 60% and in the gastric juice of 75% of patients with pernicious anemia. The incidence of pernicious anemia is approximately 25 new cases per year per 100,000 persons older than 40 years. The average age at onset is about 60 years. Nearly 2% of free-living individuals older than 60 years in Southern California had undiagnosed pernicious anemia, with minimal clinical manifestations of cobalamin deficiency; significantly, in this cohort, 4% of white and African American women had pernicious anemia. Nonetheless, pernicious anemia can be found in persons of all ages, races, and ethnic origins. About 30% of patients have a positive family history, and there is an association with other autoimmune diseases (polyglandular autoimmune syndrome, Graves' disease, Hashimoto's thyroiditis, vitiligo, Addison's disease, idiopathic hypoparathyroidism, primary ovarian failure, myasthenia gravis, type 1 diabetes, adult hypogammaglobulinemia).

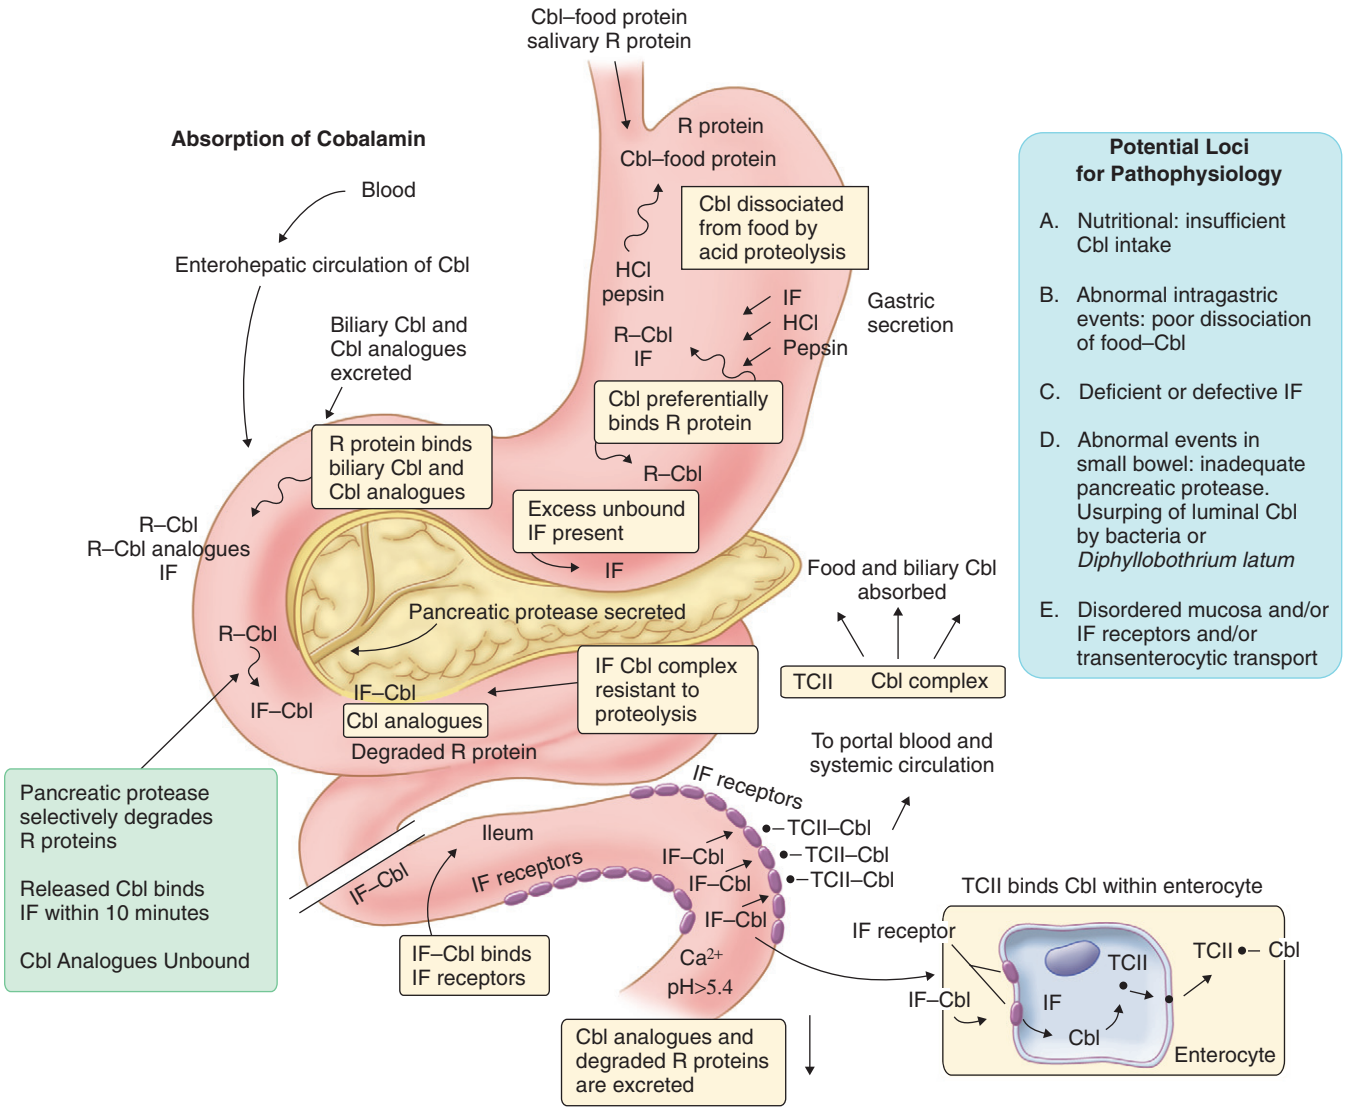

FIGURE 167-1. Components and mechanism of cobalamin absorption, with an indication of the locus for malabsorption. Cbl = cobalamin; IF = intrinsic factor; TCII = transcobalamin II. (From Antony AC. Megaloblastic anemias. In: Hoffman R, Benz EJ Jr, Shattil SJ, et al, eds. *Hematology: Basic Principles and Practice,* 4th ed. Philadelphia: Churchill Livingstone; 2005:519-556.)

Abnormal Events Precluding Absorption of Cobalamin

In pancreatic insufficiency (Chapter 142) with a deficiency of pancreatic protease, there is a failure to break down the R proteins to which cobalamin is preferentially bound in the stomach; this precludes the transfer of cobalamin to intrinsic factor. However, with the widespread early use of pancreatic protease replacement, frank cobalamin deficiency is uncommon. Endogenous pancreatic protease can be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger-Ellison syndrome (Chapter 201). Further, if the pH of the luminal contents in the ileum is less than 5.4, the binding of the intrinsic factor–cobalamin complex to cubam receptors will be precluded.

Bacterial overgrowth in the small bowel (arising from stasis, impaired motility, and hypogammaglobulinemia; Chapter 144) favors colonization by bacteria, which can usurp free cobalamin before it can bind to intrinsic factor. This problem can be reversed by a short course of antibiotic therapy. Individuals heavily infested with the fish tapeworm *Diphyllobothrium latum* (acquired by consuming raw or partially cooked freshwater fish from lakes in Russia, Japan, Switzerland, Germany, and the United States) can become cobalamin deficient when these long (10 m) adult worms in the jejunum avidly usurp cobalamin. After the worms have been expelled (with a single oral dose of praziquantel 10 to 20 mg/kg), cobalamin replenishment is curative.

Disorders of the Intrinsic Factor Receptors or Mucosa

Because the distal ileum has the greatest density of cubam receptors, the removal, bypass, or dysfunction of only 1 to 2 feet of terminal ileum can result in cobalamin malabsorption. Among drugs, the biguanides (e.g., metformin) decrease intrinsic factor and acid secretion and can inhibit the transenterocytic transport of cobalamin in up to a third of patients. This can be avoided by taking calcium (1.2 g/day). Other drugs (extended-release potassium chloride, cholestyramine, colchicine, neomycin) can also impair the transepithelial transport of cobalamin.

Acquired Cobalamin Deficiency

Nitrous oxide (N_2O) irreversibly inactivates cobalamin and results in a state of functional intracellular cobalamin deficiency, which can be bypassed by the administration of 5-formyl-THF (leucovorin). Although N_2O exposure during prolonged surgery can induce megaloblastosis, especially in those with marginal or low cobalamin stores, chronic intermittent (surreptitious, accidental, or occupational) exposure more frequently leads to neuromyelopathic manifestations, in which magnetic resonance imaging shows T2-weighted hyperintensity in affected areas of the spinal cord. Capsules used for making whipped cream are a cheap and easy source of N_2O in the community, and at one college, about 3% of students inhaled it monthly in an on-campus "nitrous club."

Folates

Normal Physiology

Absorption and Transport

In general, only half the folate in food, which is mainly in polyglutamylated form, is nutritionally available (bioavailable), whereas 85% of folic acid added to food or ingested as a supplement is bioavailable. The small intestine can

absorb folic acid unchanged, but food folate polyglutamates must be hydrolyzed to monoglutamate by folate polyglutamate hydrolase at the brush border before transport into enterocytes. A luminal surface, proton-coupled, folate transporter protein, which has a low pH optimum in the acid microclimate of the duodenum and jejunum, facilitates the efficient transport of folates into enterocytes, where it is reduced to THF and methylated before being released into plasma as methyl-THF. The normal serum folate level is maintained by dietary folate intake and by an efficient enterohepatic circulation.

From plasma, there is a rapid uptake of folate (methyl-THF and folic acid) into tissues by two physiologic transport processes for cellular entry. Membrane-associated folate receptors bind and take up physiologically relevant methyl-THF, folic acid, and some newer antifolates with high affinity at concentrations found in serum. Following folate receptor–mediated endocytosis, a proton-coupled folate transporter then helps export folate from acidified endosomes into the cytoplasm of cells and also into the cerebrospinal fluid (CSF). Another transporter (reduced folate carrier) is a low-affinity but high-capacity system that can also mediate the uptake of methyl-THF and pharmacologic folates (methotrexate and folinic acid well, but folic acid poorly) into a variety of cells. Passive diffusion also operates to transport folate across biologic membranes at supraphysiologic folate concentrations.

Cellular Retention and Excretion

Polyglutamylation of folate is the major factor in intracellular retention. After glomerular filtration, folate receptors on the brush border membranes of proximal renal tubular cells bind luminal folate and transport it back into blood.

Intracellular Metabolism and Cobalamin-Folate Interactions

After cellular uptake, methyl-THF must first be converted to THF via methionine synthase. Only then can the THF be polyglutamylated by folate polyglutamate synthase, which allows it to play a central role in one-carbon metabolism. THF can be converted to 10-formyl-THF, which can be used for de novo biosynthesis of purines, and to methylene-THF, which can be used for the synthesis of thymidylate.

The central role of methylene-THF is that it can be used either in the thymidylate cycle via thymidylate synthase for the synthesis of thymidine and DNA or in the methylation cycle via methionine synthase, but only after its conversion to methyl-THF by methylene-THF reductase. Inactivation of methionine synthase during cobalamin deficiency results in accumulation of the substrate methyl-THF, which cannot be polyglutamylated and thus leaks out of the cell, resulting in an intracellular THF deficiency and the reduction of one-carbon metabolism. This process explains why cobalamin deficiency responds to replacement with folic acid, which can be converted to THF via dihydrofolate reductase, or to replacement with 5-formyl-THF (folinic acid), which bypasses methionine synthase and can be converted to methylene-THF or 10-formyl-THF via intermediates.

Pathogenesis of Folate Deficiency

Folate deficiency can arise from decreased supply (reduced intake, absorption, transport, or utilization) or increased requirements (from metabolic consumption, destruction, or excretion). One individual may have multiple causes of folate deficiency, but specific tests to define each mechanism are not available clinically. Folate deficiency varies among different populations, and nutritional folate insufficiency is the most common cause worldwide in all age groups, with women and children in developing countries at highest risk. Although food folate fortification has dramatically reduced the prevalence of folate deficiency in the United States, it can still be found among some elderly, infirm, or socially isolated individuals with poor diets.

Nutritional Causes (Decreased Intake or Increased Requirements)

With an abrupt reduction in folate consumption, body stores of folate are adequate for approximately 4 months. However, these stores are depleted faster in individuals who chronically have a negative folate balance and often have multiple nutritional deficiencies (and diseases) that tip them into frank folate deficiency. A seasonal reduction in folate-rich foods, poverty, cultural or ethnic diets that are intrinsically low in folates, cooking techniques that destroy folate, and the anorexia that accompanies chronic illnesses are among the many reasons for folate deficiency, especially in developing countries.

Patients with hematologic diseases involving increased intrinsic cell proliferation or with increased compensatory erythropoiesis in response to chronic peripheral red blood cell destruction are at risk. Folate deficiency in the face of chronic hemolysis can lead to an acute reticulocytopenic (aplastic) crisis, an unexpected increase in transfusion requirements, or a fall in platelets. Exfoliative skin diseases (Chapter 446) also cause folate deficiency when there is an increased demand from excess loss of skin cells.

Pregnancy and Infancy

Poor folate intake during pregnancy is a very common cause of megaloblastic anemia in developing countries because pregnancy and lactation require additional folate for growth of the fetus and maternal tissues. Physiologic transplacental folate transport, which relies on the continued intake of adequate dietary folate by the mother, involves the capture of maternal folate by placental folate receptors, followed by displacement of this pool by dietary folates, a process that leads to transfer to the fetal circulation along a downhill concentration gradient. However, mothers with short intervals between pregnancies, with twin pregnancies, or with hyperemesis gravidarum are unable to maintain adequate folate stores, leading to premature, low-birthweight infants and other predominantly midline developmental abnormalities in the fetus. Low maternal folate status has also been associated with behavioral abnormalities (hyperactivity-inattention and peer problems) in offspring during early childhood. Autoantibodies to folate receptors in mothers have been linked to recurrent neural tube defects among some populations.

Cerebral folate deficiency can be caused by a mutation in folate receptors that perturbs folate transport into the CSF, leading to severe developmental regression in early childhood associated with movement disturbances, epilepsy, and leukodystrophy that is reversed by folinic acid. Alternatively, cerebral folate deficiency can be acquired when autoantibodies to folate receptors (which develop against consumed bovine milk folate-binding proteins that share epitopes with human folate receptors) bind to folate receptors on the choroid plexus and thereby reduce folate transport to the central nervous system. The folate receptor autoantibody titer decreases with the restriction of bovine milk intake but promptly increases upon rechallenge. Cerebral folate deficiency responds to high doses of folinic acid and a bovine milk–free diet. Reduction of folate transport to the central nervous system associated with folate receptor autoantibodies also occurs in two autism spectrum disorders: Rett syndrome and infantile low-functioning autism with neurologic abnormalities. High doses of oral folinic acid can normalize the CSF folate and lead to partial or complete clinical recovery in 12 months.

Hereditary folate malabsorption, an autosomal recessive syndrome, is due to a mutation in the proton-coupled folate transporter that results in the defective transport of folates across the small intestine and across the choroid plexus into the CSF. The proton-coupled folate transporter functions distal to folate receptors in the choroid plexus to facilitate folate transfer to the CSF, and a loss-of-function mutation of the proton-coupled folate transporter can independently interrupt physiologic folate delivery to the brain, despite intact folate receptors. The CSF/blood folate ratio in healthy humans is 3 : 1, but in those with hereditary folate malabsorption, CSF folate is very low or undetectable. Patients present with folate deficiency anemia, hypoimmunoglobulinemia with recurrent infections, chronic diarrhea, and neurologic abnormalities (seizures or mental retardation) that are irreversible if left untreated. High parenteral doses of folinic acid can ensure passive diffusion into the CSF and lead to significant clinical improvement in these children.

Tropical and Nontropical (Celiac) Sprue

With the development of intestinal mucosal abnormalities, patients are at increased risk for folate malabsorption. In tropical sprue (Chapter 142), a dramatic response to a 4- to 6-month course of oral folic acid (5 mg/day) plus tetracycline (250 mg four times a day) can effect a cure in 60% or more of patients. In the short term, malabsorption leads to folate deficiency, but later in the chronic phase of the disease (>3 years), malabsorption of cobalamin also develops. In addition, iron deficiency (Chapter 162), pellagra, and beriberi (Chapter 225) may coexist in these patients.

Drugs

Excess alcohol consumption at the expense of a balanced diet may be the most common cause of folate deficiency in the United States. Inhibition of dihydrofolate reductase by trimethoprim and pyrimethamine or methotrexate can be acutely reversed by the administration of 5-formyl-THF (folinic acid). Sulfasalazine induces megaloblastosis in two thirds of subjects taking full doses (>2 g/day) by decreasing the breakdown of folate polyglutamates to monoglutamates before absorption or by inducing Heinz body hemolytic anemia, which leads to increased requirements. Sulfasalazine, pyrimethamine, and proton pump inhibitors also inhibit the human proton-coupled

folate transporter, reducing folate absorption. Oral contraceptives may increase folate catabolism, whereas anticonvulsants can reduce absorption and induce microsomal liver enzymes. Antineoplastics and antiretroviral antinucleosides (azidothymidine) induce megaloblastosis by perturbing DNA synthesis.

CLINICAL MANIFESTATIONS

The finding of macrocytosis (increased mean corpuscular volume [MCV]) on a routine complete blood count may be the first clinical manifestation. In other patients, the findings may be dominated by the condition causing the deficiency of cobalamin or folate, such as malabsorption, alcoholism, or malnutrition (see Table 167-1).

The clinical manifestations of folate deficiency may include hematologic (pancytopenia with megaloblastic bone marrow), cardiopulmonary (secondary to anemia), gastrointestinal (megaloblastosis with or without malabsorption), dermatologic (hyperpigmentation of the skin, premature graying), genital (megaloblastosis of the cervical epithelium), infertility (sterility), and psychiatric (primarily a flat affect) symptoms. If patients have additional neurologic findings, other diseases that predispose to folate deficiency (e.g., alcoholism with thiamine deficiency) or associated cobalamin deficiency must be considered. Because megaloblastosis secondary to either folate or cobalamin deficiency results in functional folate deficiency, the hematologic manifestations of both deficiencies, including pancytopenia with megaloblastic bone marrow, are indistinguishable (see later). However, only cobalamin deficiency results in a patchy demyelinating process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord (Chapter 425). This widespread demyelination begins in the dorsal columns in the thoracic segments of the spinal cord and then spreads contiguously to involve the corticospinal tracts and later the spinothalamic and spinocerebellar tracts. Hematologic manifestations, neurologic manifestations, or both may dominate the clinical picture.

With chronic hyperhomocysteinemia associated with cobalamin or folate deficiency (or both), there may be additional clinical manifestations that stem from the fact that homocysteine is a risk factor for occlusive vascular diseases such as coronary artery disease, stroke, and peripheral arterial disease (Chapter 51), as well as arterial and venous thromboembolism (Chapters 81 and 179). Hyperhomocysteinemia is also associated with significant complications of pregnancy (preeclampsia, placental abruption or infarction, recurrent miscarriage) and poor pregnancy outcomes (preterm delivery, neural tube defects, congenital heart defects, intrauterine growth retardation). In addition, there is reduced bone mineral density, with an increased fracture risk, and a greater chance of small-vessel cerebrovascular disease–related stroke. Despite the failure of homocysteine-lowering therapy for the secondary prevention of atherosclerotic disease, this does not negate the risk. Several clinical conditions are benefited by folate supplementation or homocysteine-lowering therapy with combined folic acid, cobalamin, and pyridoxine.[1-7] By inference, patients can present clinically with any of these additional conditions when they have long-standing untreated hyperhomocysteinemia.

DIAGNOSIS

Diagnostic Approach to the Patient

The general approach to a patient with megaloblastic anemia is first to *recognize* that megaloblastic anemia is present; then to *distinguish* whether folate, cobalamin, or combined folate and cobalamin deficiencies have led to the anemia; and finally to diagnose the *underlying disease* and *mechanism* causing the deficiency (see Table 167-1).

Although deficiencies of cobalamin and folate are only two of the causes of macrocytosis, they become increasingly more likely as the MCV increases (see Fig. 167-2). Because perturbed DNA synthesis from any cause (including folate and cobalamin deficiency) results in megaloblastosis of bone marrow precursor cells, the red cells released into the circulation have an MCV that is often greater than 110 fL; on the peripheral blood smear, these large cells appear oval in shape (macro-ovalocytes). When compared with mature red cells, which normally have a central area of pallor that occupies about one third of the cell diameter, the central pallor of macro-ovalocytes is significantly reduced. Assessment of the corrected reticulocyte count is a good starting point to distinguish conditions in which macrocytes are not accompanied by megaloblastosis in the bone marrow (Fig. 167-2). On the hematoxylin-eosin–stained peripheral blood smear, reticulocytes, which are normally 20% larger than mature red cells, are recognized by their polychromatophilic staining; when they are prematurely released from the bone marrow during the stress of acute blood loss or hemolysis, these so-called shift reticulocytes are even larger. In liver disease, an altered lipid composition of the erythrocyte membrane results in an increased cell surface without a proportionate increase in volume; these so-called thin macrocytes are recognized on the peripheral blood smear by their larger area of central pallor (much greater than one third the cell diameter). Thin macrocytes are also found in the post-splenectomy state (because reticulocytes, which normally undergo a form of "remodeling" with a loss of membrane lipids during their maturation in the spleen, escape this process in splenectomized individuals).

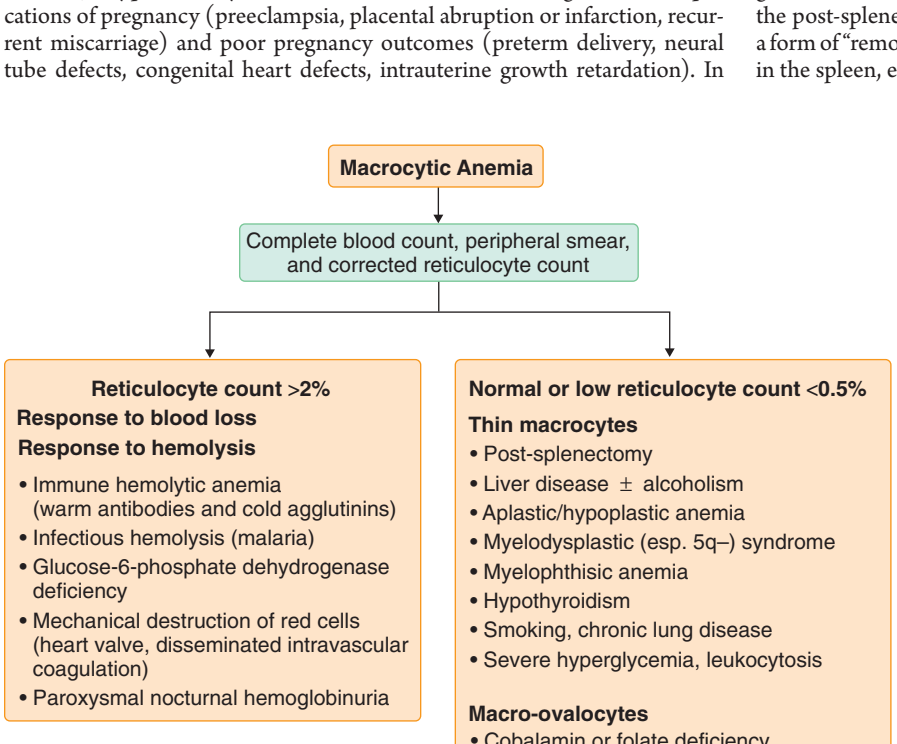

FIGURE 167-2. Algorithm for the evaluation of patients with macrocytosis.

The frequency with which a high MCV is found depends on the patient population studied. Thus, in a U.S. hospital, up to two thirds of cases of macrocytosis (MCV ≥100) can be due to drug therapy (chemotherapy, antiretroviral therapy) or alcoholism and liver disease. But in a developing country where a substantial percentage of the population is vegetarian or near-vegetarian, insufficient intake of cobalamin, folate, or both, with an associated iron deficiency resulting in a dimorphic anemia (with a large red cell distribution width from a mix of macrocytic and microcytic cells), would be common.

The underlying condition predisposing to the development of folate deficiency usually began within the previous 6 months and often dominates the overall clinical picture. Alcoholism can be identified as the basis for folate deficiency from the history and physical examination, but associated thiamine deficiency may result in a more complex manifestation, such as heart failure from cardiovascular disease ("wet beriberi") and peripheral neuropathy ("dry beriberi") with Wernicke-Korsakoff syndrome (Chapters 225 and 425). By contrast, cobalamin deficiency takes several years to manifest clinically. Therefore, the underlying condition is more chronic, symptoms develop more insidiously, and defining the cause is a clinical challenge.

History and Physical Examination

The dietary history may be revealing (food faddism, vegetarianism), whereas the medical or family history may uncover blood diseases, gluten sensitivity, autoimmune diseases, epilepsy treated with an anticonvulsant, use of offending drugs, previous hemolytic anemia, past surgery (e.g., gastrectomy, fistula, bowel resection), inhalation of N_2O, or a travel history predictive for tropical sprue.

Physical examination of cobalamin-deficient vegetarians or those with pernicious anemia may reveal well-nourished individuals. By contrast, patients with folate deficiency are poorly nourished and may have other stigmata of multiple deficiencies from malabsorption (Chapter 142). Associated deficiency of vitamins A, D, and K or protein-calorie malnutrition, or both, may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Varying degrees of pallor with lemon-tint icterus (a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis. The skin may reveal either a diffuse brownish pigmentation or abnormal blotchy tanning. Premature graying is observed in both light- and dark-haired individuals.

Examination of the mouth may reveal glossitis, with a smooth (depapillated), beefy-red tongue and occasional ulceration of the lateral surface. Thyromegaly may be observed with pernicious anemia and associated autoimmune thyroid disease, but it also raises suspicion for (nonmegaloblastic) macrocytosis related to hypothyroidism. The characteristic findings of heart failure from severe anemia may be accompanied by mild splenomegaly and extramedullary hematopoiesis.

In prolonged cobalamin deficiency, neurologic examination reveals evidence of involvement of the posterior columns as well as the pyramidal, spinocerebellar, and spinothalamic tracts. Posterior column dysfunction results in loss of position sense in the index toes (before great toe involvement) (Chapter 425) and loss of the ability to discern vibration of a high-pitched (256 cycles/second) tuning fork. Diminished vibratory sensation and proprioception of the lower extremities are the most common early objective signs. Neuropathic involvement of the legs precedes that of the arms. Upper motor neuron signs may be modulated by the subsequent involvement of peripheral nerves. A positive Romberg's sign and a Lhermitte's sign may be elicited. Loss of sphincter and bowel control or involvement of cranial nerves, such as optic neuritis, may be accompanied by other dysfunction of the cerebral cortex, including dementia, psychoses, and disturbances of mood. Folate deficiency in adults does not give rise to significant neurologic findings. Thus, the coexistence of folate deficiency with neurologic disease should prompt investigations to exclude cobalamin and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

Nutritional cobalamin deficiency in developing countries can manifest as florid pancytopenia, mild hepatosplenomegaly, fever, and thrombocytopenia, with the neuropsychiatric syndrome developing as a later manifestation. However, cobalamin-related neurologic disease has also been found in patients with only mild to moderate anemia secondary to cobalamin deficiency in both developing and developed countries. Between 25 and 50% of patients who have neuropsychiatric abnormalities attributable to cobalamin deficiency may have a normal hematocrit and MCV if they have adequate folate stores to protect them from hematologic abnormalities. In fact, in the United States, there is often an inverse correlation between the hematocrit and neurologic disease in cobalamin deficiency—most subjects have mild neurologic deficits, and 25% have only moderate deficits, with paresthesias or ataxia as the initial symptoms.

Laboratory Tests

Megaloblastosis

To establish the diagnosis of megaloblastosis, the evaluation begins with a complete blood count, MCV (which often reveals a steady increase over a period of several months or years), peripheral smear, and reticulocyte count; a low reticulocyte count with macro-ovalocytes suggests an underlying megaloblastic anemia (see Fig. 167-2). Classic megaloblastosis from cobalamin or folate deficiency may be accompanied by a hemoglobin level of less than 5 g/dL. Neutropenia and thrombocytopenia occur less commonly than anemia and are usually not severe. Occasionally, however, neutrophil counts less than 1000/μL and platelet counts less than 50,000/μL can be seen. Additional abnormalities supporting intramedullary hemolysis include elevated levels of serum lactate dehydrogenase and bilirubin, as well as decreased serum haptoglobin levels.

Peripheral Smear

In peripheral blood, the earliest manifestation of megaloblastosis is an increase in MCV with macro-ovalocytes (up to 14 μm). Nuclear hypersegmentation of neutrophils, diagnosed if more than 5% of polymorphonuclear leukocytes have five lobes or if more than 1% have six lobes on the smear (Fig. 167-3), strongly suggests megaloblastosis, especially when associated with macro-ovalocytosis. However, neutrophil hypersegmentation is not sensitive for the diagnosis of *mild* cobalamin deficiency, and macrocytosis is absent in nearly 50% of cases. There may be associated teardrop-shaped erythrocytes and anisocytosis with mild leukopenia and thrombocytopenia.

Megaloblastic anemia can be masked when there is a coexisting condition that neutralizes the tendency to generate large cells, such as iron deficiency (Chapter 162) or thalassemia (Chapter 165). In these situations, giant myelocytes and metamyelocytes in bone marrow and hypersegmented neutrophils in bone marrow and peripheral blood (see Fig. 167-3) are important clues to a masked megaloblastosis. This problem is clinically relevant because appropriate replacement with cobalamin or folate elicits a maximal hematologic response only when any associated iron deficiency is corrected. Conversely, if a combined iron and cobalamin deficiency (after gastrectomy) or iron and folate deficiency (with pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

Cobalamin and Folate Levels

Laboratory evaluation of suspected cobalamin or folate deficiency begins with measurement of the serum levels of these vitamins and then progresses to confirmatory tests (Table 167-2). Use of clinical information can improve the pretest probability of serum cobalamin and folate levels. Moreover, without detailed clinical information, the combined results of serum cobalamin, folate, and metabolite tests are not sufficiently unambiguous to diagnose and distinguish cobalamin deficiency from combined cobalamin plus folate deficiency.

Serum Cobalamin Levels

A low serum cobalamin level (<200 pg/mL) is a valuable (albeit relatively insensitive) indicator of cobalamin deficiency when compared with metabolite levels. Serum cobalamin is less than 300 pg/mL in 99% of patients with clinical hematologic or neurologic manifestations of cobalamin deficiency,

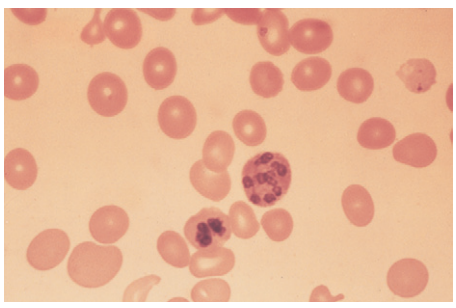

FIGURE 167-3. Megaloblastic anemia. The peripheral blood has oval macrocytes (large red blood cells) and marked neutrophil hypersegmentation.

TABLE 167-2 STEPWISE APPROACH TO THE DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCY

MEGALOBLASTIC ANEMIA *OR* NEUROLOGIC-PSYCHIATRIC MANIFESTATIONS CONSISTENT WITH COBALAMIN DEFICIENCY *PLUS* TEST RESULTS ON SERUM COBALAMIN AND SERUM FOLATE

Cobalamin (pg/mL)*	*Folate† (ng/mL)*	*Provisional Diagnosis*	*Proceed with Metabolites?‡*
>300	>4	Cobalamin/folate deficiency unlikely	No
<200	>4	Consistent with cobalamin deficiency	No
200-300	>4	Rule out cobalamin deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with combined cobalamin plus folate deficiency or with isolated folate deficiency	Yes
>300	2-4	Consistent with folate deficiency or with anemia unrelated to vitamin deficiency	Yes

TEST RESULTS ON METABOLITES: SERUM METHYLMALONIC ACID AND TOTAL HOMOCYSTEINE

Methylmalonic Acid (Normal = 70-270 nM)	*Total Homocysteine (Normal = 5-14 μM)*	*Diagnosis*
Increased	Increased	Cobalamin deficiency confirmed; folate deficiency still possible (i.e., combined cobalamin plus folate deficiency possible)
Normal	Increased	Folate deficiency likely; <5% may have cobalamin deficiency
Normal	Normal	Cobalamin and folate deficiencies excluded

*Serum cobalamin levels: abnormally low = <200 pg/mL; clinically relevant low-normal range = 200-300 pg/mL.
†Serum folate levels: abnormally low = <2 ng/mL; clinically relevant low-normal range = 2-4 ng/mL.
‡Any frozen-over sample from the serum folate or cobalamin determination can be subjected to metabolite tests.

whereas a cobalamin level greater than 300 pg/mL suggests folate deficiency or another cause of macrocytosis or neurologic disease.

About 90% of older patients with serum cobalamin levels less than 200 pg/mL show evidence of true tissue cobalamin deficiency, but individuals with neuropsychiatric disorders attributed to cobalamin deficiency may not have anemia and may have normal or only minimally depressed cobalamin levels. The serum cobalamin concentration is falsely low in the absence of true cobalamin deficiency in patients with folate deficiency (one third of patients), pregnancy, multiple myeloma, transcobalamin I deficiency, megadose or vitamin C therapy, or when the serum contains other radioisotopes (e.g., ^{99m}Tc, ^{67}Ga, ^{125}I) from organ scanning.

A falsely raised cobalamin level in the presence of a true cobalamin deficiency leads to clinical manifestations if uncorrected. Examples include an artificial increase in transcobalamin I and II, which can occur with myeloproliferative disorders, hepatomas, and fibrolamellar hepatic tumors; when transcobalamin II–producing macrophages are activated in autoimmune diseases, monoblastic leukemias, and lymphomas; and on the release of cobalamin from hepatocytes during active liver disease in cobalamin-deficient patients. Studies suggest that approximately 10% of the U.S. population, especially the elderly, have true cobalamin deficiency manifested by low or low-normal serum cobalamin levels, as well as elevated levels of serum methylmalonic acid (MMA) and homocysteine that fall to normal with cobalamin therapy.

Serum Folate Levels

When combined with a clinical picture of megaloblastic anemia and the measurement of cobalamin levels, serum folate is the cheapest and best initial biochemical test to diagnose folate deficiency. Although red blood cell folate levels by microbiologic assay correlate well with hepatic folate stores, they are not widely available, and the newer radioisotopic or colorimetric assays are too unreliable for routine clinical use.

The serum folate level is highly sensitive to the intake of a single folate-rich meal. Nutritional folate deficiency first leads to a decline in the serum folate level below normal (<2 ng/mL) in about 3 weeks; thus, it is a sensitive indicator of negative folate balance. Isolated reduction of serum folate in the absence of megaloblastosis (i.e., a false-positive result) occurs in one third of hospitalized patients with anorexia and acute alcohol consumption, in normal pregnancy, and in those using anticonvulsants; because these groups are also at high risk for folate deficiency, additional testing with metabolites or an empirical therapeutic trial may be required. Conversely, in 25 to 50% of alcohol abusers (Chapter 32) with folate deficiency, serum folate levels may be low normal or borderline low.

Metabolite Levels—Homocysteine and Methylmalonic Acid

The serum homocysteine and MMA values rise in proportion to the severity of deficiency (see Table 167-2). Although serum MMA and homocysteine tests are the "gold standard" for confirming the diagnosis of cobalamin deficiency, they are too expensive to use for screening. Serum MMA levels are elevated in more than 95% of patients with clinically confirmed cobalamin deficiency (with median values of 3500 nM). Serum homocysteine concentrations are elevated in both cobalamin deficiency (median values of 70 μM) and folate deficiency (median values of 50 μM). Both homocysteine and MMA rise with dehydration or renal failure. Propionic acid, derived from anaerobic fecal bacterial metabolism, can also contribute to MMA values, which can be lowered by a course of metronidazole. Thus, although these metabolites can help distinguish between isolated cobalamin and folate deficiency, an increase in both metabolites cannot differentiate between isolated cobalamin deficiency and combined cobalamin plus folate deficiency. The abnormally high metabolites return to normal in a week when replaced with the appropriate (deficient) vitamin.

Clinicians can use serum MMA and homocysteine to assist in the diagnosis in patients with (1) borderline cobalamin and folate levels; (2) existing conditions known to perturb folate and cobalamin tests, leading to difficulties in interpreting the results; (3) low levels of both cobalamin and folate, in which case a high MMA level is useful to confirm cobalamin deficiency (rather than attributing the condition to folate deficiency alone); and (4) low serum cobalamin levels when there is an alternative explanation for the syndrome that led to the test (e.g., a diabetic or alcoholic patient with peripheral neuropathy or an alcoholic patient with a high MCV and low cobalamin level without anemia). In the context of diagnosing a subclinical deficiency of cobalamin (or folate) based on increased serum MMA or homocysteine (or both) despite normal serum cobalamin (or folate) levels, a positive diagnosis can be made only after reversal of laboratory values following treatment with cobalamin (and/or folate) has been demonstrated.

Bone Marrow Examination

In florid hematologic disease with or without neurologic disease suggestive of cobalamin or folate deficiency, the identification of nucleated red cells with megaloblastic changes in the peripheral smear—which reflects the morphology in the bone marrow—can clinch the diagnosis of megaloblastosis. If not found, a bone marrow aspirate can be invaluable in making the rapid diagnosis of megaloblastosis. However, in the outpatient setting, when there is less urgency because the anemia is mild to moderate and the patient has a suggestive peripheral smear, or when the manifestation is primarily neuropsychiatric, a good case can be made to initiate the sequence of diagnostic tests without bone marrow aspiration and proceed with the measurement of serum levels of vitamins or metabolites (see Table 167-2 and Fig. 167-2).

In a bone marrow aspirate (Fig. 167-4), which is better than biopsy for observing megaloblastosis, the cells are actually proliferating very slowly despite what looks like exuberant cell proliferation with numerous mitotic figures. In early cobalamin or folate deficiency, normoblasts may dominate the marrow, with only a few megaloblasts seen, but the full spectrum of megaloblastic hematopoiesis is observed in florid deficiency and is accompanied by varying degrees of pancytopenia. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, sieve-like pattern. The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large, sieve-like immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. The majority of megaloblastic cells (80 to 90%) die in the bone marrow and are scavenged by macrophages in a process called *ineffective erythropoiesis* or *intramedullary hemolysis*. There is an

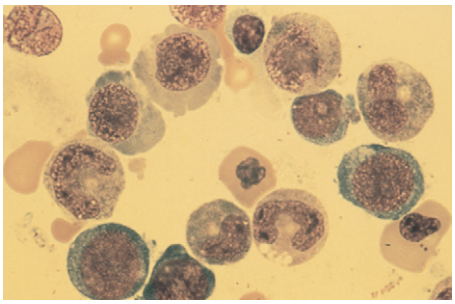

FIGURE 167-4. Megaloblastic anemia. A bone marrow aspirate shows red blood cell precursors that are giant megaloblasts with nuclear-cytoplasmic dissociation (nuclear maturation lagging behind cytoplasmic maturation). Megaloblastic changes in the leukocyte series are shown by the "giant metamyelocyte."

absolute increase in leukopoiesis, with megaloblastic cells also having a sieve-like chromatin. Giant (20 to 30 μm) metamyelocytes and "band" forms are pathognomonic for megaloblastosis. Hypersegmented polymorphonuclear leukocytes may be seen in the marrow and peripheral blood. Megakaryocytes may be normal or increased in number and can exhibit complex hypersegmentation, with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is decreased in severe megaloblastosis.

Determining the Cause of the Vitamin Deficiency

By the time the megaloblastic state is established, the cause of the folate deficiency is usually clear from the history, physical examination, and clinical setting. With rare exceptions, adults with cobalamin deficiency have either cobalamin malabsorption or dietary cobalamin insufficiency. All these conditions can be treated similarly with either monthly parenteral cobalamin or daily oral cobalamin. However, identifying the likely basis for malabsorption can point to the need for additional diagnostic tests (e.g., intestinal biopsy, examination of stool for malabsorption or *D. latum* infestation) and specific therapy (e.g., gluten-free diet, folate, antibiotics, anthelmintics). This evaluation, in turn, indicates whether cobalamin replacement should be lifelong. At this juncture in the diagnostic evaluation, the Schilling test, which was discontinued in 2003, once provided invaluable information on the locus and mechanism of cobalamin malabsorption. Now, only 60% of patients with pernicious anemia can be confidently identified through the measurement of serum anti–intrinsic factor antibodies. However, because most of the conditions predisposing to cobalamin deficiency (see Table 167-1) should be clinically evident by the time cobalamin deficiency is apparent, it is possible to identify several conditions through a detailed dietary history or past medical history that suggests esophagogastroduodenal disease, pancreatic insufficiency, impaired bowel motility, or other autoimmune diseases. The physical examination can provide additional clues and suggest focused testing for rarer conditions (stool for ova, anti–tissue transglutaminase antibodies, lipase, gastrin, intestinal biopsy, or radiographic contrast studies for stasis, strictures, or fistulas). For the younger patient with megaloblastic anemia, juvenile pernicious anemia and congenital intrinsic factor deficiency warrant the measurement of gastric juice for intrinsic factor and achlorhydria and DNA for mutations in cubam receptor (amnionless, cubulin genes) for hereditary megaloblastic anemia and Immerslund-Gräsbeck syndrome.

Measurement of a rise in blood holo-transcobalamin (cobalamin-bound transcobalamin II) levels after the administration of oral cobalamin can indicate the absorption of orally administered doses of cobalamin in otherwise healthy individuals or vegetarians; however, this test must still be clinically validated among various cohorts of patients with cobalamin malabsorption (see Table 167-1).

TREATMENT

Rx

First, blood is drawn for a determination of serum folate and cobalamin levels (and enough for the measurement of metabolite levels later, if indicated), and bone marrow aspiration is performed, if necessary, to confirm megaloblastosis. If the patient is decompensated or decompensation is imminent, the patient is then transfused slowly with 1 U of packed red cells; diuretics are administered, if necessary; and both cobalamin and folate are started at full doses. If the patient is moderately symptomatic, transfusions should be avoided because a dramatic improvement in well-being is likely to occur within 2 to 3 days of starting appropriate vitamin replacement, even before hematologic improvement. If the patient is well compensated or is in the ambulatory setting, diagnostic testing should proceed in an orderly sequence (see Fig. 167-2 and Table 167-2) before initiating therapy.

Drug Dosage

Therapy with full doses of parenteral cobalamin (1 mg/day) and oral folate (folic acid 1 to 5 mg) before the type of vitamin deficiency has been established should be reserved for severely ill patients. An aggressive scheme to replace cobalamin rapidly is 1 mg/day of intramuscular or subcutaneous cyanocobalamin (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg/month for life. Because 1 to 2% of an oral dose is absorbed by passive diffusion, even in patients with malabsorption of physiologic cobalamin for any reason, an equally effective alternative to maintenance therapy with monthly cobalamin injections is the daily administration of 2-mg cobalamin tablets orally after rapidly replenishing cobalamin parenterally. In patients with malabsorption of food-bound cobalamin, cobalamin doses of 1 mg/day are required. For patients with nutritional cobalamin deficiency (vegetarians) without absorptive problems, after cobalamin stores are replenished with 2 mg/day of oral cobalamin for at least 3 months, smaller oral cobalamin doses of 5 to 10 μg, using tablets or equivalent cobalamin-fortified foods, taken for life, are sufficient.

Subclinical cobalamin deficiency does not inexorably progress to clinical cobalamin deficiency; indeed, mild or borderline abnormal biochemical results tend to remain unchanged, fluctuate above or below normal values, or even spontaneously resolve. Some physicians follow these patients and treat them with cobalamin only when they exhibit symptoms or signs of frank cobalamin deficiency. Others err on the side of caution, preferring to preemptively replenish depleted cobalamin stores; these patients are treated for 6 months with high-dose daily oral cobalamin (1 mg), and then serum cobalamin levels are followed.

Oral folate (folic acid) at doses of 1 to 5 mg/day results in adequate absorption despite intestinal malabsorption of physiologic food folate. Therapy should be continued until complete hematologic recovery is documented; the subsequent duration of therapy is dictated by the cause. Folinic acid bypasses any block in one-carbon metabolism induced by methotrexate, trimethoprim-sulfamethoxazole, or N_2O.

Prophylaxis with Cobalamin or Folate

Cobalamin must be given to infants of cobalamin-deficient mothers, as well as to patients who have undergone total gastrectomy. For vegetarians, cobalamin-fortified foods (soy or rice beverages, fortified cereals, nutritional yeast) or oral cobalamin tablets 5 to 10 μg/day should suffice. For those with malabsorption of cobalamin from any other mechanism (see Table 167-1), cobalamin replacement is achieved with 1- to 2-mg tablets taken orally each day.

Periconceptional folate supplementation for all normal women (400 μg/day of folic acid) and for women who have previously delivered a baby with a neural tube defect (4 mg/day of folic acid) is now standard and prevents nearly three quarters of neural tube defects. Women of childbearing age who are taking anticonvulsant medications (phenytoin, phenobarbital, carbamazepine) are also at increased risk for delivering babies with neural tube defects and should routinely take 1 mg of folic acid daily. Folate supplementation throughout pregnancy also helps prevent premature delivery of low-birthweight infants and is recommended for premature infants and lactating mothers. Folic acid supplements (1 mg/day orally) are taken by patients with hemolysis or myeloproliferative diseases and to reduce the toxicity of methotrexate in patients with rheumatoid arthritis and psoriasis. Individuals in whom cobalamin deficiency develops while undergoing long-term folate replacement have a pure neurologic syndrome.

The mandatory fortification of food (flour, enriched pasta, cornmeal, cereal foods) with 140 and 150 μg of folic acid per 100 g in the United States and Canada, respectively, has led to several beneficial effects (Table 167-3). Indeed, 94% of U.S. adults who do not consume supplements or consume less than 400 μg/day of folic acid from supplements do not exceed the upper intake limit for folic acid (>1 mg/day), which has potential to mask cobalamin deficiency.

PROGNOSIS

The general response to cobalamin replacement is a dramatic improvement in well-being, with alertness, a good appetite, and resolution of a sore tongue. Megaloblastic hematopoiesis reverts to normal within 12 hours and resolves by 48 hours; the only persistent findings may be giant metamyelocytes in the bone marrow and hypersegmented neutrophils in the blood for up to 14 days. The reticulocyte count peaks by days 5 to 8, followed by a rise in the red cell count, hemoglobin level, and hematocrit. By the end of the first week, the white blood cell count rises, sometimes with a transient left shift, as does the platelet count; both normalize by approximately 2 months.

TABLE 167-3 BENEFICIAL EFFECTS OF HOMOCYSTEINE-LOWERING THERAPY ON NONHEMATOPOIETIC SYSTEMS

FOLIC ACID, COBALAMIN, PYRIDOXINE SUPPLEMENTATION
Reduction in hip fracture[1]
Reduction in progression of carotid intima media thickness (surrogate marker of early subclinical arteriosclerosis)[2]
Reduction in age-related macular degeneration[3]
FOLIC ACID SUPPLEMENTATION
Reduction in stroke[4]
Reduction in rate of cognitive decline among healthy elderly[5]
Reduction in age-related (sensorineural) hearing loss[6]
Reduction in recurrence of neural tube defects[7]
FOLIC ACID FORTIFICATION OF FOOD (POPULATION-BASED STUDIES)
Reduction in neural tube defects (anencephaly, spina bifida, encephalocele, meningocele, iniencephaly)
Reduction in cleft lip with or without cleft palate
Reduction in severe congenital heart disease (endocardial cushion defects, conotruncal defects)
Reduction in congenital pyloric stenosis, stenosis of the pelvicoureteric junction, limb reduction defects, omphalocele
Reduction in stroke mortality
Decreased risk of low-birthweight and small-for-gestational-age babies

With cobalamin replacement, the degree of reversal of neurologic damage is generally inversely related to the extent of disease and the duration of signs and symptoms. Most neurologic abnormalities improve in up to 90% of patients with documented subacute combined degeneration, and most signs and symptoms of less than 3 months' duration are reversible. With signs and symptoms of longer duration, there is invariably some residual neurologic dysfunction. The maximal response often takes up to 6 months, but recovery beyond 12 months is unusual.

Incorrect treatment of cobalamin deficiency with folate does not improve the neuropsychiatric abnormalities, which will continue to progress; hematologic improvements often occur, however. Alternatively, there may be associated iron deficiency or hypothyroidism that needs treatment or another hemoglobinopathy (e.g., sickle cell disease, thalassemia) that limits the normalization of hemoglobin values.

In patients with pernicious anemia, subsequent iron deficiency anemia (Chapter 162), osteoporosis (Chapter 251) with fractures of the proximal end of the femur and vertebrae, gastric cancer (Chapter 198), and cancer of the buccal cavity and pharynx can develop. Some experts recommend periodic endoscopic surveillance.

168 APLASTIC ANEMIA AND RELATED BONE MARROW FAILURE STATES

GROVER C. BAGBY

DEFINITION

Aplastic anemia is a life-threatening syndrome characterized by failure of the bone marrow to produce peripheral blood cells and their progenitors. Diverse diseases and environmental factors can cause this syndrome, but its hallmark is bone marrow hypocellularity and hypoplasia of the erythroid, myeloid, and megakaryocyte lines (Fig. 168-1).

EPIDEMIOLOGY

In Europe and North America, the annual incidence is 2 per 1 million persons, and in Asia, 4 to 7 per 1 million. No age group is exempt, and although the syndrome occurs most often in young adults, the age distribution of newly diagnosed patients is bimodal, with peaks at 15 to 25 years and at 60 to 65 years.

PATHOBIOLOGY

Pathology

Peripheral blood pancytopenia is universally present in patients with aplastic anemia, but bone marrow biopsy is required to establish the diagnosis. The diagnosis will be clear-cut if the biopsy specimen is of sufficient size and has been obtained from an anatomic site that has never been exposed to extensive trauma or radiation. As shown in Figure 168-1B, some residual lymphoid cell populations can be found in marrow specimens. Although these lymphoid cells may be of pathophysiologic importance, it is the absence of *nonlymphoid* hematopoietic cells that is important in establishing the diagnosis of this syndrome. However, if the hematopoietic marrow has been suppressed (or "replaced") by the infiltration of neoplastic cells or fibroblasts, the diagnosis of aplastic anemia cannot be made. Therefore, the diagnosis requires not only a dearth of hematopoietic cells in the marrow but also an empty bone marrow.

Some bone marrow failure syndromes affect only one lineage. In those cases, only the marrow precursors of that lineage are missing. In patients with agranulocytosis, for example, there are rare neutrophils and neutrophil precursors present, and the ratio of erythroid to myeloid cells is very high. Likewise, in patients with the disorder known as pure red cell aplasia, few erythroid cells are detectable in the marrow, but the other lineages are well represented and functional. These two disorders are examples of bone marrow failure syndromes but are not examples of aplastic anemia, which involves global suppression of all hematopoietic lineages.

Pathophysiology

Marrow aplasia in a few patients (10%) can be attributed to an inherited bone marrow failure syndrome, but most cases are acquired and caused by factors other than an inherited gene mutation. In all cases, it is clear that the causative factors, genetic or environmental, injure pluripotent hematopoietic stem cells. This is in contrast to the case of the lineage-restricted disorders ,wherein the causative agents and factors suppress the growth and development of unipotent progenitor cells committed to that particular lineage. Radiation, viral diseases, cytotoxic drugs, and chemicals are known causes of aplastic anemia, but the most common form of acquired aplastic anemia is immunologically mediated, and evidence is emerging that some marrow failure states attributed to viral infection or to idiosyncratic drug reactions may also result

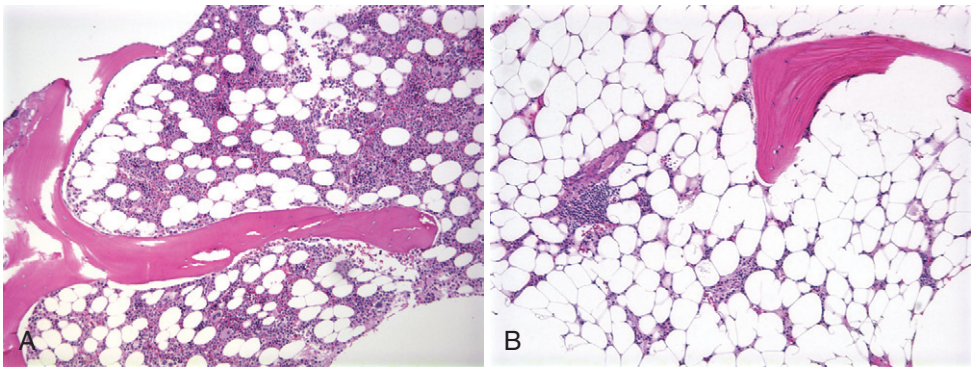

FIGURE 168-1. Two bone marrow biopsy samples from different patients. A. This specimen, from a normal individual, shows an abundance of hematopoietic cells, including myeloid and erythroid precursors and normal-appearing megakaryocytes. **B,** A specimen from a patient with severe aplastic anemia shows few detectable hematopoietic cells, and those that can be seen (one small nest) are largely lymphocytes. Lymphoid cells are often detectable and probably play an important pathophysiologic role in many cases of acquired idiopathic aplastic anemia, a disorder that is most often immunologically mediated. (Courtesy of Dr. Ken Gatter, Oregon Health and Science University.)

   b. Paroxysmal nocturnal hemoglobinuria
   c. Inherited bone marrow failure syndromes

from immune suppression of hematopoiesis. The pathogenesis of the major causes of aplastic anemia and related bone marrow failure states is outlined in Table 168-1.

Pathogenesis

Autoimmune Aplastic Anemia

Acquired Aplastic Anemia

In patients with the most common form of acquired aplastic anemia, autologous lymphocytes suppress the replicative activity and induce the death of hematopoietic stem and progenitor cells. Evidence supporting this model are to be found in studies demonstrating that: (1) removal of T lymphocytes from cultured bone marrow cells enhances hematopoiesis in vitro; (2) patients with aplastic anemia can be effectively treated with immunosuppressive therapy alone; (3) oligoclonal T cells in the marrow and blood of aplastic anemia patients contain high intracellular levels of the myelosuppressive cytokines interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α); (4) the IFN-γ/TNF-α-positive T-cell populations are suppressed in patients who respond to immunosuppressive therapy but are not suppressed in patients who do not respond; and (5) the syndrome can be modeled in mice by infusing alloreactive lymphocytes that induce marrow failure.

Drug Induced

Although a wide variety of drugs have been associated with aplastic anemia, the association is loose. Much of the evidence is circumstantial and, apart from drugs that are known to be directly toxic to the marrow (e.g., chemotherapeutic agents; Table 168-2), the cases are not related to total dose of the suspect agent. These "idiosyncratic" reactions are likely autoimmune. Some agents, chloramphenicol being the classic paradigm, are capable of inducing dose-related myelosuppression in all treated patients (which abates after discontinuation of the drug) and rare idiosyncratic aplastic responses as well (which do not remit after discontinuation of the agent). Drugs that have been repeatedly associated with aplastic anemia are listed in Table 168-2.

Infections

HEPATITIS. About 2 to 5% of patients with severe aplastic anemia have had viral hepatitis (Chapters 150 and 151). Some cases were associated with hepatitis A or B, but most patients with the hepatitis-aplasia syndrome have had hepatitis of unclear type (non-A, -B, -C, -E, or -G). Most patients with this syndrome are younger than 20 years. The natural course is rapid, with a 1-year mortality rate of more than 90%. The immune system is likely involved in the pathophysiology of this syndrome because immunosuppressive therapy has been reported to induce meaningful remissions.

EPSTEIN-BARR VIRUS. In rare patients with aplastic anemia, evidence of active Epstein-Barr virus (EBV) infection has been discovered (Chapter 385). Because the virus does not infect progenitor cells or stem cells, it is most likely that the virus induces an aberrant immune response that generates either immunoglobulin- or T-lymphocyte–mediated hematopoietic suppression. Because only a minority of EBV-infected aplastic patients describe a history of typical infectious mononucleosis, it is equally likely that the aplastic state came first and that EBV was later reactivated.

Autoimmune-Mediated Failure of Single Hematopoietic Lineages

Agranulocytosis

Agranulocytosis is characterized by severe neutropenia and suppression of granulopoiesis. This disorder can be an idiosyncratic reaction to certain drugs and most likely involves immune suppression of granulopoietic progenitor cells. The disease almost always abates when the offending drug is discontinued. Agranulocytosis also occurs in patients with established autoimmune diseases, including systemic lupus erythematosus, Sjögren's syndrome, and rheumatoid arthritis. In some cases, the disorder is caused by myelosuppressive antibodies, and in others, by T lymphocytes that suppress granulopoiesis. Immunosuppressive therapy is often effective in such patients and should be used in patients whose agranulocytosis is severe and associated with recurrent infections.

Pure Red Cell Aplasia

Severe normochromic, normocytic anemia with a marked decrease in reticulocyte number is sometimes associated with selective hypoplasia of the erythroid marrow without loss of megakaryocytes and myeloid precursor cells. In immunocompromised hosts and patients with chronic hemolytic diseases, this disorder, known as pure red cell aplasia, can be caused by parvovirus B19 infection (Chapter 379), an agent that infects erythroid precursor cells and likely generates an erythroid suppressive immune response. This disease can also be mediated by T lymphocytes or natural killer cells that suppress cells of the erythroid lineage and in more uncommon cases by antibody-dependent

TABLE 168-2 DRUGS AND TOXINS ASSOCIATED WITH APLASTIC ANEMIA

DOSE DEPENDENT

Antineoplastic Agents

Antimetabolites: fluorouracil, mercaptopurine, 6-thioguanine, methotrexate, cytosine arabinoside, gemcitabine, fludarabine, cladribine, pentostatin, hydroxyurea

Alkylating and cross-linking agents: busulfan, cyclophosphamide, chlorambucil, nitrogen mustard, melphalan, cisplatin, carboplatin, ifosfamide, nitrosoureas (BCNU and CCNU), mitomycin C

Cytotoxic antibiotics: daunorubicin, doxorubicin, mitoxantrone

Plant alkaloids: vinblastine, paclitaxel

Topoisomerase inhibitors: etoposide

Antimicrobial Agents

Chloramphenicol, dapsone, fluorocytosine

Anti-Inflammatory and Antirheumatic Agents

Colchicine

Insecticides

Chlordane, chlorophenothane (DDT), lindane, parathion

Other Chemicals

Benzene

Benzene-containing chemicals: kerosene, chlorophenols, carbon tetrachloride

DOSE INDEPENDENT

Idiosyncratic, likely immune mediated

(*Note:* Most agents on this list should be considered to be possibly associated with aplastic anemia.)

Antimicrobial Agents

Chloramphenicol, dapsone, sulfonamides, tetracycline, methicillin, amphotericin, quinacrine, chloroquine, pyrimethamine

Anticonvulsants

Hydantoins, carbamazepine, phenacemide, primidone, ethosuximide

Anti-Inflammatory Agents

Phenylbutazone, indomethacin, ibuprofen, oxyphenylbutazone, sulindac, naproxen

Antiarrhythmic Drugs

Quinidine, tocainide, procainamide

Metals

Gold, arsenic, mercury, bismuth

Antihistamines

Cimetidine, ranitidine, chlorpheniramine, pyrilamine, tripelennamine

Diuretics

Acetazolamide, furosemide, chlorothiazide, methazolamide

Hypoglycemic Agents

Chlorpropamide, tolbutamide

Antithyroid Drugs

Propylthiouracil, potassium perchlorate, methylthiouracil, methimazole, carbimazole

Antihypertensive Agents

Methyldopa, enalapril, captopril

Sedatives

Chlordiazepoxide, chlorpromazine, meprobamate, prochlorperazine

suppression of erythropoiesis. Pure red cell aplasia can also develop as a complication of thymoma (Chapters 99 and 430) and in these circumstances is likewise caused by oligoclonal T-cell expansion that specifically suppresses erythroid progenitor cells. This disorder can also be associated with drug exposure (e.g., isoniazid, chlorpropamide, and phenytoin), lymphoid neoplasms (chronic lymphocytic leukemia; Chapter 190), and myelodysplasia (Chapter 188). Rarely, adults with Diamond-Blackfan anemia present with isolated erythroid suppression, but the degree to which the erythroid marrow is suppressed rarely matches the profound suppression seen in acquired cases of immune-mediated pure red cell aplasia.

Direct Stem Cell Toxicity

Radiation

The severity of myelosuppression induced by radiation and the degree to which the marrow can recover from that injury depend on the radiation dose, the timing of exposure, and the fraction of hematopoietic tissues exposed. Low-dose total body radiation causes transient marrow suppression. High doses of total body radiation (700 to 1000 cGy) induce severe injury to the stem cell pool with persistent and life-threatening marrow failure. When limited bone marrow sites are radiated to very high doses (4000 cGy or more), the relatively radioresistant bone marrow stromal cells are eradicated, and thereafter that marrow space can never support hematopoietic activity.

Chemicals

Benzene suppresses the bone marrow in a dose-dependent manner, and chronic exposure to it has been linked with aplastic anemia and myeloid leukemogenesis. Benzene and many of its catabolites are directly toxic to stem cells, damage DNA, suppress the supportive function of the bone marrow microenvironment, and accentuate the responsiveness of hematopoietic progenitor cells to intramedullary apoptotic cues that arise during the inflammatory response. Kerosene, carbon-tetrachloride, and chlorophenols contain benzene, as do many other like products used for paint stripping, refinishing, and degreasing (see Table 168-2).

Drugs

Many agents in use for the treatment of malignant diseases are predictably myelosuppressive and can induce aplastic anemia because they are directly toxic to stem and progenitor cells in the marrow (see Table 168-2). These myelosuppressive responses are completely predictable and dose dependent. In practical terms, unless the patient receives a drug overdose or has an undiagnosed genetic disorder that predisposes the patient to respond to the agent in an exaggerated way (e.g., Fanconi anemia [FA]), most patients treated for neoplastic diseases develop reversible bone marrow aplasia or hypoplasia and recover bone marrow function within a matter of days.

Other Aplastic States

Pregnancy

Aplastic anemia can be diagnosed in pregnancy. In addition, some patients with aplastic anemia have become pregnant after the diagnosis. The prognosis in both instances is poor, and most fatal outcomes are due to bleeding complications. Some women, who have been fortunate enough to recover bone marrow function postpartum, develop aplastic anemia with a subsequent pregnancy. The pathogenesis and causal relationship between pregnancy and aplastic anemia remain unknown but may reflect immunologic activation during pregnancy.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder that results from the expansion of a clone of hematopoietic stem cells whose progeny are incapable of anchoring essential proteins to their membranes (Chapter 163). The defect is caused by an inactivating somatic mutation of *PIGA*, an X-linked gene that encodes a protein essential for synthesis of the membrane anchor glycosyl phosphatidylinositol (GPI). Some of the GPI-anchored proteins (e.g., CD55 and CD59) are important in normal red cells to protect them from activated complement. Their loss results in chronic intravascular hemolysis. Two less clearly defined features of PNH are thromboembolism, of which there is a very high relative risk in the PNH patient population (Chapter 179), and aplastic anemia. The emergence of "PNH clones" is not uncommon in patients with acquired aplastic anemia, and experimental evidence supports the idea that the evolution of *PIGA*-deficient stem cells is an adaptive response to the immune attack. How the *PIGA*-deficient cells fend off cytotoxic T cells is less clear, but it is likely that their pool expands because they accomplish that task somehow. In effect, in the setting of an immune attack, *PIGA*-deficient stem cells are more fit than normal stem cells, but the complement-sensitive red cells to which they give rise have a short lifespan.

Inherited Bone Marrow Failure Syndromes

Some inherited bone marrow failure syndromes can present in adolescence and adulthood. They include dyskeratosis congenita, Fanconi anemia (FA), and Diamond-Blackfan anemia. The molecular pathogenesis of the bone marrow failure seen in these diseases is unclear. Although the genetic basis of these disorders has been well defined in the past decade, the canonical functions of the proteins encoded by these genes is distinct (Table 168-3) for each disease. For example, in dyskeratosis, the mutations occur in genes that encode proteins and RNAs involved in telomere maintenance. In FA, the mutations involve proteins involved in the DNA-damage response, and in

TABLE 168-3 DISTINGUISHING CLINICAL FEATURES OF THE INHERITED BONE MARROW FAILURE SYNDROMES THAT MAY BE INITIALLY DIAGNOSED IN ADULTHOOD

DISTINGUISHING FEATURES	*Diseases*		
	FANCONI ANEMIA	**DYSKERATOSIS CONGENITA**	**DIAMOND-BLACKFAN ANEMIA**
History	Skeletal and renal malformations, low birthweight, pancytopenia, family member with bone marrow failure, myelodysplasia (MDS), acute myelogenous leukemia (AML), or squamous cell carcinoma at an early age. Family member with Fanconi anemia	Intrauterine growth retardation, developmental delay, and short stature. Family history of MDS, AML, marrow failure, abnormal fingernails or toenails, leukoplakia, head and neck cancer, or pulmonary fibrosis	Low birthweight, arm and thumb deformities at birth
Physical findings	Thumb and radial malformations, hyperpigmented skin lesions (cafe au lait spots), short stature, MDS, AML, squamous cell carcinoma at young age, renal and cardiac malformations, microcephaly, hypogonadism	Lacy reticular pigmentation of skin, dystrophic fingernails and toenails, premature graying of hair, hair loss, short stature, oral leukoplakia, squamous cell cancer of head and neck, pulmonary fibrosis, osteopenia, hypogonadism	Triphalangeal thumbs, short stature, arm anomalies
Genes inactivated	*FANCA, FANCB, FANCC, FANCD1* (aka *BRCA2), FANCD2, FANCE, FANCF, FANCG* (aka *XRCC9), FANCI, FANCJ* (aka *BACH1* and *BRIP1), FANCL* (aka *PHF9* and *POG), FANCM* (aka *Hef),* and *FANCN* (aka *PALB2)* These genes encode proteins known to protect the genome from excessive damage induced by chemical crosslinking agents. These genes account for most cases of Fanconi anemia.	*DKC1, TERC, TERT, TINF2, NOLA2,* and *NOLA3* These genes encode proteins known to participate in maintenance of telomeres. They account for only half of dyskeratosis cases, so there are additional genes to be discovered.	*RPS17, RPS19, RPS24, RPL5, RPL11,* and *RPL35A* These genes encode ribosomal proteins. They account for only half of cases, so there are additional genes to be discovered.
Screening and diagnostic tests	1. Chromosomal breakage test (in response to mitomycin C or diepoxybutane) 2. Complementation analysis (flow cytometric analysis of G_2 arrest in melphalan-exposed cells after transduction with retroviral vectors expressing normal Fanconi anemia genes) 3. Gene sequencing	1. Quantitative analysis of telomere length ("flow FISH") 2. Gene sequencing	*Note:* Isolated erythroid failure is more common than full blown aplastic anemia. 1. There are no screening tests, although serum ADA is often elevated. 2. Gene sequencing

ADA = adenosine deaminase; FISH = fluorescent in situ hybridization.

Diamond-Blackfan anemia, inactivating mutations involve ribosomal proteins known to be involved in ribosome biogenesis. Whether loss of these canonical functions is linked with the pathogenesis of marrow failure is unclear. In fact, studies on hematopoietic cells have revealed noncanonical functions of some of these proteins. Some of the FA proteins, for example, not only function to protect the genome, but also participate directly in survival signaling pathways for hematopoietic cells. Interestingly, some of the pathways disrupted in mutant cells result in hyperactivation of precisely those same cytokine signaling pathways involved in the pathogenesis of acquired autoimmune aplastic anemia.

Genetics

The genetic basis of inherited bone marrow failure syndromes is being rapidly solved. Some of these syndromes (e.g., Shwachman-Diamond syndrome, amegakaryocytic thrombocytopenia, and severe congenital neutropenia) are almost always diagnosed in early life. However, some may be first diagnosed in adulthood (e.g., dyskeratosis congenita, FA, and Diamond-Blackfan anemia). It is critically important to consider these three disorders early in the evaluation of adults with aplastic anemia because the treatment of such patients with conventional stem cell transplantation regimens is associated with high mortality rates (especially in dyskeratosis congenita and FA). Furthermore, immunosuppressive therapy plays no role in these diseases. The clinical and laboratory manifestations of these three diseases and the findings that should prompt genetic testing in such patients are reviewed in Table 168-3. Importantly, adults who present with these diseases were not born with aplastic anemia. Instead, aplasia develops over time and gives rise to symptoms in adulthood. Prospective studies of children and adults who present with bone marrow failure have indicated that nearly 10% will have previously unsuspected FA.[1] Diagnostic consideration of a hereditary form of aplastic anemia should not be limited to children.

CLINICAL MANIFESTATIONS

The natural course of aplastic anemia is influenced by its severity. Patients with hypoplastic bone marrow have severe aplastic anemia if they meet two of the following laboratory criteria: (1) absolute neutrophil count less than 0.5×10^9/L, (2) platelet count less than 20×10^9/L, or (3) reticulocytes less than 20×10^9/L. Patients who do not have severe aplastic anemia often progress to severe aplasia, but the pace is slow (about 40% will have progressed in 5 years). Severe aplastic anemia is a life-threatening condition that, untreated, is associated with a mortality rate of 80% in the 24 months after diagnosis. Treatment of any cohort of patients with severe aplastic anemia will prolong life, and many patients, particularly those who have received stem cell transplants, will be cured.

History

Symptoms of this syndrome, cause notwithstanding, are almost always reflective of low blood counts. The most common presenting symptoms are those associated with thrombocytopenia and anemia. Low platelet counts are associated with bleeding, often epistaxis and bleeding gums, bruising with minor or no trauma, and menorrhagia. Anemia accounts for the nearly universal symptoms of fatigue and dyspnea on mild exertion. Some aplastic patients may present with intercurrent bacterial or fungal infection (because of severe neutropenia), but these cases are less common. Family histories that include any of the features listed in Table 168-3 should raise suspicion of an inherited bone marrow failure syndrome.

Physical Examination

Pallor and tachycardia at rest are common signs of anemia but can be absent or unnoticeable in younger patients and in patients whose aplasia is of very recent onset. Often hemorrhagic manifestations classic for thrombocytopenia are found: petechiae (cutaneous or palatal), ecchymoses, and epistaxis. The most common form of aplastic anemia, autoimmune, is rarely associated with lymphadenopathy or hepatosplenomegaly, and when such findings are present, alternative diagnoses should be considered and painstakingly ruled out. Likewise, short stature, endocrinopathies, osteopenia, findings of developmental anomalies of the skin, nails, hands, or arms, or malformations of the heart, liver, or genitourinary tract should trigger concerns of an inherited bone marrow failure disease (see Table 168-3).

Initial Laboratory Findings

Pancytopenia (anemia, leukopenia, and thrombocytopenia) is a universal presenting finding. The morphology of neutrophils, platelets, and red cells on peripheral blood smear is usually normal unless there is concurrent iron deficiency due to bleeding.

DIAGNOSIS

Diagnostic Evaluation

The evaluation of pancytopenic patients first requires examination of the peripheral blood smear. If there are morphologic or clinical signs of vitamin B_{12} or folic acid deficiency (e.g., hypersegmented neutrophils and oval macrocytes), those disorders should be ruled out because a bone marrow aspiration and biopsy would not be required in those conditions. In severe aplastic anemia, the peripheral blood smear will not show nucleated red blood cells or other signs that the marrow might be infiltrated with abnormal cells. All patients in whom B_{12} and folate deficiency have been ruled out require a bone marrow aspiration and biopsy. Obtaining both types of samples is important. The biopsy best assesses overall bone marrow cellularity and provides the most sensitive evidence for some infiltrative processes. The aspirated sample can be examined microscopically for the presence of abnormal cells but also provides cells for cytogenetic analyses (which can provide evidence supporting hypoplastic myelodysplasia and acute leukemia). Rarely in the early stages of aplasia, the biopsy can be somewhat cellular. A repeat biopsy in 1 to 2 weeks might be required to establish the diagnosis clearly. As summarized in Figure 168-2, once the diagnosis of aplastic anemia has been made, a series of additional tests must be obtained. In light of the life-threatening nature of this disease, the tests must be obtained simultaneously, but they serve three distinct purposes.

Ruling Out Aplastic Anemia Variants that Are Treated Differently

The best therapeutic option for many different aplastic states is often matched sibling donor stem cell transplantation, but there are some aplastic states that are managed differently. For example, a child with an inherited marrow failure syndrome might have a human leukocyte antigen (HLA)-identical sibling who also has the same genetic defect. If such a diagnosis has been overlooked, the recipient will likely die from complications of the conditioning regimen (e.g., patients with FA are highly intolerant of radiation and crosslinking agents used in conventional conditioning regiments, and patients with dyskeratosis suffer excessive post-transplantation morbidity and mortality) or possibly because the transplanted stem cells (from the undiagnosed affected sibling donor) are equally unfit. Patients with dyskeratosis congenita and children with the Shwachman-Diamond syndrome are also intolerant of conventional transplantation regimens and often suffer severe pulmonary and hepatic toxicity. Although patients with Diamond-Blackfan anemia are more tolerant of standard conditioning regimens, they are more apt to respond to glucocorticosteroid therapy, and if they are transplanted with stem cells from an undiagnosed affected sibling, they too will do poorly. Finally, patients with PNH should be identified using flow cytometric quantification of CD55- and CD59-deficient red cells because more than half of patients with severe aplastic anemia will have PNH clones; when treated with immunosuppressive therapy, the PNH clone often expands and causes clinically significant signs of PNH (hemolysis and thrombosis).

Tests Helpful in Supportive Care

At some point during the course of the disease, red cell and platelet transfusions will be necessary. Radiated and filtered blood products are used to prevent transfusion-associated graft-versus-host disease (GVHD), reduce alloimmunization, and reduce the complication of cytomegalovirus (CMV) infection. ABO and HLA typing are required. Infections can be of bacterial, viral, or fungal origin and must be quickly diagnosed and treated not only because the patients are often neutropenic but also because, once definitive therapy begins, it is likely they will be receiving immunosuppressive therapy (either through primary immunosuppression or through stem cell transplantation). In the acutely infected, severely neutropenic patient, once cultures and biopsies are obtained, empirical antibiotic therapy should be prescribed even before the culture results are available. Post-transplantation CMV infection is best avoided in CMV-seronegative recipients by using CMV-negative blood products (Chapter 180). Many centers routinely infuse radiated and filtered ("CMV-safe") blood products and therefore no longer routinely screen for CMV seronegativity.

Evaluating the Patient as a Candidate for Stem Cell Transplantation

Timing of treatment depends on the severity of the aplastic anemia and the age of the patient (Table 168-4). Patients with mild marrow hypoplasia and mild bone marrow suppression can be followed closely to determine what the pace of hypoplasia might be. In patients up to 40 years of age with either severe acquired aplastic anemia or transfusion dependence, steps should be taken to evaluate them promptly for stem cell transplantation therapy by seeking HLA-identical siblings and, in appropriate cases, searching for matched unrelated donors.

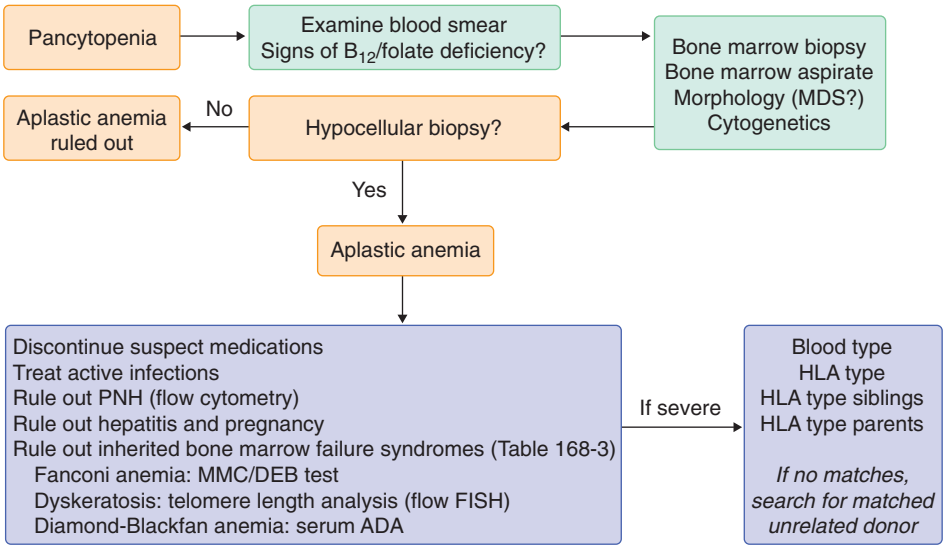

FIGURE 168-2. A pathway for the diagnostic management of patients with aplastic anemia. Patients who present with pancytopenia will require bone marrow biopsy and aspiration unless there are signs of vitamin B_{12} or folate deficiency. If the bone marrow is as cellular as that shown in Fig. 168-1A, the diagnosis of aplastic anemia has been effectively ruled out because the diagnosis requires bone marrow hypocellularity (see Fig. 168-1B). In all patients, regardless of severity, suspect medications should be discontinued, active infections should be treated without delay, and paroxysmal nocturnal hemoglobinuria (PNH) should be excluded, as should pregnancy and hepatitis. For patients with positive family histories or any one of the findings listed in Table 168-3, and all patients younger than 40 years, inherited marrow failure syndromes should be ruled out with screening tests. Patients with severe aplastic anemia are those who have at least two of the following: absolute neutrophil count of less than 0.5×10^9/L, platelet count of less than 20×10^9/L, or reticulocyte count of less than 20×10^9/L. These patients must be treated with definitive therapy and should be evaluated for stem cell transplantation with human leukocyte antigen (HLA) typing (patient and family members) and, if necessary, a search for matched unrelated donors. ADA = adenosine deaminase; DEB = diepoxybutane; FISH = fluorescent in situ hybridization; MDS = myelodysplasia; MMC = mitomycin C.

TABLE 168-4 TREATMENT RECOMMENDATIONS FOR PATIENTS WITH SEVERE ACQUIRED IDIOPATHIC APLASTIC ANEMIA*

	AGE < 20 YR		AGE 20-40 YR		AGE > 40 YR	
HLA-identical sibling?	Yes	No	Yes	No	Yes	No
First-line treatment	MSBMT	IST	MSBMT	IST	IST	IST
Second-line treatment	IST or second MSBMT	IST or MUDT or CBT	IST	IST or MUDT	MSBMT	IST. For failures, consider MUDT.

*This general set of recommendations cannot be applied to patients with inherited bone marrow failure syndromes because they do not respond to immunosuppressive therapy (IST).
CBT = umbilical cord blood transplantation; IST = immunosuppressive therapy; MSBMT = matched sibling bone marrow transplant; MUDT = matched unrelated donor transplant.
Adapted from Bacigalupo A, Passweg J. Diagnosis and treatment of acquired aplastic anemia. *Hematol Oncol Clin North Am*. 2009;23:159-170.

Differential Diagnosis

Most classic aplastic anemia patients have immunologically mediated disease. Notwithstanding strong evidence in support of this mechanism from some research laboratories over the past 30 years, there exists no validated screening tool that can either rule in or rule out immune-mediated disease, a fact that is complicated by the evidence that some cases of drug- and virus-induced disease are also immunologically mediated. Therefore, idiopathic autoimmune aplastic anemia remains a diagnosis of exclusion. For this reason, the obligation of the diagnostician is to consider disease induced by chemical or viral agents and radiation and disease associated with pregnancy. It is also most important to rule out PNH and inherited bone marrow failure syndromes (see Fig. 168-2).

Cytotoxic Drugs, Chemicals, and Radiation

A fastidiously obtained medication history is important. Any drug with the potential of inducing aplastic anemia should be discontinued. It is equally important to ask patients about alternative therapies that they might not consider being "medicines." Some herbal remedies are known to contain molecules (e.g., phenylbutazone) not listed on the label but associated with aplasia (see Table 168-2). A history of exposure to radiation or to chemicals with myelosuppressive capacities (see Table 168-2) should likewise be obtained. Tests for benzene metabolites detect only acute exposure and are not reliable indicators of cumulative exposure in individual patients. Although it is intuitively obvious and prudent to discontinue the use of agents that might have inflicted severe stem cell injury, by the time the injury has progressed to the point of severe aplastic anemia, most of these patients are in need of the same types of therapy prescribed for patients with autoimmune aplastic anemia.

Idiosyncratic Drug Responses

If a medication history unearths an exposure to an agent known to be associated with idiosyncratic (not related to dose) responses, the agent must likewise be discontinued. Because it is likely that these responses are immunologically mediated, the patient should be treated no differently from patients with severe idiopathic aplastic anemia, and the patient should be evaluated as a stem cell transplantation candidate. If, during the diagnostic evaluation of the patient and potential donors, there are signs that the marrow is recovering on its own, a more conservative approach can be taken.

Paroxysmal Nocturnal Hemoglobinuria

PNH can be ruled out by screening for CD55 and CD59 on the surface of granulocytes, monocytes, and red cells using flow cytometry. The proper diagnosis of PNH requires the absence of these or other GPI-anchored proteins on at least two hematopoietic cell types. Other characteristic features of this syndrome can be a high low-density lipoprotein level, high indirect bilirubin, low haptoglobin, and a positive urine hemosiderin test.

Fanconi Anemia

FA should be considered in any adult of any age with a family history of aplastic anemia, acute myelogenous leukemia or myelodysplasia, or a squamous cell carcinoma at an unusually young age. This disease should also be considered in any patient with any physical finding listed in Table 168-3 or in patients with a family member who has any of these findings. Unfortunately, some patients with FA meet none of these standards, so some hematologists advocate testing for it in all patients with aplastic anemia patients who are younger than 40 years. This disease can be ruled out by obtaining a chromosomal breakage test (see Table 168-3). Here, either lymphocytes or skin fibroblasts are exposed to mitomycin C or diepoxybutane for a period of 2 to 3 days, after which metaphase chromosomes are examined for chromosomal breaks and quadriradial forms (in FA cells, these four-armed interchromosomal forms involve at least two chromosomal breaks). If the clinical context is suggestive (see Table 168-3), but results of the lymphocyte chromosomal breakage test are negative or equivocal, testing of skin fibroblasts is required to rule out the diagnosis. Once the diagnosis is made, history, physical examination, blood counts, and chromosomal breakage tests should be performed on all immediate family members.

There are at least 13 different FA genes (see Table 168-3), and sequencing them all using cells from every patient is not practical at this time. Fortunately, the involved gene can be first identified by a variety of more affordable complementation analyses. In this type of test, normal FA genes are introduced into primary cells of the patient in vitro, and the one gene that corrects the defect (i.e. ,reduces hypersensitivity to cross-linking agents [melphalan, mitomycin C, or diepoxybutane]) represents the gene of interest. That gene can then be fully sequenced to identify the precise mutation, information that will be of value to family members for family planning purposes. In rare instances, it can also aid in applying preimplantation genetic diagnosis and in vitro fertilization, a process that has successfully resulted in unaffected offspring and ideal cord-blood stem cell donors for transplantation of an affected sibling.

Dyskeratosis Congenita

Dyskeratosis congenita should be considered in any aplastic adult of any age with a family member who has had aplastic anemia. It should be likewise considered if either the patient or a family member has had acute myelogenous leukemia, myelodysplasia, nail dystrophy, lacy skin pigmentation, pulmonary fibrosis, oral leukoplakia, squamous cell carcinoma at an unusually young age, or any other physical finding listed in Table 168-3. This disease can be frequently ruled out by quantifying the length of telomeres in circulating white cells using a flow cytometric method. Because some of the physical findings overlap, FA should be ruled out in all patients being evaluated for dyskeratosis congenita. The dyskeratosis test quantifies telomere length using fluorescence in situ hybridization. Lymphocytes from dyskeratosis patients have extremely short telomeres (i.e., at or less than the 1st percentile). If two or three leukocyte types from a given patient are above the 1st percentile, the diagnosis of dyskeratosis is unlikely. If telomeres are in the diagnostic range, genetic testing is warranted. It is not yet known whether this test will become a "gold-standard" test as reliable as the chromosomal breakage test is for FA because some investigators report that very short telomeres can be found in patients who have other causes of bone marrow failure. Unlike the genetic strategy employed with FA (at least today), complementation analyses are not routinely performed in dyskeratosis. The molecular diagnosis is based on gene sequencing. Once the diagnosis is made and even before the establishment of a molecular genetic diagnosis (see Table 168-3), all immediate family members of the patient should be seen individually, their history taken, and their physical examination performed along with peripheral blood counts and telomere length analysis.

Diamond-Blackfan Anemia

Diamond-Blackfan anemia is an inherited bone marrow failure syndrome that more often exhibits selective erythroid failure and is an unusual cause of full-blown severe aplastic anemia. Although some patients can present in adulthood, most are discovered within the first year of life and present with anemia but less commonly neutropenia and thrombocytopenia. Phenotypic abnormalities like short stature and skeletal defects are the exception in this disease. There are no screening tests as reliable as those used for FA and dyskeratosis congenita. However, in patients with unexplained erythroid failure, the finding of an elevated adenosine deaminase level in the serum, although unexplained, is strongly suggestive of this disease. Because no helpful screening test exists, there are no reliable or standardized complementation tests.

Consequently, genetic diagnosis requires the application of gene sequencing methods (see Table 168-3).

Other Diagnostic Considerations

Aplastic anemia has been reported in recipients of organ allografts (in which mismatched T cells [either from the donated graft or from blood products that had not been irradiated] induce severe aplasia), patients with myelodysplasia (Chapter 188), patients with congenital and acquired immunodeficiency states (Chapter 258), and patients with established autoimmune diseases including systemic lupus erythematosus (Chapter 274) and eosinophilic fasciitis (Chapter 448), a disease characterized by painful swelling of the skin and subcutaneous tissue.

TREATMENT

Rx

For patients with more mild forms of aplastic anemia, aggressive therapy may not be indicated. A passive approach is more problematic in patients with FA and dyskeratosis congenita because transplantation early in life is better tolerated, immunosuppressive therapy is ineffective, and stem cell transplantation provides the only hope for cure of bone marrow failure. If there is evidence of an underlying autoimmune-mediated disease (e.g., isolated granulopoietic or erythroid failure in patients with rheumatic diseases or thymoma), immunosuppressive therapy alone is often highly effective.

Hematopoietic Stem Cell Transplantation: Matched Sibling Donor

For patients with severe aplastic anemia, stem cell transplantation offers the advantages of immunosuppression, an infusion of new "healthy" stem cells, and the expectation that the lymphoid cells that suppressed the marrow in the first place will be replaced by more normal cells that have no myelosuppressive capacity. This expectation is borne out by large retrospective studies indicating the superiority of stem cell transplantation over immunosuppressive therapy alone in the treatment of severe aplastic anemia. Naturally, this approach is relevant to a minority of patients because only 25 to 30% will have an HLA-matched sibling.

Stem cells derived from the bone marrow, not the peripheral blood, should be the source of donor cells. Studies testing the comparative effectiveness of peripheral blood as a source of stem cells demonstrated that the peripheral blood source was associated with excess mortality stemming from an increased incidence of chronic GVHD. The recipient (in whom congenital marrow failure syndromes have been ruled out) initially receives high-dose cyclophosphamide with antithymocyte globulin (ATG) as the preparative regimen. Immunosuppressive therapy begins 2 to 4 days before infusion of stem cells. Common post-transplantation immunosuppression combines cyclosporine and methotrexate. The complication of graft failure with this approach is infrequently seen (<5%), grades II to IV acute GVHD is seen in 30 to 50% of recipients, 25% have chronic GVHD, and short-term (2-year) survival after transplantation is nearly 90%. Ten-year survival rates are highly age dependent: 83%, 73%, and 68% for recipients in the first, second, and third decades of life, respectively. In patients 40 years of age or older, the 10-year survival rate is only 51%. Treatment choices adjusted for patient age are presented in Table 168-4.

Hematopoietic Stem Cell Transplantation: Matched Unrelated Donor

The use of bone marrow from an HLA-matched unrelated donor should be considered for patients who have no HLA-identical siblings, have failed immunosuppressive therapy, and are refractory to transfused platelets. Results have not been as favorable as those associated with the use of marrow from HLA-identical siblings, but this strategy has improved in the past decade in part because of more accurate selection of HLA-matched donors and in part because of adjustments made with pretransplantation conditioning regimens. In fact, in some pediatric populations, some centers are now reporting identical outcomes in children transplanted with marrow cells from HLA-matched related and matched unrelated donors. Conditioning regimens without ATG are associated with inferior outcomes, and less toxic conditioning regimens appear to have improved survival (65% for patients older than 16 years and 75% for those 16 years of age or younger). The improvements have been encouraging enough to recommend strongly that unrelated donor searches be initiated at the time of diagnosis for any patient younger than 30 years. Adults older than 30 years should be considered candidates for alternative donor stem cell transplantation if they have failed two attempts at immunosuppressive therapy because newer fludarabine-based conditioning regimens have improved outcomes of matched unrelated donor transplants remarkably.

Immunosuppressive Therapy

Treatment with ATG alone prolongs survival when compared with supportive care alone, and for patients with mild aplastic anemia (not severe), either no treatment or ATG alone is sufficient. In patients with severe aplastic anemia, however, the combination of ATG and cyclosporine is superior to treatment with ATG alone.■ The combination reduces mortality and induces more rapid and higher overall response rates than does ATG as a single agent. Doses vary from center to center, but ATG is given at doses of 12 to 40 mg/kg/day for 4 to 5 days, and cyclosporine doses of 5 to 10 mg/kg/day (targeting blood levels of 150 to 250 ng/mL) are prescribed for 6 months, after which cyclosporine is slowly tapered over a period of 1 year or more. The median time to response is 120 days. Complete responses are defined as the resolution of pancytopenia and the development of normal blood counts. Relapses are uncommon in complete responders (10%). Partial responders are those whose counts do not normalize but who no longer require transfusion support. Forty to 60% of these patients will relapse in 5 years, but most will respond to a repeat course of immunosuppressive therapy. Some will require chronic immunosuppressive therapy with cyclosporine to remain transfusion independent. Those with unresponsive relapses have a poor prognosis.

All age groups can benefit from immunosuppressive therapy. Long-term survival rates do vary with the age of the treated population. In patients younger than 20 years, 10-year survival rates are 80%, but these rates progressively decline to 25% in patients older than 70 years. However, when adjusted for the survival of an age-matched population using the standardized mortality ratio, the corrected risk for death is highest in young patients and declines as age increases. Advanced age is not a contraindication for the prescription of immunosuppressive therapy.

There are some caveats of importance related to the use of immunosuppressive therapy in aplastic anemia patients. First, patients may experience allergic reactions during infusions of ATG. This should not necessarily dissuade one from continuing this agent. Slowing the infusion after premedication with glucocorticosteroids and antihistamines often solves this problem. Fever and rigor can be signs of cytokine release from the targeted T-cell pool, so they likewise should not be used as a reason to stop treatment. Second, if a responsive patient later relapses, a second course of ATG is frequently effective and should be used. Third, it seems clear that a long interval between diagnosis of aplastic anemia and the initiation of immunosuppressive therapy is a negative predictor of response. Treatment should begin as soon as possible; certainly within 3 weeks of initial diagnosis. Fourth, the inclusion of hematopoietic growth factors during immunosuppressive therapy provides no benefit.■

Diamond-Blackfan Anemia and Pure Red Cell Aplasia

Although the mechanism by which glucocorticosteroids induce remissions in patients with Diamond-Blackfan anemia is unknown, nearly 80% of patients initially respond. Prednisone treatment is started at 2 mg/kg/day and is tapered after the hemoglobin increases to 10 g/dL. Most patients require a low every-other-day dose, but 15% remain in remission off steroids altogether. In those cases, survival to age 40 years is nearly universal. Of patients who require ongoing steroid support, 75% reach age 40 years. Only half of the patients with steroid-resistant severe anemia survive to age 40 years. Pure red cell aplasia may respond to a synthetic erythropoietin receptor agonist.

Supportive Care

Platelet Transfusions

In the absence of bleeding or infection, platelet transfusions are commonly administered only when the platelet count declines to 10,000/mL or less, but in the presence of active infection or bleeding, transfusion thresholds are often set at 20,000/mL or higher. If bleeding and infection coexist, it is prudent to rule out disseminated intravascular coagulation because fresh-frozen plasma or cryoprecipitate may be required along with platelet transfusions. Drugs (e.g., aspirin) that inhibit platelet function must be avoided, as should activities that might result in trauma. Menstrual activity should be suppressed with oral contraceptives or other agents.

Red Cell Transfusions

Filtered packed red blood cells should be provided to meet the needs of the patient's daily activities. There is no established hemoglobin target number for this purpose, but as a general rule, the number is higher in elderly patients than in young patients. Children with hemoglobin levels of as low as 6 g/dL can compensate reasonably. Adults with underlying cardiopulmonary disease may have symptomatic anemia at 8 g/dL. If chronic transfusion therapy is required, the development of iron overload may require chelation therapy.

Management of Infections

The major infectious challenges result from the immunosuppression used (either as primary therapy or as a component of a stem cell transplantation regimen) more than the neutropenia. For that reason, antibacterial, antiviral, and antifungal prophylaxis is routinely used in transplant recipients. In many centers, patients treated with immunosuppressive therapy alone are treated similarly for a 2- to 3-month period following ATG administration. Importantly, the onset of fever requires prompt clinical evaluation and antibiotic therapy as described in Chapter 289.

PREVENTION

Apart from public health measures controlling exposures to benzene, aromatic hydrocarbons, and radiation, little can be done to prevent acquired aplastic anemia. In the inherited bone marrow failure syndromes, prevention is quite achievable. Once the proband is identified, other affected family members, carriers, and siblings with no mutant allele can be identified, and genetic results can be applied in family planning even to the extent of preimplantation genetic diagnosis followed by in vitro fertilization. Because all somatic cells of children and adults with FA are hypersensitive to alkylating agents and oxidative stress, they must not receive standard doses of radiation or alkylating agents either for transplant conditioning or for treatment of squamous cell carcinoma.
